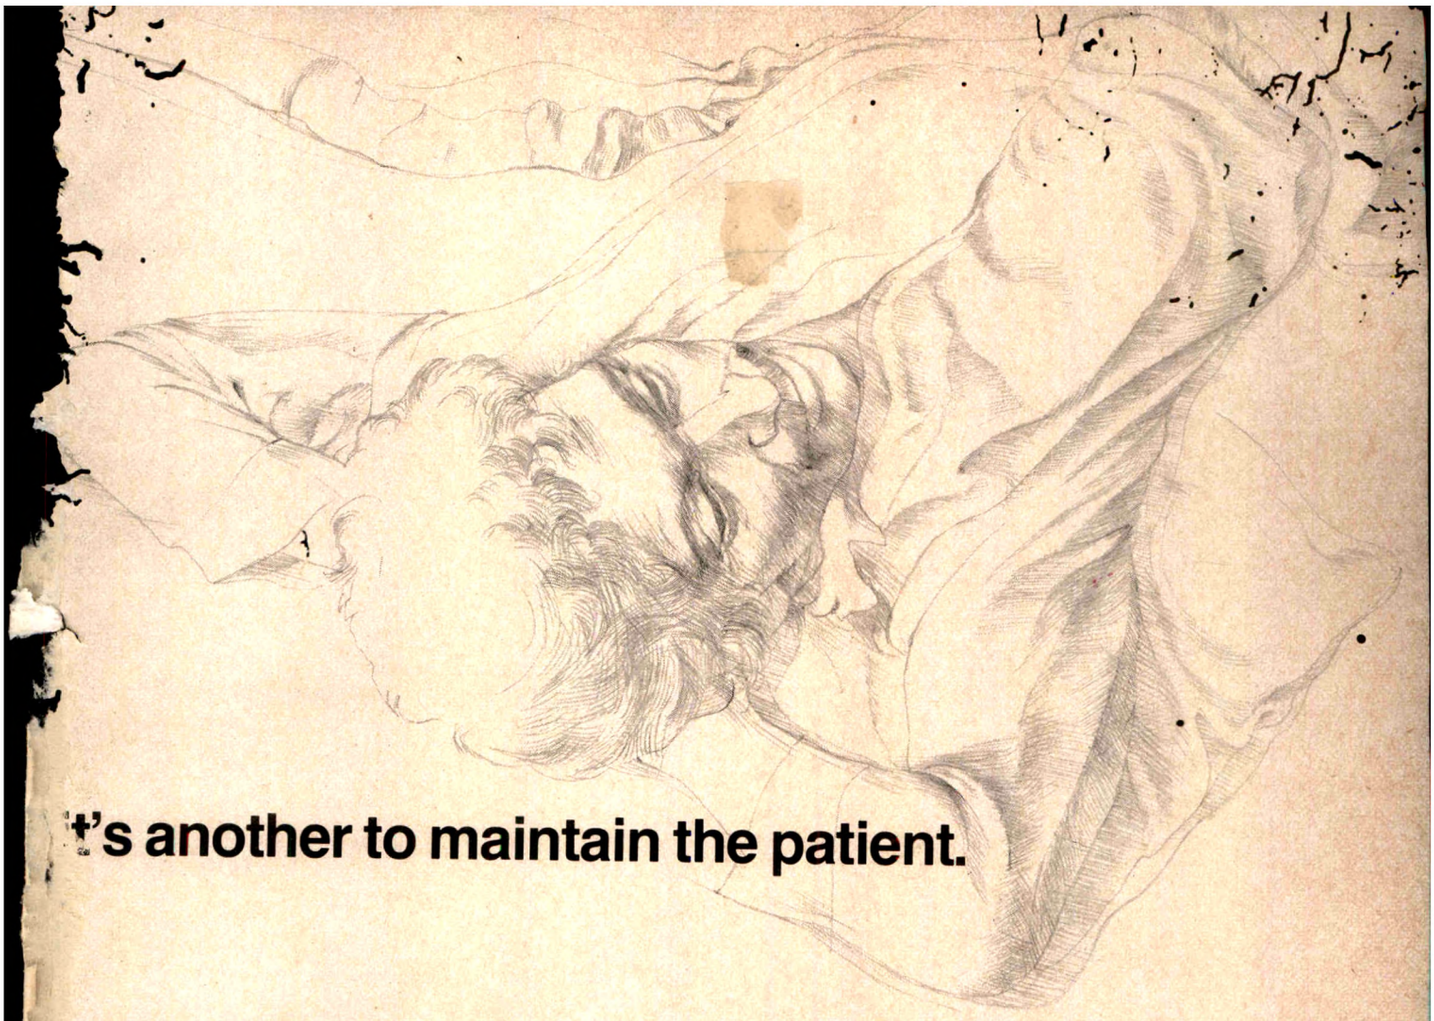
In the treatment of atrial fibrillation...

it's one thing to restore the rhythm.



t's another to maintain the patient.

How to brake the heart. The modern ethod of choice for *conversion* of atrial fibrillation normal sinus rhythm is direct current countershock. *aintaining* normal sinus rhythm—and maintaining e patient—is another matter. A "pharmacologic acemaker" that has a fundamental antiarrhythmic tion is Quinaglute® (quinidine gluconate). A specific maintaining normal sinus rhythm, Quinaglute s certain distinct advantages for long-term control:

the unique Dura-Tab® construction permits adual release of quinidine gluconate to maintain erapeutic quinidine plasma levels for 8 to 12 hours.

the convenient 8 or 12 hour dosage schedule elps avoid middle of the night dosage and early norning reversion.

Quinaglute Dura-Tabs are well tolerated with ew gastrointestinal disturbances

QUINAGLUTE® Dura-Tabs®
quinidine gluconate) 5 gr. (0.33 Gm.)
"a pharmacologic pacemaker"

Indications: For the prevention of premature atrial, nodal or ventricular contractions. For maintenance of normal sinus rhythm following conversion by other techniques of atrial, nodal or ventricular tachycardia, atrial flutter and fibrillation (paroxysmal or chronic).
Contraindications: Same as for other forms of quinidine, including partial A-V or complete heart block; intraventricular conduction defects, especially marked QRS widening; sensitivity to quinidine; renal disease with significant azotemia; development of cardiotoxic effects (conduction defects or ventricular premature beats, ventricular tachycardia, or flutter) while taking the drug; marked cardiac enlargement with congestive failure; poor renal function especially with tubular acidosis.
Precautions: Same as for quinidine. To detect idiosyncrasy, e.g., febrile reactions, skin eruptions, thrombocytopenic purpura, and respiratory embarrassment, administer preliminary test dose of single tablet of quinidine sulfate. Use extreme caution in patients with severe heart disease, congestive heart failure, digitalis intoxication, renal insufficiency. Administer cautiously, if at all, to senile patients. Hospitalization (for close observation, ECG monitoring and possibly plasma quinidine levels) indicated when administering large doses with patients presenting increased risk. With the dosage regimen (see "Dosage") of 2 tablets every 8 hours, higher blood levels than necessary for maintenance of normal sinus rhythm could be reached, whereas with 1 tablet every 12 hours, the blood levels may be too low to maintain normal sinus rhythms. Should not be used during pregnancy.
Adverse reactions: Instruct patients to report any symptoms of cinchonism at once (including tinnitus, decreased auditory acuity, vertigo, blurred vision, color perception disturbances, photophobia, diplopia, night blindness, scotomata, reduced visual fields, mydriasis, and respiratory distress); the drug should be discontinued immediately if such symptoms or evidence of hypotension occur. If gastrointestinal disturbances (rarely reported) occur, they may be minimized by administering the drug with food, or if they persist, dosage should be decreased.
Dosage: The dosage varies considerably depending upon the general condition and cardiovascular state of the patient. The quantity and frequency of administration must be determined for each patient. For the prevention of premature atrial, nodal or ventricular contractions, the dose usually ranges from 1 to 2 tablets every 8 or 12 hours. For maintenance of normal sinus rhythm following conversion by other techniques of atrial fibrillation, tachycardia or flutter, 2 tablets every 12 hours or 1½-2 tablets every 8 hours are usually required. The occasional patient may be maintained in normal rhythm on a dosage of 1 tablet every 12 or 8 hours. Occasionally larger or more frequent dosage may be required, but such increases should be used only after thorough evaluation of the patient, including serial electrocardiograms and determination of plasma quinidine levels. The ideal dosage is the minimum amount of total dose and frequency of daily administration that will prevent premature contractions, paroxysmal tachycardias, and maintain normal sinus rhythm.
Supplied: Bottles of 100 and 250 tablets.

Cooper Laboratories, Inc., Wayne, N.J. 07470, U.S.A.

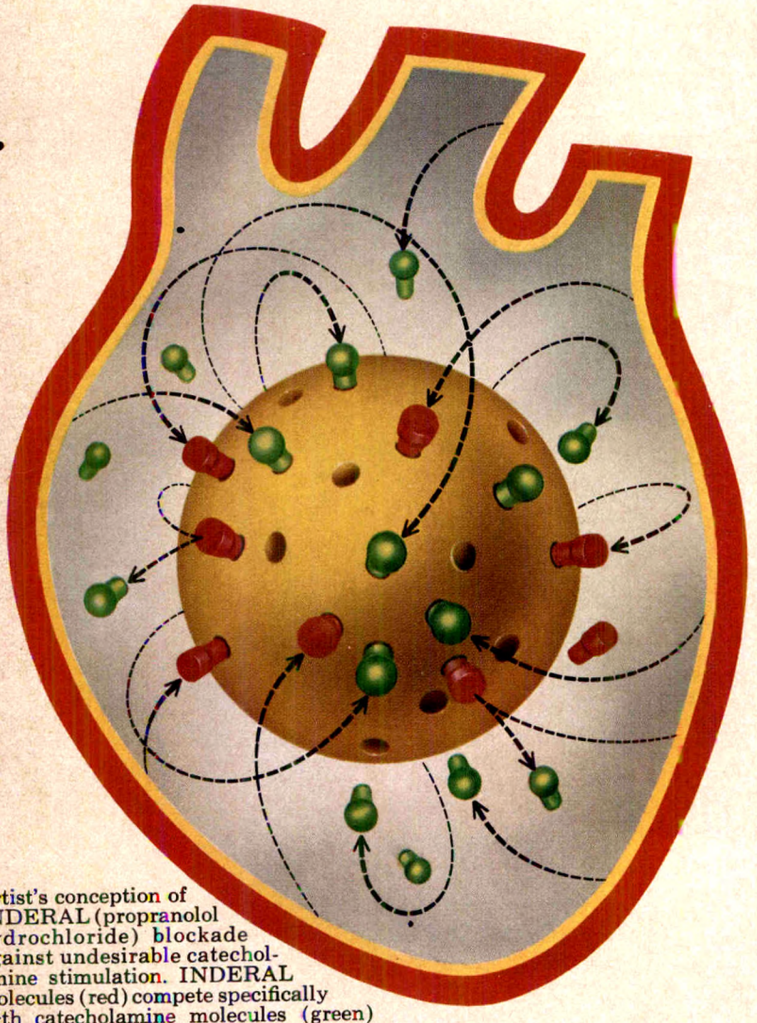
When the heart is under catecholamine siege

INDERAL®

Brand of

propranolol hydrochloride

The beta-adrenergic blocking agent for many cardiac arrhythmias



Artist's conception of INDERAL (propranolol hydrochloride) blockade against undesirable catecholamine stimulation. INDERAL molecules (red) compete specifically with catecholamine molecules (green) for available beta-receptor sites in cardiac tissue. With fewer catecholamine molecules gaining access to these sites, beta-adrenergic stimulation is reduced proportionately.

P 24,106

As the first beta-adrenergic blocking agent in clinical cardiologic use, INDERAL (propranolol hydrochloride) helps prevent or control catecholamine-induced supraventricular cardiac arrhythmias by means of a unique mechanism of action.

Excitatory adrenergic activity from sympathetic nerve endings and the adrenal medulla is mediated in myocardial and pacemaker tissue via beta receptors. Through blockade of undesirable catecholamine stimulation at these sites, INDERAL decreases impulse formation and conduction, and thus the rate and force of myocardial contraction. The clinical benefit is generally a reduction of supraventricular rate, a slowing of ventricular response, and restoration to sinus rhythm in many cases. In responsive patients, a subsequent maintenance regimen of 10 to 30 mg. INDERAL three or four times daily can prevent recurrence or reduce the frequency and severity of paroxysmal attacks.

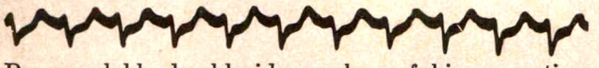
With its unique site of action, INDERAL does not interfere with the therapeutic actions of nonadrenergic cardiotonic agents. Thus INDERAL can be used in combination—or alone—to control arrhythmias when other drugs have failed to produce a satisfactory response.

INDERAL is especially effective in the management of catecholamine-induced supraventricular arrhythmias. The response of ventricular arrhythmias is generally less predictable.

INDERAL has proved to be of particular value in the control of digitalis-induced arrhythmias.

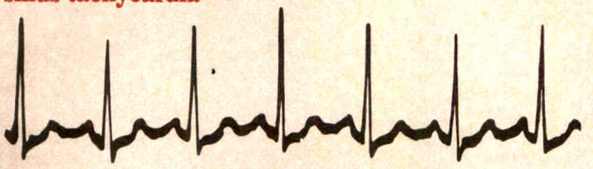
Proved effective over 6 years' clinical use

paroxysmal atrial tachycardia[1-8]



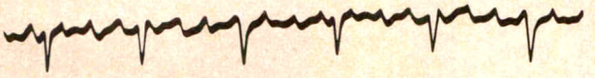
Propranolol hydrochloride may be useful in preventing recurrent attacks of paroxysmal atrial tachycardia "including attacks which may be a part of the Wolff-Parkinson-White syndrome."[1]

sinus tachycardia[9]



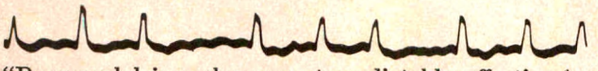
Sonnenblick "would use propranolol hydrochloride in treating a rapid sinus tachycardia which is poorly tolerated by the circulation—if the tachycardia were not due to some underlying process such as occult blood loss."[9]

atrial flutter[4-6,8-11]



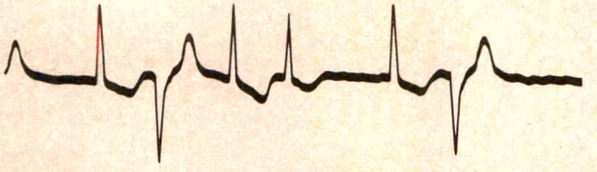
"In the presence of atrial flutter, ventricular rate is often difficult to control, and, as with an atrial fibrillation, propranolol hydrochloride should be added when the flutter is not being controlled by digitalis, especially in the presence of mitral valve disease."[9]

atrial fibrillation[1,3-10]



"Propranolol is perhaps most predictably effective in the treatment of patients with atrial fibrillation. It reduces the ventricular rate by prolonging the functional refractory period of the atrioventricular node. This occurs whether or not the patient is receiving digitalis."[3]

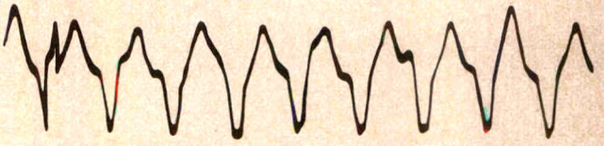
arrhythmias of digitalis intoxication[1,3-6,8-10]



"Propranolol has been especially useful in treating patients with arrhythmias in the presence of established or suspected digitalis toxicity. All too common is the clinical situation in which we know the patient has had digitalis, but do not know whether he is toxic to digitalis. Propranolol may be a very useful drug in this situation."[1]

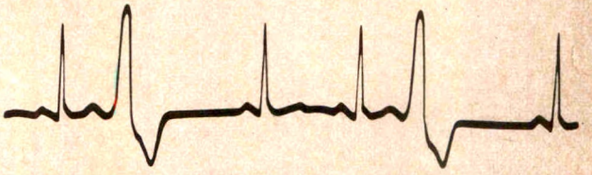
According to Wehrmacher, propranolol hydrochloride "is probably the treatment of choice for digitalis-induced tachyarrhythmias."[10]

ventricular tachycardias (when a matter of minutes in controlling the arrhythmia may mean life or death and when cardioversion technics are not available)[3,4,7,9,10,12]



"There appears to be a special place for the use of propranolol in patients with prolonged cardiac arrest associated with resistant, recurrent ventricular fibrillation. Propranolol has been shown to have an anti-fibrillatory effect, and we [the clinicians] believe it should be used when standard resuscitation methods and drugs have not produced a satisfactory cardiac rhythm."[12]

arrhythmias associated with anesthesia in selected cases[3,10,12-15]



In the treatment of cardiac disturbances occurring during and/or following halothane anesthesia for cardiovascular operations, 141 episodes in 115 patients "responded consistently to 1 to 2 mg. of propranolol intravenously without serious side effects. The onset of the drug's action was apparent within one to three minutes after its injection."[13]

Also recommended in the management of hypertrophic subaortic stenosis...[5,10,16]

Oral administration has produced symptomatic improvement in a large majority of patients, some treated for several days, and others for as long as several months.[10]

...and pheochromocytoma[3,6,8,10,17,18]

"When surgical removal [of the tumor in pheochromocytoma] is impossible, administration of both α- and β-adrenergic blocking drugs is essential for long-term control."[10]

Administered with awareness of the Contraindications, Warnings, Precautions, and Adverse Reactions, INDERAL (propranolol hydrochloride) provides a valuable tool in controlling a wide variety of cardiac arrhythmias, including cases that have proved refractory to previous therapy with other drugs.

With judicious use of INDERAL in suitably selected patients, symptomatic improvement is most frequently obtained; restoration to sinus rhythm is often possible.

BETA-BLOCKADE / **INDERAL®**
(propranolol hydrochloride)

Ayerst®

(See last page of advertisement for prescribing information)

BRIEF SUMMARY
(For full prescribing information, see package circular.)

INDERAL®
(propranolol hydrochloride)

A beta-adrenergic blocking agent

BEFORE USING INDERAL (PROPRANOLOL HYDROCHLORIDE), THE PHYSICIAN SHOULD BE THOROUGHLY FAMILIAR WITH THE BASIC CONCEPT OF ADRENERGIC RECEPTORS (ALPHA AND BETA), AND THE PHARMACOLOGY OF THIS DRUG.

INDICATIONS

Cardiac Arrhythmias

1) Supraventricular arrhythmias

a) Paroxysmal atrial tachycardias, particularly those arrhythmias induced by catecholamines or digitalis or associated with the Wolff-Parkinson-White syndrome. (See W-P-W under WARNINGS.)

b) Persistent sinus tachycardia which is non-compensatory and impairs the well-being of the patient.

c) Tachycardias and arrhythmias due to thyrotoxicosis when causing distress or increased hazard and when immediate effect is necessary as adjunctive, short term (2-4 weeks) therapy.

May be used with, but not in place of, specific therapy. (See Thyrotoxicosis under WARNINGS.)

d) Persistent atrial extrasystoles which impair the well-being of the patient and do not respond to conventional measures.

e) Atrial flutter and fibrillation when ventricular rate cannot be controlled by digitalis alone, or when digitalis is contraindicated.

2) Ventricular tachycardias

Ventricular arrhythmias do not respond to propranolol as predictably as do the supraventricular arrhythmias.

a) Ventricular tachycardias

With the exception of those induced by catecholamines or digitalis, INDERAL is not the drug of first choice. In critical situations when cardioversion technics or other drugs are not indicated or are not effective, INDERAL may be considered. If, after consideration of the risks involved, INDERAL is used, it should be given intravenously in low dosage and very slowly. (See DOSAGE AND ADMINISTRATION.) *Care in the administration of* INDERAL *with constant electrocardiographic monitoring is essential as the failing heart requires some sympathetic drive for maintenance of myocardial tone.*

b) Persistent premature ventricular extrasystoles which do not respond to conventional measures and impair the well-being of the patient.

3) Tachyarrhythmias of digitalis intoxication

If digitalis-induced tachyarrhythmias persist following discontinuance of digitalis and correction of electrolyte abnormalities, they are usually reversible with *oral* INDERAL. Severe bradycardia may occur. (See OVERDOSAGE OR EXAGGERATED RESPONSE.)

Intravenous propranolol hydrochloride is reserved for life-threatening arrhythmias. Temporary maintenance with oral therapy may be indicated. (See DOSAGE AND ADMINISTRATION.)

4) Resistant tachyarrhythmias due to excessive catecholamine action during anesthesia

Tachyarrhythmias due to excessive catecholamine action during anesthesia may sometimes arise because of release of endogenous catecholamines or administration of catecholamines. When usual measures fail in such arrhythmias, INDERAL may be given intravenously to abolish them. All general inhalation anesthetics produce some degree of myocardial depression. Therefore, when INDERAL is used to treat arrhythmias during anesthesia, it should be used with extreme caution and constant ECG and central venous pressure monitoring. (See WARNINGS.)

Hypertrophic Subaortic Stenosis

INDERAL is useful in the management of hypertrophic subaortic stenosis, especially for treatment of exertional or other stress-induced angina, palpitations, and syncope. INDERAL also improves exercise performance. The effectiveness of INDERAL in this disease appears to be due to a reduction of the elevated outflow pressure gradient which is exacerbated by beta receptor stimulation. Clinical improvement may be temporary.

Pheochromocytoma

After primary treatment with an alpha-adrenergic blocking agent has been instituted, INDERAL may be useful as *adjunctive* therapy if the control of tachycardia becomes necessary before or during surgery.

It is hazardous to use INDERAL unless alpha-adrenergic blocking drugs are already in use, since this would predispose to serious blood pressure elevation. Blocking only the peripheral dilator (beta) action of epinephrine leaves its constrictor (alpha) action unopposed.

In the event of hemorrhage or shock, there is a disadvantage in having both beta and alpha blockade since the combination prevents the increase in heart rate and peripheral vasoconstriction needed to maintain blood pressure.

With inoperable or metastatic pheochromocytoma, INDERAL may be useful as an adjunct to the management of symptoms due to excessive beta receptor stimulation.

CONTRAINDICATIONS

INDERAL is contraindicated in: 1) bronchial asthma; 2) allergic rhinitis during the pollen season; 3) sinus bradycardia and greater than first degree block; 4) cardiogenic shock; 5) right ventricular failure secondary to pulmonary hypertension; 6) congestive heart failure (see WARNINGS) unless the failure is secondary to a tachyarrhythmia treatable with INDERAL; 7) in patients on adrenergic-augmenting psychotropic drugs (including MAO inhibitors), and during the two week withdrawal period from such drugs.

WARNINGS

CARDIAC FAILURE: Sympathetic stimulation is a vital component supporting circulatory function in congestive heart failure, and inhibition with beta-blockade always carries the potential hazard of further depressing myocardial contractility and precipitating cardiac failure. INDERAL acts selectively without abolishing the inotropic action of digitalis on the heart muscle (*i.e.* that of supporting the strength of myocardial contractions). However, the inotropic action of digitalis may be reduced by INDERAL's opposite inotropic effect. The effect of INDERAL and digitalis are additive in depressing AV conduction.

IN PATIENTS WITHOUT A HISTORY OF CARDIAC FAILURE, continued depression of the myocardium over a period of time can, in some cases, lead to cardiac failure. In rare instances, this has been observed during INDERAL therapy. Therefore, at the first sign or symptom of impending cardiac failure, patients should be fully digitalized, and the response observed closely: (a) if cardiac failure continues, INDERAL therapy must be immediately withdrawn; (b) if tachyarrhythmia is being controlled, patients should be maintained on combined dosage and the patient closely followed until threat of cardiac failure is over.

IN PATIENTS WITH THYROTOXICOSIS, possible deleterious effects from long term use have not been adequately appraised. Special consideration should be given to propranolol's potential for aggravating congestive heart failure. Propranolol may mask the clinical signs of continuing hyperthyroidism or complications and give a false impression of improvement. Propranolol does not distort thyroid function tests.

IN PATIENTS WITH WOLFF-PARKINSON-WHITE SYNDROME, several cases have been reported in which, after propranolol, the tachycardia was replaced by a severe bradycardia requiring a demand pacemaker. In one case this resulted after an initial dose of 5 mg. propranolol.

IN PATIENTS DURING ANESTHESIA with agents that require catecholamine release for maintenance of adequate cardiac function, beta blockade will impair the desired inotropic effect. Therefore, INDERAL (propranolol hydrochloride) should be titrated carefully when administered for arrhythmias occurring during anesthesia.

IN PATIENTS UNDERGOING MAJOR SURGERY, beta blockade impairs the ability of the heart to respond to reflex stimuli. For this reason, with the exception of pheochromocytoma, INDERAL should be withdrawn 48 hours prior to surgery, at which time all chemical and physiologic effects are gone according to available evidence. However, in case of emergency surgery, since INDERAL is a competitive inhibitor of beta receptor agonists, its effects can be reversed by administration of such agents, *e.g.* isoproterenol or levarterenol. However, such patients may be subject to protracted severe hypotension. Difficulty in restarting and maintaining the heart beat has also been reported.

IN PATIENTS PRONE TO NONALLERGIC BRONCHOSPASM (*e.g.* CHRONIC BRONCHITIS, EMPHYSEMA), INDERAL should be administered with caution since it may block bronchodilation produced by endogenous and exogenous catecholamine stimulation of beta receptors.

DIABETICS AND PATIENTS SUBJECT TO HYPOGLYCEMIA: Because of its beta-adrenergic blocking activity, INDERAL may prevent the appearance of premonitory signs and symptoms (pulse rate and pressure changes) of acute hypoglycemia. Especially important with labile diabetics.

USE IN PREGNANCY: The safe use of INDERAL in human pregnancy has not been established. Use of any drug in pregnancy or women of childbearing potential requires that the possible risk to mother and/or fetus be weighed against the expected therapeutic benefit.

PRECAUTIONS

Patients receiving catecholamine depleting drugs such as reserpine should be closely observed if INDERAL is administered. The added catecholamine blocking action of this drug may then produce an excessive reduction of the resting sympathetic nervous activity. Occasionally, the pharmacologic activity of INDERAL may produce hypotension and/or marked bradycardia resulting in vertigo, syncopal attacks, or orthostatic hypotension.

In chronically treated patients, dosage should be gradually reduced over a two week period when it is anticipated that the administration of INDERAL will be discontinued. There have been a few reports of myocardial infarction occurring within 2-3 days of propranolol hydrochloride discontinuation in angina pectoris patients, but an association has not yet been established.

As with any new drug given over prolonged periods, laboratory parameters should be observed at regular intervals. The drug should be used with caution in patients with impaired renal or hepatic function.

ADVERSE REACTIONS

Cardiovascular: bradycardia; congestive heart failure; intensification of AV block; hypotension; paresthesia of hands; arterial insufficiency, usually of the Raynaud type; thrombocytopenic purpura

Central Nervous System: lightheadedness; mental depression manifested by insomnia, lassitude, weakness, fatigue; reversible mental depression progressing to catatonia; visual disturbances; hallucinations; an acute reversible syndrome characterized by disorientation for time and place, short term memory loss, emotional lability, slightly clouded sensorium, and decreased performance on neuropsychometrics

Gastrointestinal: nausea, vomiting, epigastric distress, abdominal cramping, diarrhea, constipation

Allergic: pharyngitis and agranulocytosis, erythematous rash, fever combined with aching and sore throat, laryngospasm and respiratory distress

Respiratory: bronchospasm

Hematologic: agranulocytosis, nonthrombocytopenic purpura, thrombocytopenic purpura

Miscellaneous: reversible alopecia

Clinical Laboratory Test Findings: Elevated blood urea levels in patients with severe heart disease, elevated serum transaminase, alkaline phosphatase, lactate dehydrogenase

DOSAGE AND ADMINISTRATION

The oral route of administration is preferred.

ORAL

ARRHYTHMIAS—10-30 mg. three or four times daily, before meals and at bedtime.

HYPERTROPHIC SUBAORTIC STENOSIS—20-40 mg. three or four times daily, before meals and at bedtime.

PHEOCHROMOCYTOMA—*Preoperatively*—60 mg. daily in divided doses for three days prior to surgery, concomitantly with an alpha-adrenergic blocking agent.—*Management of inoperable tumor*—30 mg. daily in divided doses.

PEDIATRIC DOSAGE

At this time the data on the use of the drug in this age group are too limited to permit adequate directions for use.

INTRAVENOUS

Intravenous administration is reserved for life-threatening arrhythmias or those occurring under anesthesia. The usual dose is from 1 to 3 mg. administered under careful monitoring, *e.g.* electrocardiographic, central venous pressure. The rate of administration should not exceed 1 mg. (1 cc.) per minute to diminish the possibility of lowering blood pressure and causing cardiac standstill. Sufficient time should be allowed for the drug to reach the site of action even when a slow circulation is present. If necessary, a second dose may be given after two minutes. Thereafter, additional drug should not be given in less than four hours. Additional INDERAL should not be given when the desired alteration in rate and/or rhythm is achieved.

Transference to oral therapy should be made as soon as possible.

OVERDOSAGE OR EXAGGERATED RESPONSE

IN THE EVENT OF OVERDOSAGE OR EXAGGERATED RESPONSE, THE FOLLOWING MEASURES SHOULD BE EMPLOYED:

BRADYCARDIA—ADMINISTER ATROPINE (0.25 to 1.0 mg.): IF THERE IS NO RESPONSE TO VAGAL BLOCKADE, ADMINISTER ISOPROTERENOL CAUTIOUSLY

CARDIAC FAILURE—DIGITALIZATION AND DIURETICS

HYPOTENSION—VASOPRESSORS, *e.g.* LEVARTERENOL OR EPINEPHRINE (THERE IS EVIDENCE THAT EPINEPHRINE IS THE DRUG OF CHOICE.)

BRONCHOSPASM—ADMINISTER ISOPROTERENOL AND AMINOPHYLLINE

HOW SUPPLIED

INDERAL (propranolol hydrochloride)

TABLETS—No. 461—Each tablet contains 10 mg. of propranolol hydrochloride, in bottles of 100 and 1,000.

No. 464—Each tablet contains 40 mg. of propranolol hydrochloride, in bottles of 100 and 1,000.

INJECTABLE—No. 3265—Each cc. contains 1 mg. of propranolol hydrochloride in Water for Injection. The pH is adjusted with citric acid. Supplied as: 1 cc. ampuls in boxes of 10.

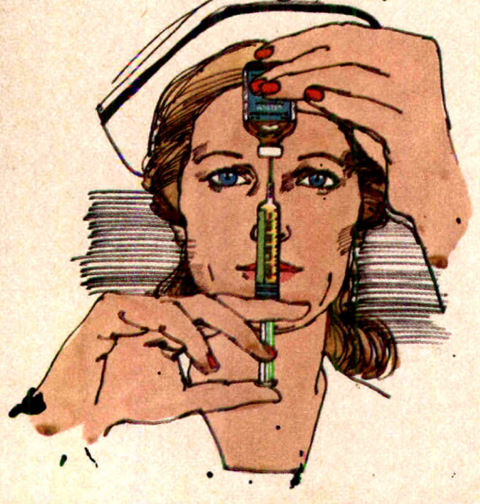
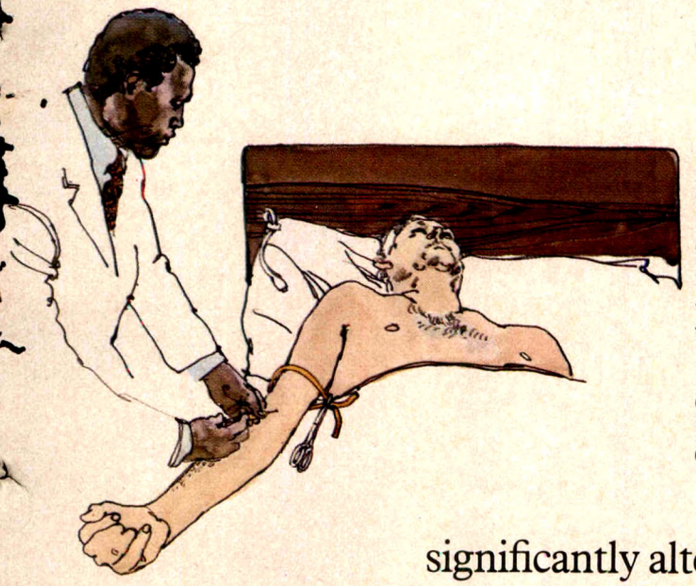
Facing cardioversion with acute anxiety

Anxiety is likely to be present in most cardiac patients about to undergo elective cardioversion. In some cases, however, psychic tension may be severe and reach disproportionate levels.

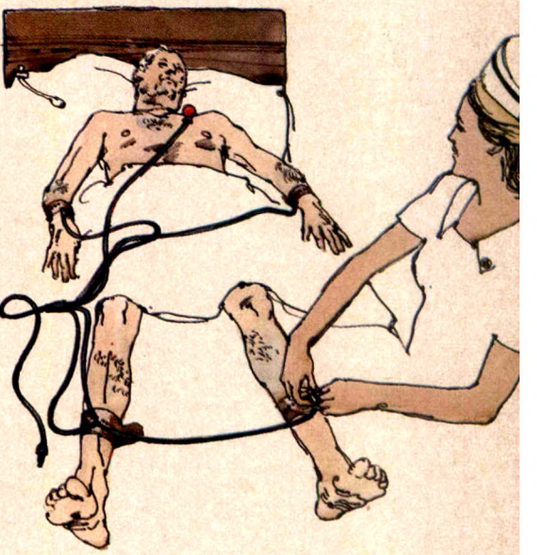


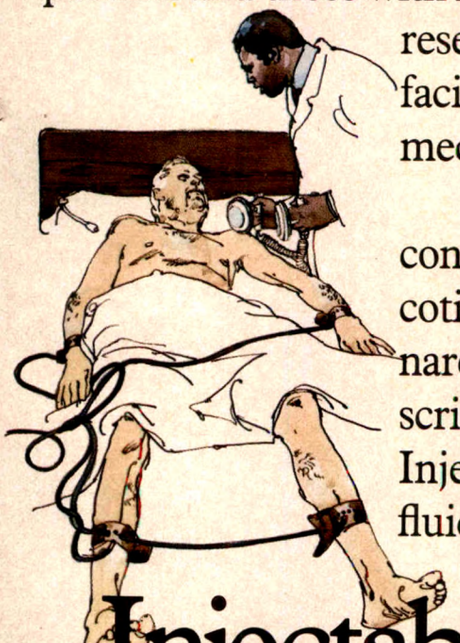
In such instances, 5 to 15 mg Injectable Valium® (diazepam), administered I.V. within 5 to 10 minutes before the procedure, is a valuable premedicant. Its calming effect on the apprehensive patient is generally prompt and pronounced, often



reducing the need for general anesthesia and O.R. scheduling. Perhaps best of all, Injectable Valium (diazepam) can markedly diminish the patient's memory of the countershock.

Injectable Valium seldom significantly alters vital signs. Nevertheless, there have been infrequent reports of hypotension and rare reports of apnea and cardiac arrest, usually following I.V. administration, especially in elderly or very ill patients and those with limited pulmonary reserve. Resuscitative facilities should be immediately available.





When given in conjunction with narcotics, a reduction of narcotic dosage should be considered. (See prescribing information.) Do not mix or dilute Injectable Valium with other drugs, solutions or fluids.

Injectable Valium® (diazepam) can ease the way

ROCHE

Before prescribing, please consult complete product information, a summary of which appears on the following page.

Prior to cardioversion, to relieve excessive anxiety and diminish recall

Injectable Valium® (diazepam)

ready-to-use 2-ml Tel-E-Ject® (disposable syringes)
10-ml vials
2-ml ampuls
} 5 mg/ml

Before prescribing, please consult complete product information, a summary of which follows:

Indications: Tension and anxiety states; somatic complaints which are concomitants of emotional factors; psychoneurotic states manifested by tension, anxiety, apprehension, fatigue, depressive symptoms or agitation; symptomatic relief of acute agitation, tremor, delirium tremens and hallucinosis due to acute alcohol withdrawal; adjunctively in: relief of skeletal muscle spasm due to reflex spasm to local pathology; spasticity caused by upper motor neuron disorders; athetosis; stiff-man syndrome; tetanus; status epilepticus and severe recurrent seizures; adjunctively in anxiety, tension or acute stress reactions prior to endoscopic and surgical procedures; cardioversion.

Contraindicated: In infants; in patients with known hypersensitivity to the drug; in acute narrow angle glaucoma; may be used in patients with open angle glaucoma receiving appropriate therapy.

Warnings: *Inject I.V. slowly, directly into vein; take at least one minute for each 5 mg (1 ml) given. Do not mix or dilute with other solutions or drugs. Do not add to I.V. fluids.* Administer with extreme care to elderly or very ill and those with limited pulmonary reserve because of possibility of apnea and/or cardiac arrest; have resuscitative facilities available. When used with narcotic analgesic eliminate or reduce narcotic dosage at least ⅓, administer in small increments. Should not be administered to patients in shock, coma, acute alcoholic intoxication with depression of vital signs. As with most CNS-acting drugs, caution against hazardous occupations requiring complete mental alertness (*e.g.*, operating machinery, driving). Advise against simultaneous ingestion of alcohol and other CNS depressants. Withdrawal symptoms (similar to those with barbiturates and alcohol) have occurred following abrupt discontinuance (convulsions, tremor, abdominal and muscle cramps, vomiting and sweating). Keep addiction-prone individuals under careful surveillance because of their predisposition to habituation and dependence. In pregnancy, nursing women or women of childbearing potential, weigh expected benefit against possible hazard to mother and child. Not recommended for OB use.

Precautions: If combined with other psychotropics or anticonvulsants, carefully consider individual pharmacologic effects—particularly with known compounds which may potentiate action of Valium (diazepam), *i.e.*, phenothiazines, narcotics, barbiturates, MAO inhibitors and other antidepressants. Protective measures indicated in highly anxious patients with accompanying depression who may have suicidal tendencies. Observe usual precautions in impaired hepatic function; avoid accumulation in patients with compromised kidney function. Laryngospasm and increased cough reflex are possible during peroral endoscopic procedures; use topical anesthetic and have necessary countermeasures available. Hypotension or muscular weakness possible, particularly when used with narcotics, barbiturates or alcohol. Use lower doses (2 to 5 mg) for elderly and debilitated; safety and efficacy in children under 12 not established.

Adverse Reactions: Drowsiness, fatigue, ataxia, venous thrombosis and phlebitis at injection site, confusion, depression, dysarthria, headache, hypoactivity, slurred speech, syncope, tremor, vertigo, constipation, nausea, incontinence, changes in libido, urinary retention, bradycardia, cardiovascular collapse, hypotension, blurred vision, diplopia, nystagmus, urticaria, skin rash, hiccups, changes in salivation, neutropenia, jaundice. Paradoxical reactions such as acute hyperexcited states, anxiety, hallucinations, increased muscle spasticity, insomnia, rage, sleep disturbances and stimulation have been reported; should these occur, use of the drug should be discontinued. Cough, depressed respiration, dyspnea, hyperventilation, laryngospasm and pain in throat and chest have been reported in peroral endoscopic procedures. Isolated reports of neutropenia, jaundice; periodic blood counts and liver function tests advisable during long-term therapy. Minor EEG changes, usually low-voltage fast activity, of no known significance.

Dosage: Usual initial adult dose is 2 to 20 mg I.M. or I.V., depending on indication and severity. Larger doses may be required in some conditions (tetanus). In acute conditions injection may be repeated within 1 hour, although interval of 3 to 4 hours is usually satisfactory. Lower doses (usually 2 to 5 mg) with slow dosage increase for elderly or debilitated patients and when sedative drugs are added. (See Warnings and Adverse Reactions.) Give I.V. injections slowly, directly into vein; take at least 1 minute for each 5 mg (1 ml); avoid small veins. I.M. should be by deep injection. Do not mix or dilute with other solutions or drugs. Do not add to I.V. fluids. Moderate psychoneurotic reactions, 2 to 5 mg I.M. or I.V. and severe psychoneurotic reactions, 5 to 10 mg I.M. or I.V., repeat in 3 to 4 hours if necessary; acute alcoholic withdrawal, 10 mg I.M. or I.V. initially then 5 to 10 mg in 3 to 4 hours if necessary; muscle spasm, 5 to 10 mg I.M. or I.V. initially, then 5 to 10 mg in 3 to 4 hours if necessary (tetanus may require larger doses); status epilepticus, severe recurrent convulsive seizures, 5 to 10 mg I.M. or I.V. initially, repeat in 2 to 4 hours if necessary. In endoscopic procedures, titrate I.V. dosage to desired sedative response, generally 10 mg or less but up to 20 mg (if narcotics are omitted) immediately prior to procedure; if I.V. cannot be used, 5 to 10 mg I.M. approximately 30 minutes prior to procedure. As preoperative medication, 10 mg I.M.; in cardioversion, 5 to 15 mg I.V., within 5 to 10 min. prior to procedure. Once acute symptomatology has been properly controlled with injectable form, patient may be placed on oral form if further treatment is required.

Management of Overdosage: Manifestations include somnolence, confusion, coma and diminished reflexes. Monitor respiration, pulse, blood pressure; employ general supportive measures, I.V. fluids, adequate airway. Use levarterenol or metaraminol for hypotension, caffeine and sodium benzoate for CNS-depressive effects. Dialysis is of limited value.

Supplied: Ampuls, 2 ml, boxes of 10; Vials, 10 ml, boxes of 1; Tel-E-Ject® (disposable syringes), 2 ml, boxes of 10. Each ml contains 5 mg diazepam compounded with 40% propylene glycol, 10% ethyl alcohol, 5% sodium benzoate and benzoic acid as buffers, and 1.5% benzyl alcohol as preservative.

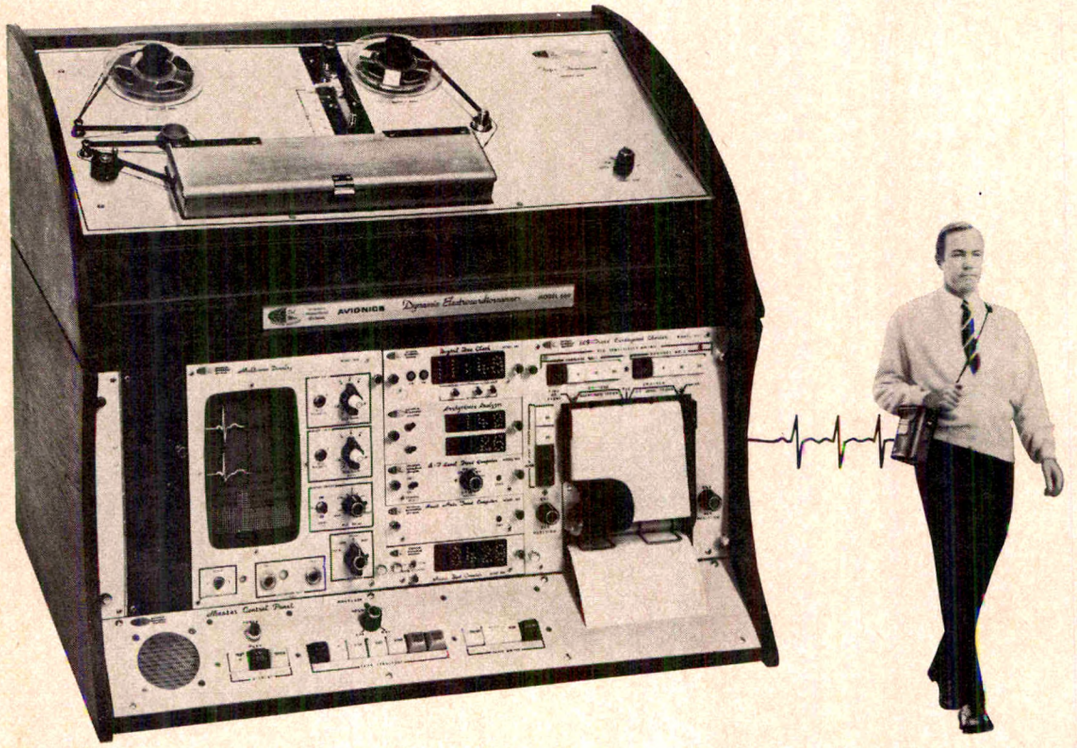
THE NEW 660 A DRAMATIC LEAP FORWARD IN DYNAMIC ELECTROCARDIOGRAPHY!



Model 660 Features:

- 2-channel playback of Holter recordings
- 2-channel paper writer
- 120:1 playback ratio (24-hour recording scanned in 12 minutes)
- Trend recording of S-T segment and heart rate
- Digital display and chart recording of ventricular and supraventricular ectopic beats
- Total heart beat counter
- Digital display clock
- Automatic time print-out on ECG write-out
- Adjustable delay loop for tape deck
- Solid state, modular design

Now available to every physician . . . an advanced ECG system for post MI follow-up, pacemaker evaluation, evaluation of drug administration, and detecting the causes of such fleeting symptoms as phantom chest pains and dizziness.

Model 425 Holter Monitor
Provides a 2-channel, 24-hour ECG recording of ambulatory patients.

Model 660 Electrocardioscanner®
Performs a 12-minute scan of the 24-hour, 2-channel tape recording and provides standard ECG documentation of abnormalities and quantification of arrhythmia and ischemic data.

AVIONICS

☐ Please send me the literature. I would like to know more about Holter monitoring and the Avionics Dynamic Electrocardiographic Systems.

☐ Send the literature, and schedule me for a visiting demonstration. I am definitely interested in acquiring this kind of equipment.

CONTENTS

CLINICAL STUDIES

1 **Comparison of Biplane and Single Plane Left Ventriculograms in Patients with Coronary Artery Disease**

PETER F. COHN, RICHARD GORLIN, DOUGLASS F. ADAMS, ROBERT A. CHAHINE, PANTEL S. VOKONAS and MICHAEL V. HERMAN

In biplane left cineventriculographic studies of 10 normal patients, volumetric analyses indicated good agreement between minor diameters in the right and left anterior oblique views and between ventricular volumes and ejection fractions determined by single plane and biplane techniques. In 50 patients with coronary artery disease more scatter in these values was attributed to loss of ventricular symmetry. The biplane technique allowed comprehensive evaluation of ventricular asynergy and overall function in patients with prior myocardial infarction and ventricular enlargement.

7 **Devolutionary Pattern of Coronary Atherosclerosis in Patients with Angina Pectoris. Coronary Arteriographic Studies**

DEMETRIOS KIMBIRIS, PETER LAVINE, HANS VAN DEN BROEK, MOOSA NAJMI and WILLIAM LIKOFF

As observed cinearteriographically in 47 patients, the devolutionary pattern of coronary arteriosclerosis in patients with angina pectoris is unpredictable and unrelated to the common risk factors. Severity of angina pectoris is the best guide to progressive coronary artery disease although progressive disease can occur without affecting angina. Not all determinants influencing myocardial perfusion are identified by cinearteriography.

12 **Effects of Factors Predisposing to Atherosclerosis on Formation of Coronary Collateral Vessels**

ROBERT A. HEINLE, ROBERT I. LEVY and RICHARD GORLIN

This study of 218 consecutive patients undergoing selective coronary angiography found no measurable clinical factors that permit prediction of coronary collateral channels in an individual patient. Factors predisposing to atherosclerosis have a similar distribution in patients with and without such collateral vessels.

17 **Hemodynamic Observations in Patients with Unstable Angina Pectoris**

DAVID S. CANNOM, DONALD C. HARRISON and JOHN S. SCHROEDER

Three distinctive hemodynamic responses to spontaneous angina were observed during monitoring of brachial and pulmonary arterial pressures in 26 patients with unstable angina pectoris and documented occlusive coronary artery disease. Group I had only increased heart rate, Group II had associated increases in brachial arterial pressure and slight increases in heart rate, Group III showed increased brachial and pulmonary arterial diastolic pressures and minimal change in heart rate. Such changes suggest different pathogenic mechanisms for spontaneous angina which may be specific for individual patients.

To convert to normal sinus rhythm, and maintain...and maintain...and maintain...

CARDIOQUIN tablets

(quinidine polygalacturonate)

Low B.I.D. or T.I.D. dosage in most cases

Greater G.I. tolerance

Full quinidine cardiodynamics

*From case records on file with the Medical Department, The Purdue Frederick Company.

BRIEF SUMMARY—INDICATIONS: CARDIOQUIN Tablets (quinidine polygalacturonate) are indicated in the treatment of: premature atrial and ventricular contractions; paroxysmal atrial tachycardia; paroxysmal AV junctional rhythm; atrial flutter; paroxysmal atrial fibrillation; established atrial fibrillation when therapy is appropriate; paroxysmal ventricular tachycardia when not associated with complete heartblock; maintenance therapy after electrical conversion of atrial fibrillation and/or flutter. CONTRAINDICATIONS: Aberrant impulses and abnormal rhythms due to escape mechanisms should not be treated with quinidine. WARNING: In the treatment of atrial flutter reversion to sinus rhythm may be preceded by a progressive reduction in the degree of AV block to a 1:1 ratio and resulting extremely rapid ventricular rate. COMPOSITION: Each CARDIOQUIN Tablet (quinidine polygalacturonate 275 mg.) is equivalent in quinidine content to 3 grains quinidine sulfate. DOSAGE AND ADMINISTRATION: Dosage must be adjusted to individual needs, both for conversion and maintenance. An initial dose of 1 to 3 tablets may be used to terminate arrhythmias, and may be repeated in 3-4 hours: If normal sinus rhythm is not restored after 3 or 4 equal doses, the dose may be increased by ½ to 1 tablet (137.5 to 275 mg.) and administered three to four times before any further dosage increase. For maintenance, one tablet may be used two to three times a day; generally one tablet morning and night will be adequate. SUPPLIED: Uncoated, scored tablets in bottles of 50.

23 **Maximal Cardiac Output During Exercise in Patients with Coronary Artery Disease**

JOHN R. McDONOUGH, RUTH A. DANIELSON, ROBERT E. WILLS and DONALD L. VINE

Measurements in 16 patients with coronary artery disease who exercised to the point of exhaustion revealed that maximal cardiac output paralleled the maximal oxygen uptake and was reflected by a plateau during the final minutes of exercise in which significantly decreased stroke volume and increased mean pulmonary arterial pressure were observed. Acute left ventricular dysfunction, rapidly reversed during the initial seconds of recovery after exercise, was the factor limiting cardiac output in these patients.

30 **Effects of Submaximal Isometric Handgrip on Left Ventricular Size and Wall Motion**

PHILIP LUDBROOK, JOEL S. KARLINER and ROBERT A. O'ROURKE

The normal response to submaximal isometric handgrip exercise at 15 percent of maximal voluntary capacity is a decrease in left ventricular size and in amplitude and velocity of left ventricular wall motion. In patients with previous myocardial infarction sustained isometric handgrip exercise proved useful to intensify or induce left ventricular wall motion abnormalities. In contrast, systolic time intervals were not useful to evaluate the left ventricular response to submaximal handgrip exercise in normal subjects or those with previous infarction.

37 **Enhanced Left Ventricular Performance with Phentolamine in Acute Myocardial Infarction**

PAUL WALINSKY, KANU CHATTERJEE, JAMES FORRESTER, WILLIAM W. PARMLEY and H. J. C. SWAN

Decreased afterload after the administration of phentolamine improved depressed left ventricular function in nine patients with acute myocardial infarction and increased left ventricular filling pressure. Similar improvement did not occur in five patients with normal left ventricular pressure.

42 **Results of Aortocoronary Artery Saphenous Vein Bypass Surgery for Ischemic Heart Disease**

MOOSA NAJMI, KIYOJI USHIYAMA, GUMERSINDO BLANCO, ALBERTO ADAM and BERNARD L. SEGAL

A 12 percent operative or early hospital mortality rate occurred in 100 consecutive patients with ischemic heart disease who had aortocoronary artery saphenous vein bypass grafts. Clinical results, as measured by angina and results of exercise stress tests, correlated best with arterial blood flow through the bypass, which was directly related to the state of the distal coronary arterial system.

EXPERIMENTAL STUDIES

49 **Closed Chest Model of Intracoronary Occlusion for Study of Regional Cardiac Function**

ELIOT CORDAY, TZU-WANG LANG, SAMUEL MEERBAUM, HERBERT GOLD, SHIGERU HIROSE, STEVEN RUBINS and MARINA DALMASTRO

This new model of experimental coronary occlusion provides the means for independent and comprehensive investigations of cardiac function in ischemic and nonischemic myocardium. Intracoronary epicardial electrocardiograms permit correlation with regional hemodynamic and metabolic events. One study using this model showed that when ventricular tachycardia occurred, the net myocardial potassium loss increased in both the occluded and nonoccluded segments of the heart to 13 percent above the preocclusion level, thereby suggesting that the nonoccluded myocardium may also be seriously affected by arrhythmias.

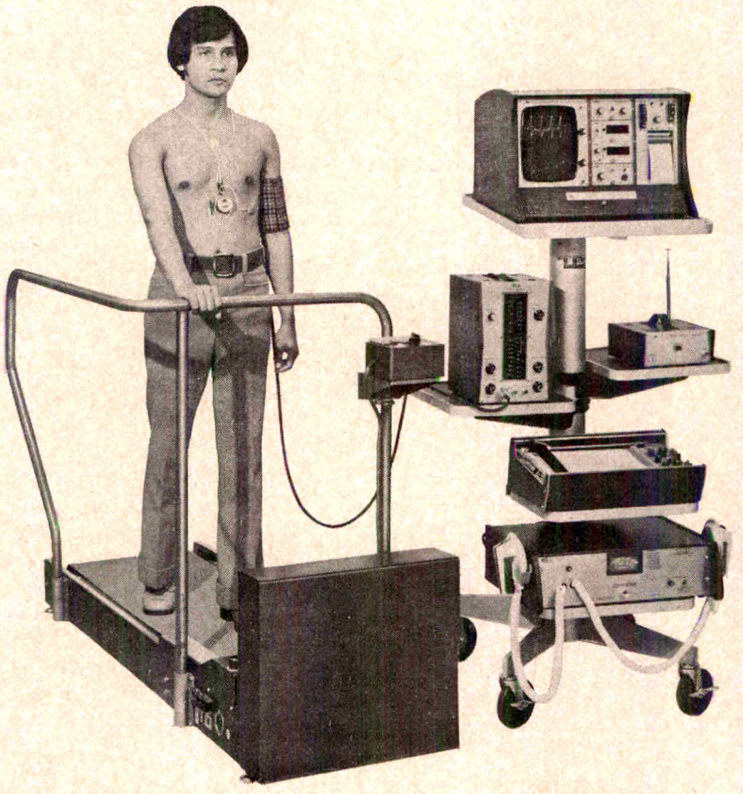
Now! A complete Exercise Stress Test Heart Monitoring System totally engineered, manufactured, marketed, and serviced by Avionics.



BASIC SYSTEM COMPONENTS

- Stress Test Heart Monitor
- Treadmill
- Telemetry
- Automatic Blood Pressurometer
- Respiratory Gas Analyzer
- Defibrillator

MODULES AND CAPABILITIES

- ST-Segment Computer
- Digital Heart Rate Meter
- Automatic Paperwriter Programmer
- 12-lead ECG Capability
- ST & H/R Trend Recording
- Patient Input Isolation Protection

For more information on the most complete exercise stress-test heart-monitoring system available — comprised only of integrally designed and clinically-proven components — return this coupon today.

☐ Please send me your Exercise Stress Test Heart Monitoring brochure. I would like to know more about this new system.

☐ Send the literature, and schedule me for a visiting demonstration. I am definitely interested in acquiring this kind of equipment.

60 Progressive Alterations of Cardiac Hemodynamic and Regional Metabolic Function After Acute Coronary Occlusion

SAMUEL MEERBAUM, TZU-WANG LANG, ELIOT CORDAY, STEVEN RUBINS, SHIGERU HIROSE, COSTANTINO COSTANTINI, HERBERT GOLD and MARINA DALMASTRO

The most striking finding in this study of 34 closed chest dogs after 3 hours of intracoronary balloon occlusion of the left anterior descending artery was the significant metabolic dysfunction, manifested by disturbed regional lactate metabolism and potassium loss, that occurred in the nonoccluded segment after the occlusion period. This change may be attributed to a decrease in regional coronary flow or to increased oxygen demands in this zone resulting from increased left ventricular overload. Individual experiments often revealed a distinct metabolic-mechanical dissociation.

69 Consequences of Reperfusion After Coronary Occlusion. Effects on Hemodynamic and Regional Myocardial Metabolic Function

TZU-WANG LANG, ELIOT CORDAY, HERBERT GOLD, SAMUEL MEERBAUM, STEVEN RUBINS, COSTANTINO COSTANTINI, SHIGERU HIROSE, JULES OSHER and VICTOR ROSEN

Reperfusion for 5 hours after 3 hours of coronary occlusion in seven closed chest dogs produced intermittent ectopic arrhythmias in five and severe shock in two dogs as well as histopathologic changes of accelerated necrosis, reactive hyperemia, hemorrhage and other apparently irreversible abnormalities. Only two animals showed persistent improvement of hemodynamic indexes. These studies indicate that serious hemodynamic, metabolic and morphologic abnormalities can occur after reperfusion.

82 Deleterious Effects Due to Hemorrhage After Myocardial Reperfusion

GERALD F. BRESNAHAN, ROBERT ROBERTS, WILLIAM E. SHELL, JOHN ROSS, Jr. and BURTON E. SOBEL

Reperfusion 5 hours after experimental coronary arterial occlusion resulted in myocardial hemorrhage and extension of myocardial infarction in 44 percent of 16 conscious dogs and was not without further hazard during evolving myocardial infarction.

87 Physiologic Basis for Assessing Critical Coronary Stenosis. Instantaneous Flow Response and Regional Distribution During Coronary Hyperemia as Measures of Coronary Flow Reserve

K. LANCE GOULD, KIRK LIPSCOMB and GLEN W. HAMILTON

Resting coronary blood flow and regional distribution are insensitive indexes for determining critical stenosis. Coronary flow responses to temporary occlusion and to selective main coronary arterial injection of sodium diatrizoate in 12 dogs demonstrated that resting coronary flow is unaltered until 85 percent of the arterial diameter is constricted, whereas maximal coronary flow is affected by constriction as small as 30 percent. Flow response and regional distribution during coronary hyperemia caused by Hypaque are valid quantitative measures for physiologically assessing critical coronary stenosis and flow reserve.

Drug-Induced Constipation

Many of the widely prescribed drug categories—antacids, analgesics, barbiturates, tranquilizers, diuretics, hematinics, antihistamines, anticholinergics, antispasmodics, narcotics, muscle relaxants, antihypertensives, antidepressants—may interfere with the regular bowel action.

The value of SENOKOT Tablets/Granules has been clearly demonstrated in drug-induced or drug-aggravated constipation. In 5 studies* SENOKOT therapy was effective in 98.5% of 613 cases.

When an essential drug you prescribe induces or aggravates constipation, Rx or recommend a SENOKOT laxative product. Compatible with antacids, clinically tested, shown not to interfere with the action of numerous drugs, it is the *natural* choice to keep things moving gently, comfortably, effectively.

Supplied: SENOKOT Tablets (small, easy-to-swallow)—Bottles of 50 and 100. SENOKOT Granules (delicious, cocoa-flavored)—4, 8 and 16 ounce (1 lb.) canisters.

*References on request.

PEDIATRIC CARDIOLOGY

95 **Cardiac Specialized Tissue in Hearts with an Apparently Single Ventricular Chamber (Double Inlet Left Ventricle)**

ROBERT H. ANDERSON, ROBERT ARNOLD, MOHINDER K. THAPAR, RICHARD S. JONES and DAVID I. HAMILTON

This investigation establishes that specialized tissue is unexpectedly situated in hearts of the "single" ventricular type. In all 14 univentricular hearts the atrioventricular node was a small hypoplastic structure in the interatrial septum. An anterior node at the junction of the right atrial appendage and the anterior interatrial septum connected the atria and ventricles. Such hearts should be distinguished from "common" ventricles in which the specialized tissue is reported to lie in the posterior position.

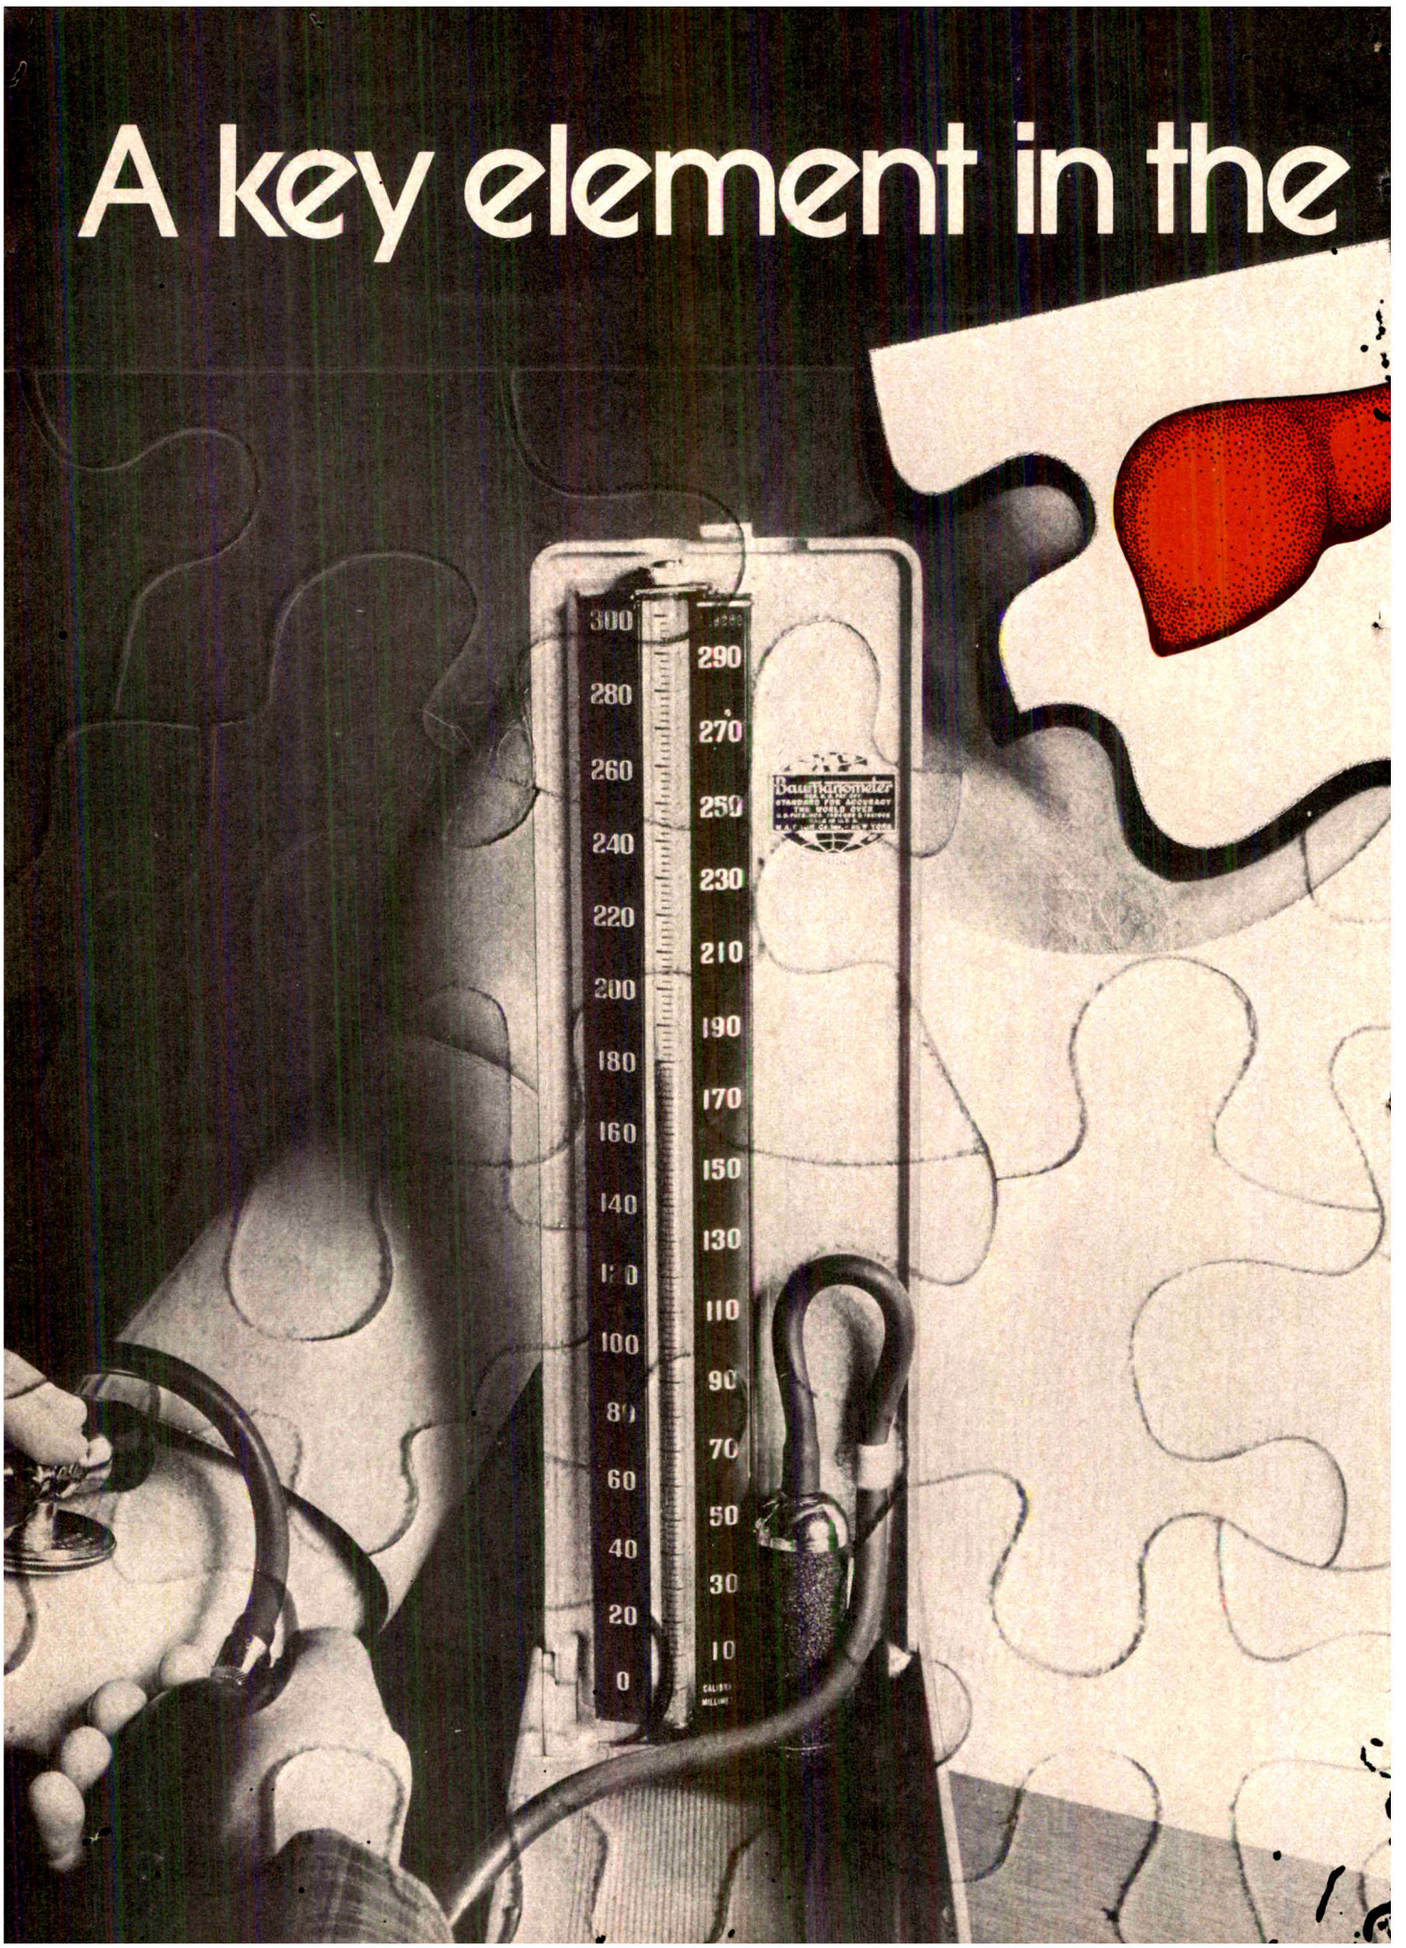
A key element in the



hypertension puzzle

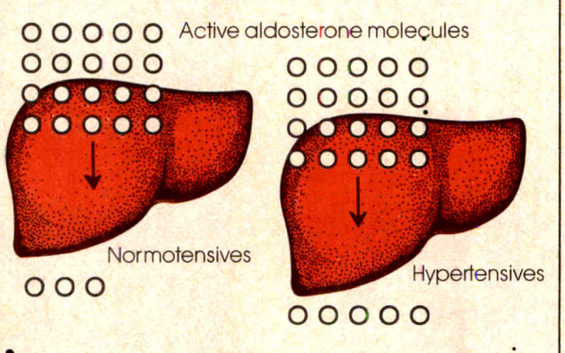
The liver metabolizes significantly less aldosterone in hypertensives than in normotensives.[1,2]

A significantly decreased hepatic MCR (metabolic clearance rate) of aldosterone, without significantly decreased SR (secretion rate), was demonstrated in approximately 90 percent of a group of 56 patients with benign essential hypertension.[1]

Thus "Failure of the aldosterone SR to fully adapt to the decrease in MCR may be responsible for a relative state of hyperaldosteronism in many patients with BEH [benign essential hypertension], even when the secretion and excretion rates are within normal range.

"It is conceivable that it is the mineralocorticoid [aldosterone] excess that is leading to an increase of sodium content in the arteriolar wall and the hypertensive process itself, in many patients with BEH."[2]

Metabolic clearance of aldosterone in hypertensives and in normotensives*



*Schematic representation

To help control the aldosterone factor in essential hypertension

Aldactazide®

(spironolactone 25 mg./hydrochlorothiazide 25 mg.)

- Spironolactone blocks the pressor effect of aldosterone at the arteriole,[3-5] and exerts natriuretic action in the distal renal tubule.
- Hydrochlorothiazide exerts additive antihypertensive effect through its action at a different renal site.
- Aldactazide helps maintain potassium balance—without the need for potassium supplements—because the potassium-sparing action of spironolactone offsets the potassium-losing effect of hydrochlorothiazide.

See following page for brief summary.

To help control the aldosterone factor in essential hypertension

Aldactazide®

(spironolactone 25 mg./hydrochlorothiazide 25 mg.)

Indications—Hypertension; edema or ascites of congestive heart failure, cirrhosis of the liver and the nephrotic syndrome; idiopathic edema. Some patients with malignant effusion may benefit from Aldactazide therapy.

Contraindications—Acute renal insufficiency, rapidly progressing impairment of the renal function. Anuria; sensitivity to thiazides or other sulfonamide-derived drugs. Probably contraindicated in acute or severe hepatic failure.

Warnings—Fixed-dose combination drugs are not indicated for initial therapy of edema or hypertension. Edema or hypertension requires therapy titrated to the individual patient. If the fixed combination represents the dosage so determined, its use may be more convenient in patient management. The treatment of hypertension and edema is not static, but must be reevaluated as conditions in each patient warrant.

Potassium supplementation is recommended only in exceptional instances, but may be considered when a glucocorticoid is also given. Utilize normal dietary sources of potassium if possible when potassium supplementation is necessary. If enteric-coated potassium is used be alert to the possible development of hemorrhagic, stenotic, ulcerated or perforated small-bowel lesions; deaths have occurred. The possibility of exacerbation or activation of systemic lupus erythematosus by sulfonamide derivatives, including thiazides, has been reported.

Administer thiazides with caution to pregnant or lactating patients. Adverse reactions which may occur in the adult (hyperbilirubinemia, thrombocytopenia, altered carbohydrate metabolism, etc.) may possibly occur in the newborn, since thiazides cross the placental barrier and may also appear in breast milk.

Precautions—Consider the possibility of fluid and electrolyte imbalance. Serum and urine electrolyte determinations are particularly important in patients with excessive vomiting or in those receiving fluids parenterally. Medications such as digitalis may also influence serum electrolytes. Warning signs of possible fluid and electrolyte imbalance are: dryness of the mouth, thirst, weakness, lethargy, drowsiness, restlessness, muscle pains, cramps or fatigue, hypotension, oliguria, tachycardia, gastrointestinal symptoms. Hypokalemia may develop with brisk diuresis in severe cirrhosis or during the concomitant use of glucocorticoids or ACTH. Inadequate oral electrolyte intake contributes to hypokalemia. Hypokalemia may cause signs of digitalis intoxication with previously tolerated doses of digitalis.

Give Aldactazide cautiously to patients with severe liver disease since thiazides can precipitate hepatic coma; discontinue if mental confusion increases. Consider also other factors that may precipitate hepatic coma, including blood in the gastrointestinal tract or preexistent potassium depletion. Reversible elevation of NPN and BUN may occur in some patients receiving Aldactazide. The most common electrolyte disturbance is dilutional hyponatremia which requires appropriate corrective measures. A true low-salt syndrome is rare; discontinue Aldactazide and administer sodium for this condition.

Although rare, the most potentially serious electrolyte disturbance is hyperkalemia; if this occurs discontinue Aldactazide and restrict potassium intake. Rarely, fatality due to hyperkalemia has been reported. Hyperkalemia is more likely to occur in severely ill patients with relatively small urine output or in patients receiving supplemental potassium; determine serum electrolytes frequently in such patients. Consider the possibility of hyperuricemia or a decrease in tolerance to glucose.

Patients with severely resistant edema may have an increased diuretic response following the addition of a potent glucocorticoid, such as 15 to 20 mg. of prednisone daily, to Aldactazide therapy. Supplemental potassium will usually be necessary in such patients and the usual precautions with glucocorticoids are necessary. Use caution if regional or general anesthesia is necessary since Aldactazide reduces vascular responsiveness to norepinephrine in such patients. Thiazides may increase responsiveness to tubocurarine. The antihypertensive effects of hydrochlorothiazide may be enhanced in patients who have undergone sympathectomy.

Pathologic changes in the parathyroid glands, with hypercalcemia and hypophosphatemia, have been observed in a few patients on prolonged thiazide therapy.

Thiazides may increase serum PBI levels without signs of thyroid disturbance.

Adverse Reactions reported with *spironolactone* use: Drowsiness and lethargy, mental confusion, diarrhea and other gastrointestinal symptoms, photosensitivity, mild androgenic manifestations (including hirsutism, menstrual irregularity, deepening of the voice), gynecomastia, inability to achieve or to maintain erection, headache, maculopapular or erythematous cutaneous eruptions, urticaria, drug fever, ataxia.

Adverse Reactions reported with *thiazide* use: purpura, thrombocytopenia, leukopenia, agranulocytosis, gastrointestinal disorders (anorexia, nausea, vomiting, diarrhea, abdominal cramps), rash, pruritus, paresthesia, acute pancreatitis, jaundice, dizziness, vertigo, headache, xanthopsia, urticaria, necrotizing angiitis, aplastic anemia, orthostatic hypotension, muscle spasm, weakness, restlessness. Reduce dosage or withdraw drug whenever adverse reactions are moderate or severe.

Dosage and Administration—Dosage should be determined by individual titration. *For essential hypertension* the daily *adult* dosage is two to four tablets in divided doses; continue treatment for two weeks or longer. Adjust the dosage according to the response of the patient. Reduce the dosage of other antihypertensive agents, particularly ganglionic blocking agents, by 50 percent since Aldactazide potentiates the action of such drugs. *For edema, ascites or effusion in adults* the average dosage is one tablet 4 times daily; dosage may range from 1 to 8 tablets daily in divided doses. The daily dosage of Aldactazide *in children* should provide 0.75 to 1.5 mg. of Aldactone® (spironolactone) per pound of body weight.

HEALTH INDUSTRY CAREERS FOR CARDIOLOGISTS AND INTERNISTS

We have many challenging assignments in industry for physicians who want to combine medical knowledge, scientific inquisitiveness and administrative skills.

Directors of

CLINICAL PHARMACOLOGY (PHASES I & II)

CLINICAL TRIALS (PHASE III)

CLINICAL DEVELOPMENT (PHASE IV)

Also, Associate Directors and Clinical Investigation Monitors.

Positions in Midatlantic, Philadelphia area and Midwest.

Physicians Board-Certified or Board-Eligible in Cardiology or Internal Medicine preferred. Academic and/or administrative background and knowledge of clinical research procedures, particularly in the cardiovascular area—a plus. Must have ability to plan, administrate, and communicate. Experience in practice or in the pharmaceutical industry desirable.

Excellent total compensation packages.

Our clients pay all fees. Send your curriculum vitae, geographic preferences, and salary requirements in confidence to:

First In Executive Search For The Health Industries

Vitatron Medical offer you 100 % pacemaker analysability

The new generation of Vitatron Medical pacemakers are completely analysable during implantation.

The new digital pacemaker analyzer MPA 1 allows post-operative determination off all important pacemaker parameters such as electrode impedance in ohms and stimulation threshold in mA.

A regular review of the data will determine the run down of a pacemaker's lifetime well in advance.

Use of Vitatron Medical VCA pacemakers eliminates the need for elective pacemaker replacement.

The Vitatron Medical analysis system enables a near 100% utilization of the pacemaker lifetime, reducing replacement to an absolute minimum.

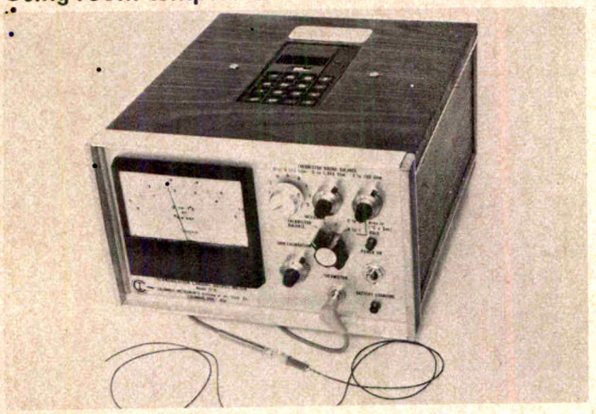
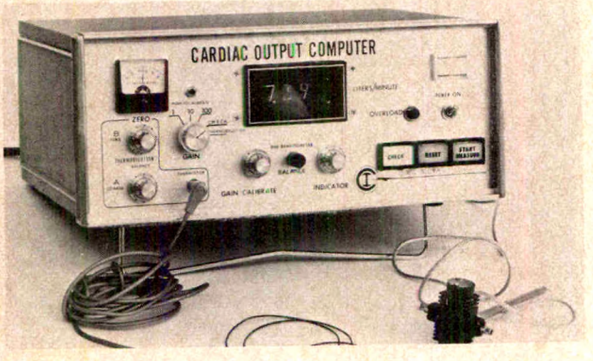
THERMODILUTION

Using room temperature indicator!



THERMODILUTION CARDIAC OUTPUT METER AND INTEGRATOR

- An intermediate instrument between the simple bridge and full scale computer.
- Battery operated—no shock hazards. Rechargeable.
- Will work with any thermistor catheter on the market; including Swan-Gantz balloon flow-directed catheter.
- Equipped with a recorder output.
- Provides information on the area under the dilution curve. (Extrapolates the dilution curve!)
- Price: $1,540.00



THERMO AND DYE DILUTION CARDIAC OUTPUT COMPUTER

- Equipped with Thermodilution and/or Dye Dilution Densitometer
- Easy calibration, automatic zeroing.
- Remote control by foot switch.
- Digital readout in L/min.
- Recorder outputs.

Enduron®

METHYCLOTHIAZIDE TABLETS

ABBOTT

Brief Summary

CONTRAINDICATIONS: Anuria.
Hypersensitivity to this or other sulfonamide-derived drugs.
The routine use of diuretics in an otherwise healthy pregnant woman with or without mild edema is contraindicated and possibly hazardous.

WARNINGS: Should be used with caution in severe renal disease. In patients with renal disease, thiazides may precipitate azotemia. Cumulative effects of the drug may develop in patients with impaired renal function.
Thiazides should be used with caution in patients with impaired hepatic function or progressive liver disease, since minor alterations of fluid and electrolyte balance may precipitate hepatic coma.
Thiazides may be additive or potentiative of the action of other antihypertensive drugs. Potentiation occurs with ganglionic or peripheral adrenergic blocking drugs.
Sensitivity reactions may occur in patients with a history of allergy or bronchial asthma.
The possibility of exacerbation or activation of systemic lupus erythematosus has been reported.

USAGE IN PREGNANCY: Usage of thiazides in women of childbearing age requires that the potential benefits of the drug be weighed against its possible hazards to the fetus. These hazards include fetal or neonatal jaundice, thrombocytopenia, and possibly other adverse reactions which have occurred in the adult.

NURSING MOTHERS: Thiazides cross the placental barrier and appear in cord blood and breast milk.

PRECAUTIONS: Periodic determination of serum electrolytes to detect possible electrolyte imbalance should be performed at appropriate intervals.
All patients receiving thiazide therapy should be observed for clinical signs of fluid or electrolyte imbalance; namely, hyponatremia, hypochloremic alkalosis, and hypokalemia. Serum and urine electrolyte determinations are particularly important when the patient is vomiting excessively or receiving parenteral fluids. Medication such as digitalis may also influence serum electrolytes. Warning signs, irrespective of cause, are: Dryness of mouth, thirst, weakness, lethargy, drowsiness, restlessness, muscle pains or cramps, muscular fatigue, hypotension, oliguria, tachycardia, and gastrointestinal disturbances such as nausea and vomiting.
Hypokalemia may develop with thiazides as with any other potent diuretic, especially with brisk diuresis, when severe cirrhosis is present, or during concomitant use of corticosteroids or ACTH.
Interference with adequate oral electrolyte intake will also contribute to hypokalemia. Digitalis therapy may exaggerate metabolic effects of hypokalemia especially with reference to myocardial activity.
Any chloride deficit is generally mild and usually does not require specific treatment except under extraordinary circumstances (as in liver disease or renal disease). Dilutional hyponatremia may occur in edematous patients in hot weather; appropriate therapy is water restriction, rather than administration of salt except in rare instances when the hyponatremia is life threatening.
In actual salt depletion, appropriate replacement is the therapy of choice.
Hyperuricemia may occur or frank gout may be precipitated in certain patients receiving thiazide therapy.
Insulin requirements in diabetic patients may be increased, decreased, or unchanged. Latent diabetes mellitus may become manifest during thiazide administration.
Thiazide drugs may increase the responsiveness to tubocurarine.
The antihypertensive effects of the drug may be enhanced in the postsympathectomy patient.
Thiazides may decrease arterial responsiveness to norepinephrine. This diminution is not sufficient to preclude effectiveness of the pressor agent for therapeutic use.
If progressive renal impairment becomes evident as indicated by a rising nonprotein nitrogen or blood urea nitrogen, a careful reappraisal of therapy is necessary with consideration given to withholding or discontinuing diuretic therapy.
Thiazides may decrease serum PBI levels without signs of thyroid disturbance.

ADVERSE REACTIONS: Gastrointestinal system reactions: Anorexia, gastric irritation, nausea, vomiting, cramping, diarrhea, constipation, jaundice (intrahepatic cholestatic jaundice), pancreatitis.
Central nervous sytem reactions: Dizziness, vertigo, paresthesias, headache, xanthopsia.
Hematologic reactions: Leukopenia, agranulocytosis, thrombocytopenia, aplastic anemia.
Dermatologic—hypersensitivity reactions: Purpura, photosensitivity, rash, urticaria, necrotizing angiitis (vasculitis) (cutaneous vasculitis).
Cardiovascular reaction: Orthostatic hypotension may occur and may be aggravated by alcohol, barbiturates, or narcotics.
Other: Hyperglycemia, glycosuria, hyperuricemia, muscle spasm, weakness, restlessness.
Whenever adverse reactions are moderate or severe, thiazide dosage should be reduced or therapy withdrawn.

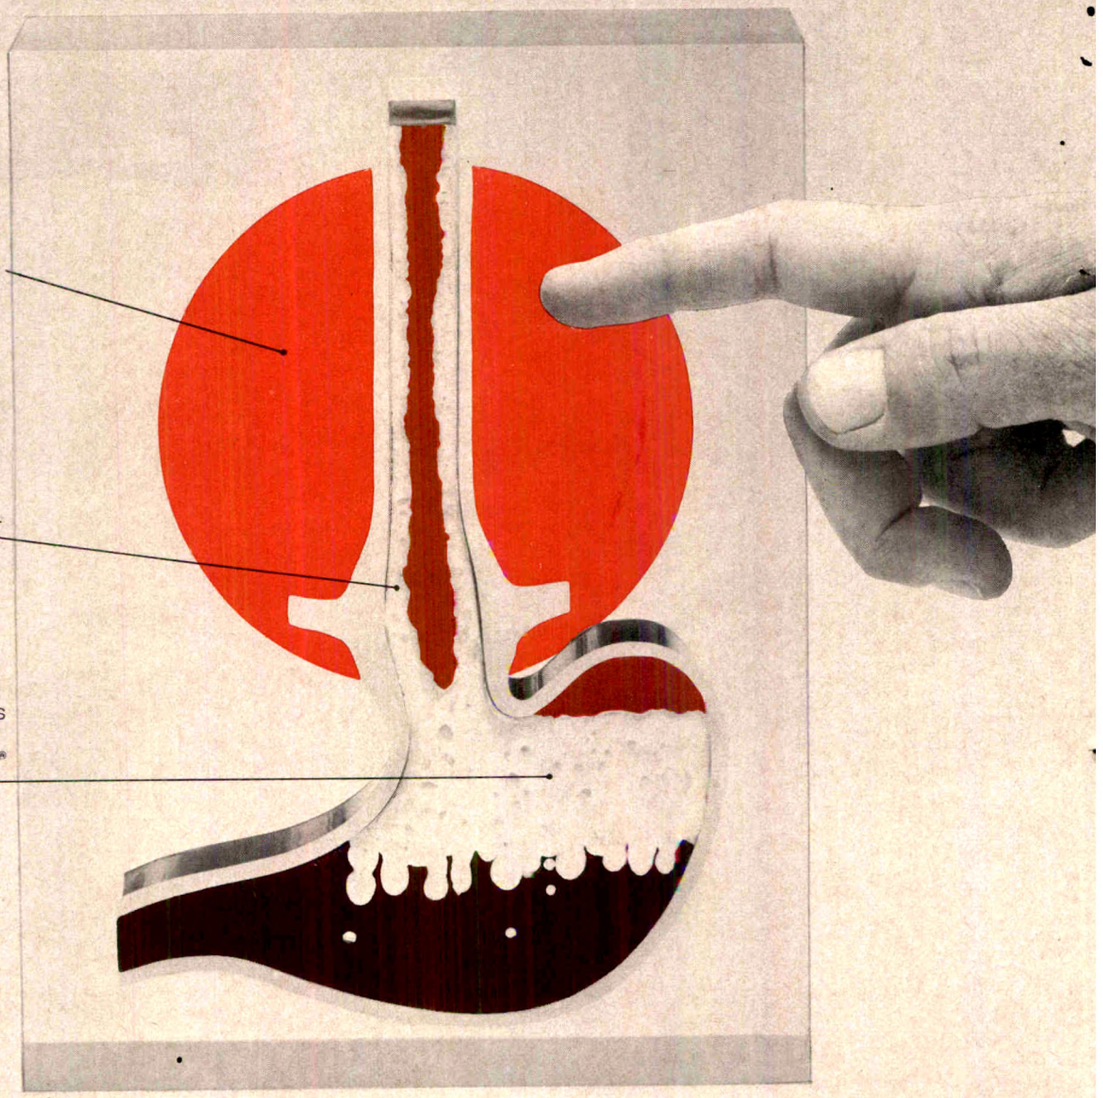
"This is the real Heartburn Zone. This is where GAVISCON® works!"

The Real Heartburn Zone
When gastric juice refluxes into the esophagus, stomach contents irritate sensitive nerve endings in esophageal mucosa to produce the pain of heartburn.

Gaviscon Coats
The Gaviscon foam coating clings to esophageal mucosa for pinpoint neutralization of gastric contents which might reflux from the stomach.

Gaviscon Floats
In the cardia and fundus of the stomach, GAVISCON® FOAMTAB® tablets form a soft, viscous layer of floating antacid foam that precedes gastric contents refluxing into the esophagus.

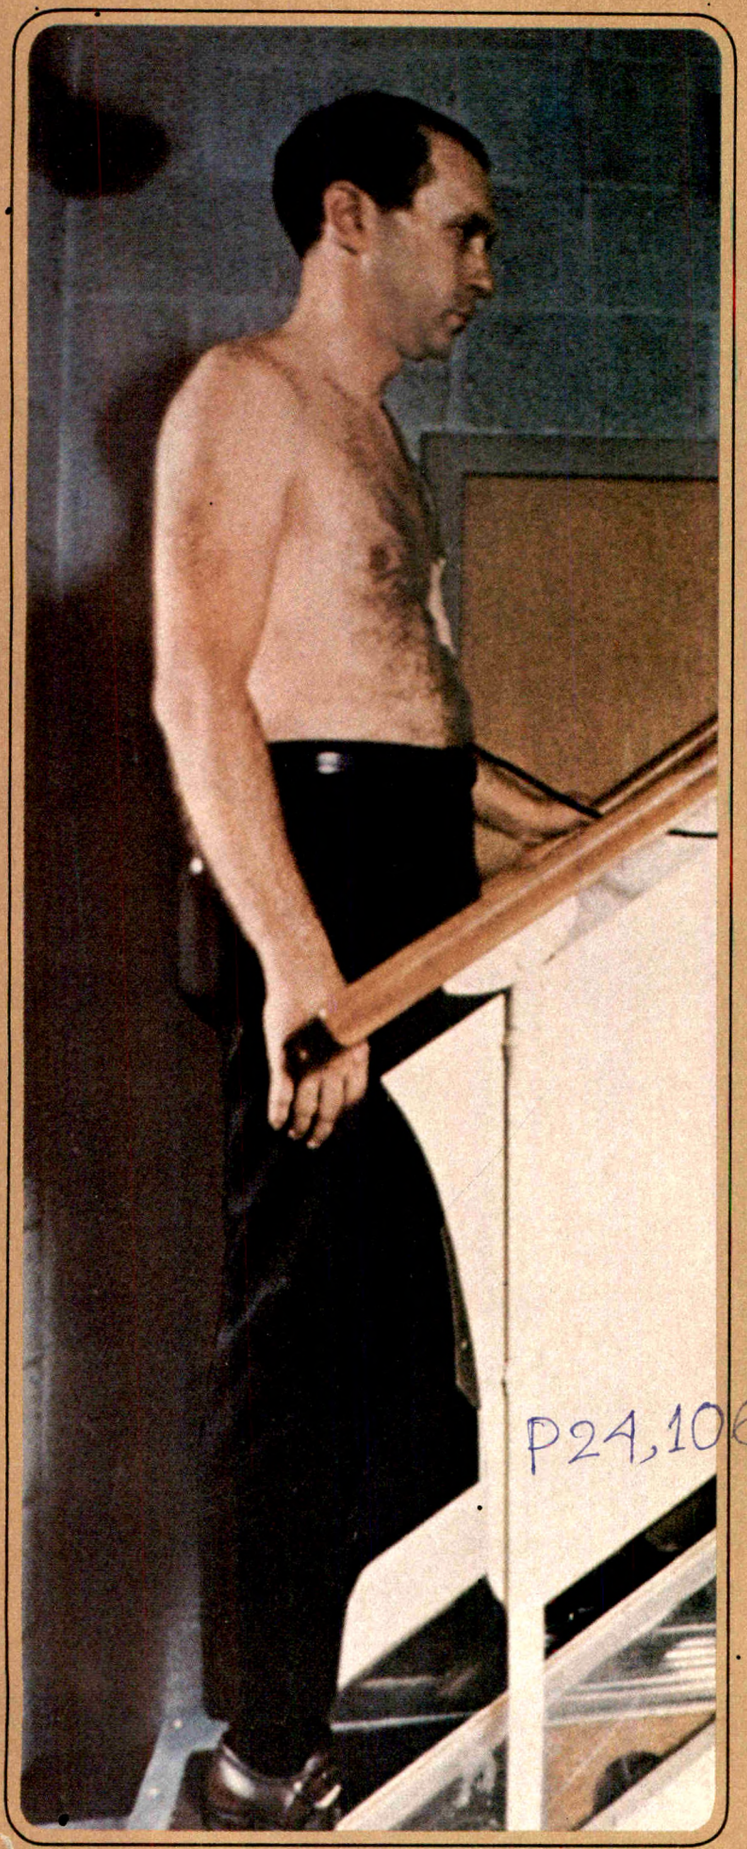


GAVISCON®

FOAMTAB®

(Alginic acid, 200 mg; aluminum hydroxide dried gel, 80 mg; magnesium trisilicate, 20 mg; sodium bicarbonate, 70 mg)
CHEWABLE ANTACID TABLETS for relief of heartburn accompanying hiatal hernia, gastroesophageal reflux, and esophagitis.

Another patient benefit product from MARION PHARMACEUTICAL DIVISION MARION LABORATORIES, INC. KANSAS CITY, MISSOURI 64137



tolerance to exercise improved for angina patients

INDICATIONS: For the prophylaxis and long-term management of patients with frequent or recurrent anginal pain and reduced exercise tolerance associated with angina pectoris, rather than for the treatment of the acute attack of angina pectoris, since its onset of action is somewhat slower than that of nitroglycerin.

PRECAUTIONS: As with other effective nitrites, some fall in blood pressure may occur with large doses. Caution should be observed in patients with a history of recent cerebral hemorrhage, because of the vasodilatation which occurs in the area. Although therapy permits more normal activity, the patient should not be allowed to misinterpret freedom from anginal attacks as a signal to drop all restrictions.

SIDE EFFECTS: No serious side effects have been reported. As with nitroglycerin or other effective nitrites, temporary vascular headache may occur during the first few days of therapy. This can be controlled by temporary dosage reduction in order to allow adjustment of the cerebral hemodynamics to the initial marked cerebral vasodilatation. These headaches usually disappear within one week of continuous therapy but may be minimized by the administration of analgesics such as Empirin® Compound.

Mild gastrointestinal disturbances occur occasionally with larger doses and may be controlled by reducing the dose temporarily.

SUPPLIED: 10 mg. chewable tablets. Bottles of 100. Also 5, 10 and 15 mg. scored tablets in bottles of 100. 10 mg. scored tablets also supplied in bottles of 1000.

Also available: Cardilate-P brand Erythrityl Tetranitrate with Phenobarbital (Warning: may be habit-forming).

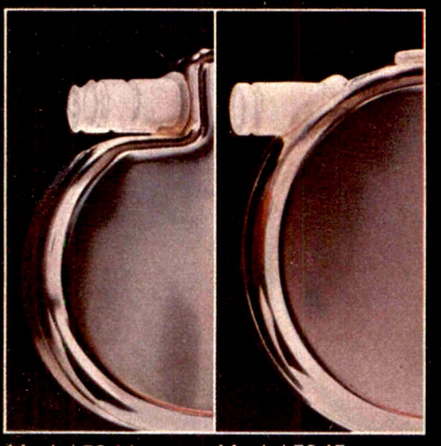
contact your local Medtronic
Representative or Medtronic
Corporate Headquarters:
Medtronic, Inc.

pacemakers conserve it.

The concept of Energy Conservation is based on one simple fact: lessen the drain on a power source and you extend its life.

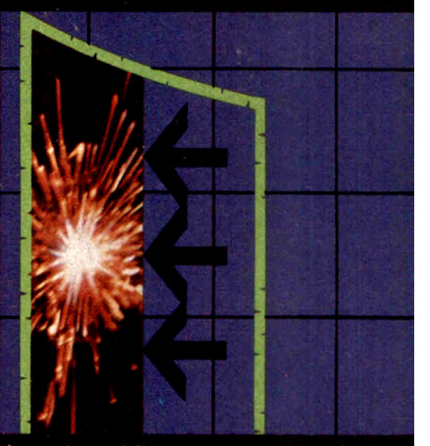
In the new Medtronic pacemakers, pulse width has been reduced to reduce the energy expenditure per pulse.

Less energy expended means longer projected life. It's that simple.



Model 5944— Bipolar Demand Pulse Generator

Model 5945— Unipolar Demand Pulse Generator



As pulse width narrows, projected life of the pulse generator is extended.

Another significant improvement combines the idea of energy compensation with a redundant cell depletion indicator. It works this way: when depletion of the first cell occurs the new Medtronic pulse generators show a decrease in rate similar to most other pulse generators. But, they also automatically increase pulse width when depletion occurs. This increase in pulse width compensates

The New Math of

It may increase diagnostic accuracy by an added 30%

If you're not testing for triglycerides, as well as for cholesterol, you may detect only 6 out of 10 patients with hyperlipidemia.[1]

If you're testing for <u>both</u> triglycerides and cholesterol, chances are you will detect more than 9 out of 10 patients (over 95%) with hyperlipidemia.[1]

The Proven Math

UP TO 35% REDUCTION OF ELEVATED CHOLESTEROL LEVELS

Cholesterol levels above 250 mg.% have decreased as much as 35%...and reductions up to 50% have been reported.[2-5]

UP TO 61% REDUCTION OF ELEVATED TRIGLYCERIDE LEVELS

Triglyceride levels above 150 mg.% have decreased as much as 61%...and reductions up to 90% have been reported.[2,5]

10 YEARS OF SUCCESSFUL OVERALL CLINICAL EXPERIENCE

Reliable cholesterol- and triglyceride-lowering effect persists as long as treatment is uninterrupted.[2,3] Xanthomata may regress or disappear completely.

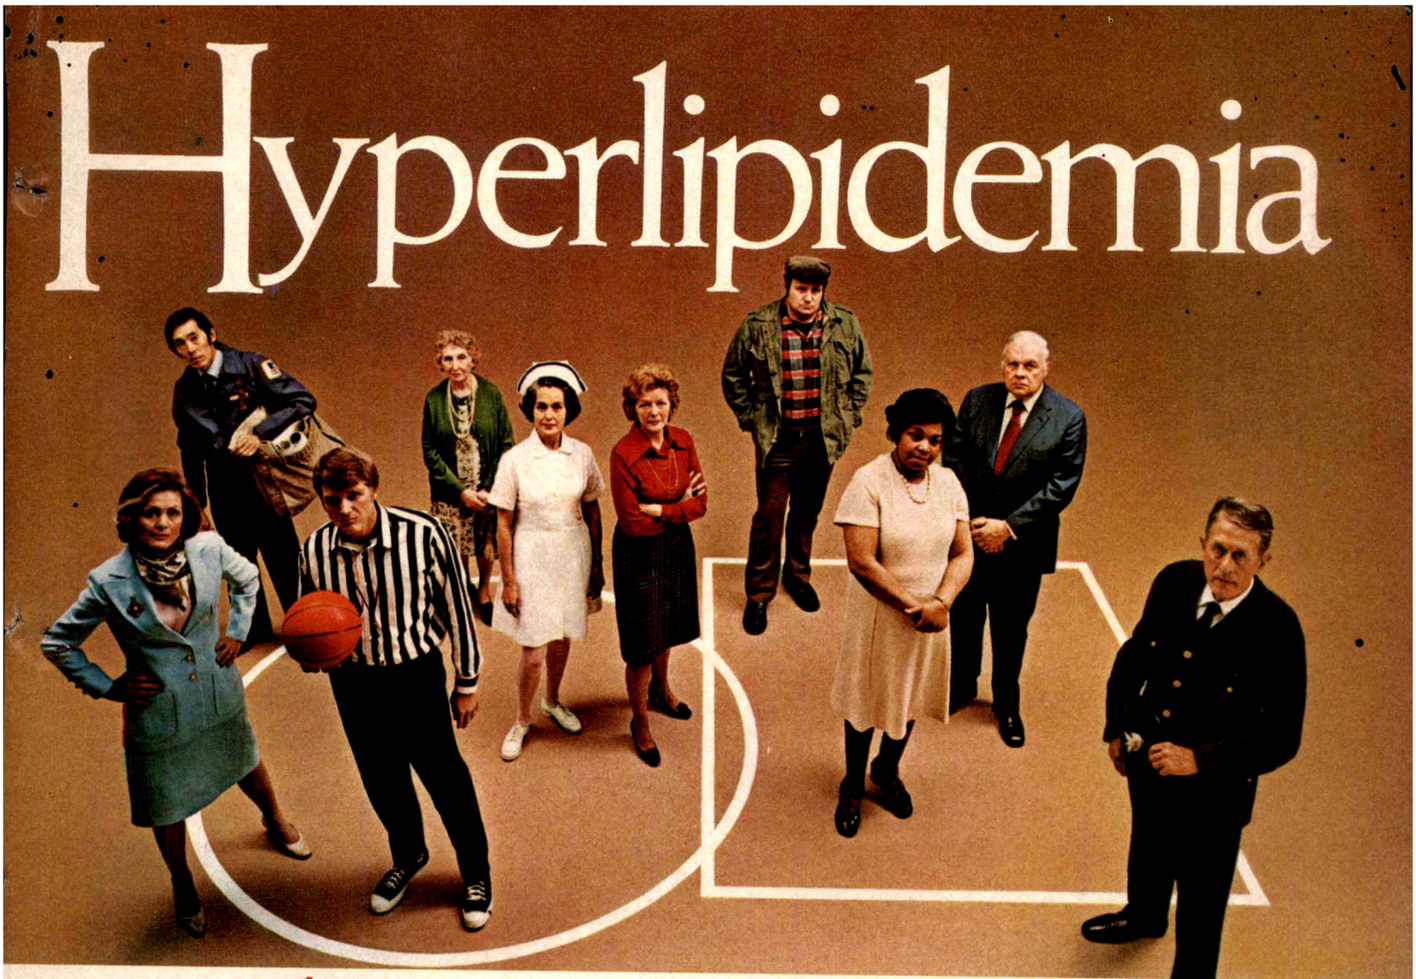
ONE ATROMID-S CAPSULE FOUR TIMES A DAY

A simple, well-accepted regimen that patients can stay with. Same dosage for *all* patients at *all* times.

IF GIVEN IN CONJUNCTION WITH ANTICOAGULANTS

WARNINGS: CAUTION SHOULD BE EXERCISED WHEN ANTICOAGULANTS ARE GIVEN IN CONJUNCTION WITH ATROMID-S (CLOFIBRATE). THE DOSAGE OF THE ANTICOAGULANT SHOULD BE REDUCED USUALLY BY ONE-HALF (DEPENDING ON THE INDIVIDUAL CASE) TO MAINTAIN THE PROTHROMBIN TIME AT THE DESIRED LEVEL TO PREVENT BLEEDING COMPLICATIONS. FREQUENT PROTHROMBIN DETERMINATIONS ARE ADVISABLE UNTIL IT HAS BEEN DEFINITELY DETERMINED THAT THE PROTHROMBIN LEVEL HAS BEEN STABILIZED.

Hyperlipidemia



# of Atromid-S®

Brand of clofibrate

the most widely prescribed lipid-lowering agent–
significantly reduces
elevated levels of cholesterol and/or triglycerides,
not just cholesterol alone

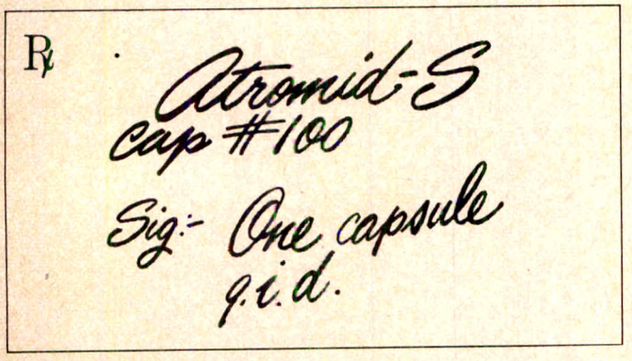
Hyperlipidemia/**Atromid-S®** (clofibrate) **Ayerst®**

AN IMPORTANT NOTE: It has not been established whether the drug-induced lowering of serum cholesterol or lipid levels has a detrimental, beneficial, or no effect on the morbidity or mortality due to atherosclerosis or coronary heart disease. Several years will be required before current investigations will yield an answer to this question.

See last page of advertisement for prescribing information.

Atromid-S® (clofibrate)

helps reduce elevated cholesterol and/or triglyceride levels — not just cholesterol alone



BRIEF SUMMARY

(For full prescribing information, see package circular.)

ATROMID-S® (clofibrate)

Antilipidemic agent for reduction of elevated serum lipids

INDICATIONS: ATROMID-S is indicated as adjunctive therapy to diet and other measures for the reduction of elevated serum cholesterol (especially the beta lipoprotein fraction) and/or triglycerides. Clofibrate appears to have a greater depressant effect on the very low density lipoproteins (S_f 20-400) rich in triglycerides than the low density lipoproteins (S_f 0-20) rich in cholesterol.

ATROMID-S is also indicated for treatment of patients with xanthoma tuberosum associated with hyperlipidemia. The skin lesions frequently regress with clofibrate.

It has not been established whether the drug-induced lowering of serum cholesterol or lipid levels has a detrimental, beneficial, or no effect on the morbidity or mortality due to atherosclerosis or coronary heart disease. Several years will be required before current investigations will yield an answer to this question.

CONTRAINDICATIONS: Clofibrate is contraindicated in pregnant women. While teratogenic studies have not demonstrated any effect attributable to clofibrate, it is known that serum of the rabbit fetus accumulates a higher concentration of clofibrate than that found in maternal serum, and it is possible that the fetus may not have developed the enzyme system required for the excretion of clofibrate.

It is contraindicated in lactating women since it is not known if clofibrate is secreted in the milk.

It is contraindicated in patients with clinically significant hepatic or renal dysfunction.

It is contraindicated in patients with primary biliary cirrhosis since it may raise the already elevated cholesterol in these cases.

WARNINGS: CAUTION SHOULD BE EXERCISED WHEN ANTICOAGULANTS ARE GIVEN IN CONJUNCTION WITH ATROMID-S. THE DOSAGE OF THE ANTICOAGULANT SHOULD BE REDUCED USUALLY BY ONE-HALF (DEPENDING ON THE INDIVIDUAL CASE) TO MAINTAIN THE PROTHROMBIN TIME AT THE DESIRED LEVEL TO PREVENT BLEEDING COMPLICATIONS. FREQUENT PROTHROMBIN DETERMINATIONS ARE ADVISABLE UNTIL IT HAS BEEN DEFINITELY DETERMINED THAT THE PROTHROMBIN LEVEL HAS BEEN STABILIZED.

Strict birth control procedures must be exercised by women of childbearing potential. In patients who plan to become pregnant, clofibrate should be withdrawn several months before conception. Because of the possibility of pregnancy occurring despite birth control precautions in patients taking clofibrate, the possible benefits of the drug to the patient must be weighed against possible hazards to the fetus.

PRECAUTIONS: Before instituting therapy with clofibrate, attempts should be made to control serum lipids with appropriate dietary regimens, weight loss in obese patients, control of diabetes mellitus, etc.

Because of the long term administration of a drug of this nature, adequate base line studies should be performed to determine that the patient has significantly elevated serum lipid levels. Frequent determinations of serum lipids should be obtained during the first few months of ATROMID-S administration, and periodic determinations thereafter. The drug should be withdrawn after three months if response is inadequate. However, in the case of xanthoma tuberosum, the drug should be employed for longer periods (even up to one year) provided that there is a reduction in the size and/or number of the xanthomata.

Subsequent serum lipid determinations should be done to detect a paradoxical rise in serum cholesterol or triglyceride levels. Clofibrate will not alter the seasonal variations of serum cholesterol peak elevations in midwinter and late summer and decreases in fall and spring. If the drug is discontinued, the patient should be placed on an appropriate hypolipidemic diet, and his serum lipids should be monitored until stabilized, as a rise in these values to or above the original base line may occur.

During clofibrate therapy, frequent serum transaminase determinations and other liver function tests should be performed since the drug may produce abnormalities in these parameters. Hepatic biopsies are usually within normal limits. These effects are usually reversible when the drug is discontinued. If the hepatic function tests steadily rise or show excessive abnormalities, the drug should be withdrawn. Therefore use with caution in those patients with a past history of jaundice or hepatic disease.

Clofibrate may produce "flu like" symptoms (muscular aching, soreness, cramping). The physician should differentiate this from actual viral and/or bacterial disease.

Use with caution in patients with peptic ulcer since reactivation has been reported. Whether this is drug-related is unknown.

The physician should monitor the patient with complete blood counts since peripheral anemia and, more frequently, leukopenia have been reported in patients who have been taking clofibrate. Whether these are drug-related is unknown.

Various cardiac arrhythmias have been reported with the use of clofibrate.

Several investigators have observed in their studies that clofibrate may produce a decrease in cholesterol linoleate but an increase in palmitoleate and oleate, the latter being considered atherogenic in experimental animals. The significance of this finding is unknown at this time.

ADVERSE REACTIONS: Of the pertinent reactions, the most common is nausea. Less frequently encountered gastrointestinal reactions are vomiting, loose stools, dyspepsia, flatulence, and abdominal distress. Reactions reported less often than gastrointestinal ones are headache, dizziness, and fatigue; muscle cramping, aching, and weakness; skin rash, urticaria, and pruritus. There have been occasional cases of dry, brittle hair and of alopecia.

The following reported adverse reactions are listed alphabetically by systems:

Cardiovascular
- Cardiac arrhythmias
- Both swelling and phlebitis at site of xanthomas

Dermatologic
- Skin rash
- Alopecia
- Allergic reaction including urticaria
- Dry skin and dry brittle hair
- Pruritus

Gastrointestinal
- Nausea
- Diarrhea
- Gastrointestinal upset (bloating, flatulence, abdominal distress)
- Vomiting
- Stomatitis and gastritis

Genitourinary
- Impotence and decreased libido
- Findings consistent with renal dysfunction as evidenced by dysuria, hematuria, proteinuria, decreased urine output. One patient's renal biopsy suggested "allergic reaction."

Hematologic
- Leukopenia
- Potentiation of anticoagulant effect
- Anemia
- Eosinophilia

Musculoskeletal
- Myalgia (muscle cramping, aching, weakness)
- "Flu like" symptoms
- Arthralgia

Neurologic
- Fatigue, weakness, drowsiness
- Dizziness
- Headache

Miscellaneous
- Weight gain
- Polyphagia

Laboratory Findings
- Abnormal liver function tests as evidenced by increased transaminase (SGOT and SGPT), BSP retention, and increased thymol turbidity
- Proteinuria
- Increased creatine phosphokinase

Reported adverse reactions whose direct relationship with the drug has not been established: increased angina, peptic ulcer, gastrointestinal hemorrhage, rheumatoid arthritis, tremors, increased perspiration, systemic lupus erythematosus, blurred vision.

DOSAGE AND ADMINISTRATION: Adult Dose: The recommended dosage for adults is one capsule (500 mg.) four times daily.

In Children: Insufficient studies have been done in children to show safety and efficacy.

DRUG INTERACTIONS: Caution should be exercised when anticoagulants are given in conjunction with ATROMID-S (clofibrate). The dosage of the anticoagulant should be reduced usually by one-half (depending on the individual case) to maintain the prothrombin time at the desired level to prevent bleeding complications. Frequent prothrombin determinations are advisable until it has been definitely determined that the prothrombin level has been stabilized.

MANAGEMENT OF OVERDOSAGE: While there has been no reported case of overdosage, should it occur, symptomatic supportive measures should be taken.

HOW SUPPLIED: ATROMID-S—No. 243—Each capsule contains 500 mg. clofibrate, in bottles of 100.

The Third Step in Angina.*

After the classic "2-Step" Test aids in a diagnosis of angina, sustained-release Nitro-Bid® (nitroglycerin) is a logical third step. Here's why.

In angina secondary to arteriosclerotic heart disease, sustained-release Nitro-Bid® (nitroglycerin) therapy assists in the "total management" of your patient.

Nitro-Bid capsules reduce sublingual nitroglycerin requirements as they reduce the number of angina attacks . . . increase exercise tolerance.

Sustained-release Nitro-Bid Plateau CAPS® provide a metered sequence of medication during the night to protect against nocturnal angina attack.

In titrating dosage, availability of different strengths "...is quite an asset..."[1]

Nitro-Bid 2.5 and Nitro-Bid 6.5 capsules afford two dosage strengths for convenience in increasing or decreasing dose to accommodate patient symptoms.

NITRO-BID® 2.5
(nitroglycerin 2.5 mg) Plateau CAPS®

NITRO-BID® 6.5
(nitroglycerin 6.5 mg) Plateau CAPS®

INDICATIONS

Based on a review of this drug by the National Academy of Sciences–National Research Council and/or other information, FDA has classified the indications as follows:

*"Possibly" effective:
For the management, prophylaxis or treatment of anginal attacks.

Final classification of the less-than-effective indications requires further investigation.

Contraindications: Recent myocardial infarction, severe anemia, glaucoma, increased intracranial pressure, idiosyncrasy.

Precautions: For ORAL, not sublingual, use. If blurring of vision or dryness of mouth occurs, discontinue drug. Tolerance may develop on long-term usage.

Adverse Reactions: Occasional transient headaches. Overdose may cause flushing, headaches, tachycardia, dizziness.

Dosage: One capsule two or three times daily at 8 to 12 hour intervals.

Reference: 1. Master, AM: The management of angina pectoris. *Modern Medicine* **38**:92-100 (Feb 23) 1970.

The art of antianginal therapy

For centuries, treating the heart's ills has been the subtlest of arts. Even today, evaluating a drug for chronic angina pectoris involves the art of medicine as well as its science.

Persantine — over a decade of use

During more than a decade of clinical experience, compounding both science and art, Persantine has often been found useful in the long-term management of chronic angina pectoris.* It may:

eliminate or reduce the frequency of anginal attacks

improve exercise tolerance

reduce nitroglycerin requirements

Persantine — give enough — long enough

The recommended dosage: 50 mg. t.i.d. at least one hour before meals. *Give enough, long enough* — several weeks or longer of continuous therapy may be needed to see response.

Persantine® Tablets of 25 mg.
dipyridamole

the non-nitrate
coronary vasodilator

*INDICATIONS—Based on a review of this drug by the National Academy of Science-National Research Council and/or other information, FDA has classified the indication as follows:

"Possibly" effective: For long-term therapy of chronic angina pectoris. Prolonged therapy may reduce the frequency or eliminate anginal episodes, improve exercise tolerance, and reduce nitroglycerin requirements. The drug is not intended to abort the acute anginal attack.

Final classification of the less-than-effective indications requires further investigation.

CONTRAINDICATIONS—No specific contraindications are known.

PRECAUTIONS—Since excessive doses can produce peripheral vasodilation, the drug should be used cautiously in patients with hypotension.

ADVERSE REACTIONS—Adverse reactions are minimal and transient at recommended dosages. Instances of headache, dizziness, nausea, flushing, weakness or syncope, mild gastrointestinal distress and skin rash have been noted during therapy. Rare cases of what appeared to be an aggravation of angina pectoris have been reported, usually at the initiation of therapy. On those uncommon occasions when adverse reactions have been persistent or intolerable, withdrawal of medication has been followed promptly by cessation of undesirable symptoms.

DOSAGE AND ADMINISTRATION—The recommended dosage is 50 mg. (2 tablets) three times a day, taken at least one hour before meals. In some cases higher doses may be necessary but a significantly increased incidence of side effects is associated with increased dosage. Clinical response may not be evident before the second or third month of continuous therapy.

For complete details, please see the full prescribing information.

4 reasons why you should continue to recommend Fleischmann's Margarine as part of a low saturated fat diet.

100% corn oil.

Each pound contains almost one cup liquid corn oil.

Clinical studies show corn oil is unsurpassed among vegetable oils in lowering serum cholesterol.

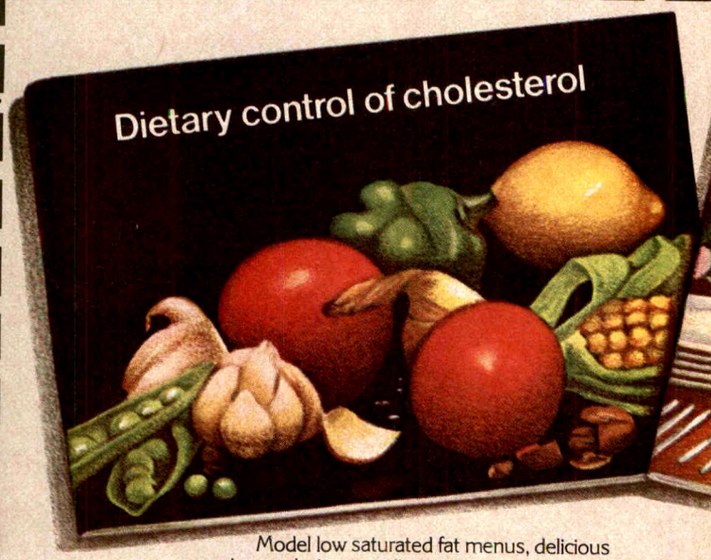
Makes sensible eating delicious.

For years you've known about the excellent P/S ratio of Fleischmann's® Margarine; it's high in polyunsaturates, low in saturated fat. Fleischmann's is made from 100% corn oil; almost one cup is important liquid corn oil. And clinical tests have shown corn oil is unsurpassed among vegetable oils for lowering serum cholesterol.[1-9] And because Fleischmann's is made from 100% corn oil, it tastes delicious.

It is reported that the natural plant sterols of corn oil, in addition to its excellent P/S ratio, may play an important role in corn oil's hypocholesteremic effect. Studies indicate that natural plant sterols exert an independent suppressant effect on serum cholesterol.[6,7,10] Corn oil has a higher content of these sterols than other commonly used vegetable oils. This unique combination of factors, P/S ratio and plant sterols, is believed responsible for corn oil being unsurpassed in lowering serum cholesterol.[4,5]

Fleischmann's Margarine can be recommended with confidence for low cholesterol/low saturated fat diets because it is made from 100% corn oil. Fleischmann's makes sensible eating delicious.

And one coupon to get our free booklets to help your patients stay on that diet.



Model low saturated fat menus, delicious recipes, calorie-controlled diets.

Tasty, nutritious and interesting dishes prepared without salt.

The Four Horsemen of Stroke...

HYPERTENSION

HEART DISEASE

DIABETES

ELEVATED CHOLESTEROL

You have your own therapeutic regimen to reduce these risk factors—the "Big Four" accelerators of stroke.

...and TIA's-the Prophetic Fifth Horseman

Transient Ischemic Attacks (TIA's) are another signal of impending stroke that is particularly ominous. In fact, 33% of patients with TIA's will develop a severe neurological deficit within 5 years.*

For such patients, PAVABID® (papaverine HCl) vasodilatation helps to preserve cerebral circulation. By reducing arterial tone, Pavabid therapy helps block vasospasm that can result in neurological damage.

*Meyer, J. S., and Gilroy, J.: *Medical Neurology*, ed 1, The Macmillan Co., 1969, p 495.

PAVABID®
(papaverine HCl, 150 mg.) Plateau CAPS®

Pavabid® Plateau CAPS® (Papaverine HCl, 150 mg.)—Each capsule contains papaverine hydrochloride, 150 mg. in a special base for prolonged therapeutic effect. *Indications:* For the relief of cerebral and peripheral ischemia associated with arterial spasm and myocardial ischemia complicated by arrhythmias. *Dosage:* One capsule every 12 hours. In difficult cases, administration may be increased to one capsule every 8 hours, or two capsules every 12 hours. *Precaution:* Use with caution in patients with glaucoma. Hepatic hypersensitivity has been reported with gastrointestinal symptoms, jaundice, eosinophilia and altered liver function tests. Discontinue medication if these occur. *Side effects:* Infrequently reported side effects of papaverine include nausea, abdominal distress, anorexia, constipation, malaise, drowsiness, vertigo, sweating and headache, diarrhea and skin rash.

PUBLISHED TO CORRECT A PREVIOUS ADVERTISEMENT WHICH THE FOOD AND DRUG ADMINISTRATION CONSIDERED MISLEADING

QUESTRAN®
(CHOLESTYRAMINE)

EACH DOSE CONTAINS 4G. OF CHOLESTYRAMINE RESIN IN 9G. OF QUESTRAN.

THE FOOD AND DRUG ADMINISTRATION CONSIDERS MISLEADING OUR ADVERTISING FOR QUESTRAN (CHOLESTYRAMINE RESIN) THAT APPEARED IN THIS JOURNAL.

THE FDA STATES THAT THE AD:

- FAILED TO ADEQUATELY EMPHASIZE THE DRUG'S LIMITATIONS THAT QUESTRAN IS INDICATED AS *ADJUNCTIVE* THERAPY TO *DIET* IN LOWERING ELEVATED CHOLESTEROL LEVELS DUE *ONLY* TO PRIMARY TYPE II HYPERLIPOPROTEINEMIA AND MAY *INCREASE* CHOLESTEROL AND TRIGLYCERIDE LEVELS IN PATIENTS WITH TYPES I, III, IV AND V.

- IMPLIED THAT QUESTRAN IS *BOTH* SAFER AND MORE EFFECTIVE THAN ANY OTHER AVAILABLE ANTILIPEMIC THERAPY FOR ITS INDICATED USE WHEN THE FACT IS THAT THIS HAS NOT BEEN ESTABLISHED BY COMPARATIVE STUDIES WITH ALL OTHER EFFECTIVE DRUGS IN TYPE II HYPERLIPOPROTEINEMIA.

- FAILED TO ADEQUATELY EMPHASIZE THAT IT HAS NOT BEEN ESTABLISHED WHETHER DRUG-INDUCED LOWERING OF SERUM CHOLESTEROL OR OTHER LIPID LEVELS HAS A DETRIMENTAL, A BENEFICIAL OR NO EFFECT ON THE MORBIDITY OR MORTALITY DUE TO ATHEROSCLEROSIS OR CORONARY HEART DISEASE.

THE ADVERTISEMENT HAS BEEN DISCONTINUED BY DIRECTION OF THE FOOD AND DRUG ADMINISTRATION.

SAFETY CONSIDERATIONS:

QUESTRAN®
(CHOLESTYRAMINE)

IMPORTANT NOTE: **IT HAS NOT BEEN ESTABLISHED WHETHER DRUG-INDUCED LOWERING OF SERUM CHOLESTEROL OR OTHER LIPID LEVELS HAS A DETRIMENTAL, A BENEFICIAL, OR NO EFFECT ON THE MORBIDITY OR MORTALITY DUE TO ATHEROSCLEROSIS OR CORONARY HEART DISEASE.**

CONTRAINDICATIONS

INDIVIDUALS HYPERSENSITIVE TO ANY OF ITS COMPONENTS AND PATIENTS WITH COMPLETE BILIARY OBSTRUCTION.

WARNINGS

DO NOT TAKE IN DRY FORM. MIX WITH WATER OR OTHER FLUIDS BEFORE INGESTING.

USE IN PREGNANCY

SAFE USE BY PREGNANT AND LACTATING WOMEN AND FETUS HAS NOT BEEN ESTABLISHED. WEIGH HAZARDS AGAINST POTENTIAL BENEFITS OF DRUG THERAPY.

USE IN CHILDREN

PRACTICAL DOSAGE SCHEDULE HAS NOT BEEN ESTABLISHED FOR INFANTS AND CHILDREN. LONG TERM DRUG ADMINISTRATION AND EFFECT IN MAINTAINING LOWERED CHOLESTEROL LEVELS UNKNOWN IN PEDIATRIC PATIENTS.

PRECAUTIONS

SINCE CHOLESTYRAMINE RESIN MAY BIND OTHER DRUGS GIVEN CONCURRENTLY, PATIENTS SHOULD TAKE OTHER DRUGS AT LEAST ONE HOUR BEFORE OR FOUR TO SIX HOURS AFTER TO AVOID IMPEDING THEIR ABSORPTION.

QUESTRAN SEQUESTERS BILE ACIDS, THEREFORE IT MAY INTERFERE WITH NORMAL FAT ABSORPTION AND THUS PREVENT ABSORPTION OF FAT SOLUBLE VITAMINS SUCH AS A, D AND K, AND AS AN ANION EXCHANGE RESIN, IT HAS A STRONG AFFINITY FOR ACIDIC MATERIALS AND MAY ALSO ABSORB NEUTRAL OR BASIC MATERIALS. CHOLESTYRAMINE RESIN MAY DELAY OR REDUCE ABSORPTION OF CONCOMITANT ORAL MEDICATION SUCH AS PHENYLBUTAZONE, WARFARIN, CHLOROTHIAZIDE (ACIDIC), TETRACYCLINE, PHENOBARBITAL, THYROID, THYROXINE PREPARATIONS, AND DIGITALIS. DISCONTINUANCE OF QUESTRAN COULD POSE A HAZARD TO HEALTH IF A POTENTIALLY TOXIC DRUG SUCH AS DIGITALIS HAS BEEN TITRATED TO A MAINTENANCE LEVEL WHILE THE PATIENT WAS TAKING QUESTRAN.

CHECK SERUM TRIGLYCERIDE LEVELS PERIODICALLY TO ENSURE THAT SIGNIFICANT CHANGES HAVE NOT OCCURRED, IN NORMAL FAT DIGESTION.

PROLONGED USE MAY PRODUCE HYPERCHLOREMIC ACIDOSIS, ESPECIALLY IN YOUNGER AND SMALLER PATIENTS WHERE THE RELATIVE DOSAGE MAY BE HIGHER.

WHEN USED AS A CHOLESTEROL LOWERING AGENT, GASTROINTESTINAL DYSFUNCTION SHOULD BE EVALUATED PRIOR TO USE.

ADVERSE REACTIONS

CONSTIPATION, IMPACTION, HEMORRHOIDS, ABDOMINAL DISCOMFORT, FLATULENCE, NAUSEA, VOMITING, DIARRHEA, HEART BURN, ANOREXIA, INDIGESTIVE FEELING, STEATORRHEA, BLEEDING TENDENCIES (HYPOPROTHROMBINEMIA—VITAMIN K DEFICIENCY), VITAMIN A AND D DEFICIENCIES, RASH, HYPERCHLOREMIC ACIDOSIS, OSTEOPOROSIS, CALCIFICATION, INCLUDING BILIARY COLIC.

HEMATOLOGIC—DECREASED PROTHROMBIN TIME, ECCHYMOSIS, ANEMIA.

CARDIOVASCULAR—CLAUDICATION, XANTHOMAS OF HANDS AND FINGERS, ANGINA, ARTERITIS, THROMBOPHLEBITIS, MYOCARDIAL INFARCTION, MYOCARDIAL ISCHEMIA, INCREASED POSTPRANDIAL ANGINA, CHEST PAINS.

HYPERSENSITIVITY—URTICARIA, ASTHMA, WHEEZING, SHORTNESS OF BREATH.

MUSCULOSKELETAL—BACKACHE, MUSCLE AND JOINT PAINS, ARTHRITIS.

NEUROLOGIC—HEADACHE, ANXIETY, VERTIGO, DIZZINESS, FATIGUE, TINNITUS, SYNCOPE, DROWSINESS, FEMORAL NERVE PAIN, PARESTHESIA.

EYE—ARCUS JUVENILIS, UVEITIS.

RENAL—HEMATURIA, DYSURIA, BURNT ODOR TO URINE, DIURESIS.

MISCELLANEOUS—WEIGHT LOSS, WEIGHT GAIN, INCREASED LIBIDO, SWOLLEN GLANDS, EDEMA, DENTAL BLEEDING.

OTHER EVENTS REPORTED IN PATIENTS TAKING QUESTRAN INCLUDE: GI-RECTAL BLEEDING, BLACK STOOLS, HEMORRHOIDAL BLEEDING, BLEEDING FROM KNOWN DUODENAL ULCER, DYSPHAGIA, HICCUPS, ULCER ATTACK, SOUR TASTE, PANCREATITIS, RECTAL PAIN, DIVERTICULITIS.

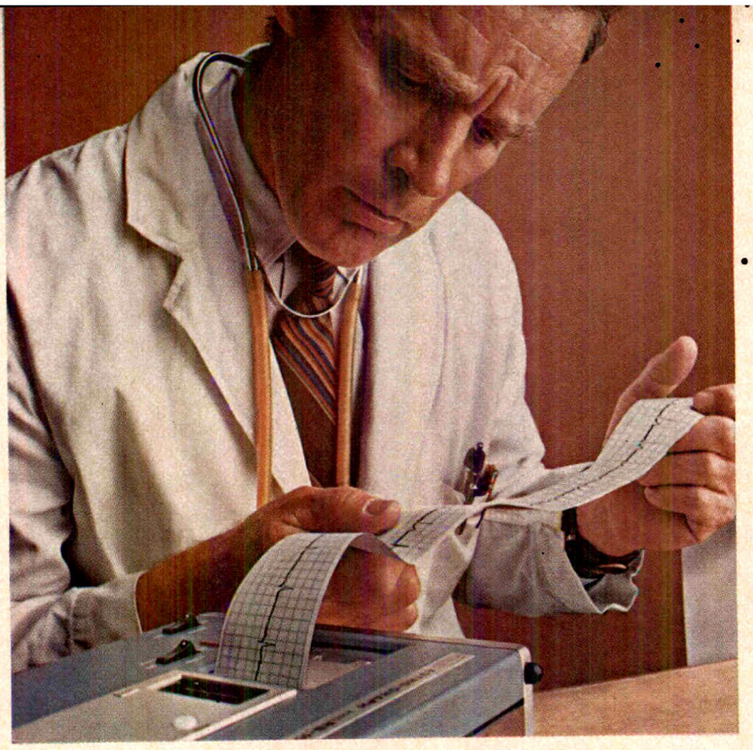
When cardiac complaints occur in the absence of organic findings, underlying anxiety may be one factor



The influence of anxiety on heart function

Excessive anxiety is one of a combination of factors that may trigger a series of maladaptive functional reactions which can generate further anxiety. Often involved in this vicious circle are some cardiac arrhythmias, paroxysmal supraventricular tachycardia and premature systoles. When these symptoms resemble those associated with actual organic disease, the overanxious patient needs reassurance that they have no

---

Before prescribing, please consult complete product information, a summary of which follows:

Indications: Relief of anxiety and tension occurring alone or accompanying various disease states.

Contraindications: Patients with known hypersensitivity to the drug.

Warnings: Caution patients about possible combined effects with alcohol and other CNS depressants. As with all CNS-acting drugs, caution patients against hazardous occupations requiring complete mental alertness (*e.g.*, operating machinery, driving). Though physical and psychological dependence have rarely been reported on recommended doses, use caution in administering to addiction-prone individuals or those who might increase dosage; withdrawal symptoms (including convulsions), following discontinuation of the drug and similar to those seen with barbiturates, have been reported. Use of any drug in pregnancy, lactation, or in women of childbearing age requires that its potential benefits be weighed against its possible hazards.

Precautions: In the elderly and debilitated, and in children over six, limit to smallest effective dosage (initially 10 mg or less per day) to preclude ataxia or oversedation, increasing gradually as needed and tolerated. Not recommended in children under six. Though generally not recommended, if combination therapy with other psychotropics seems indicated, carefully consider individual pharmacologic effects, particularly in use of potentiating drugs such as MAO inhibitors and phenothiazines. Observe usual precautions

organic basis and that reduction of excessive anxiety and emotional overreaction would be medically beneficial.

The benefits of antianxiety therapy

Antianxiety medication, when used to complement counseling and reassurance, should be both effective and comparatively free from undesirable side effects. More than 13 years of extensive clinical experience has demonstrated that Librium (chlordiazepoxide HCl) fulfills these requirements with a high degree of consistency. Because of its wide margin of safety, Librium may generally be administered for extended periods, at the physician's discretion, without diminution of effect or need for increase in dosage. (See summary of prescribing information.) If cardiovascular drugs are necessary, Librium is used concomitantly whenever anxiety is a clinically significant factor. (See Precautions.) Librium should be discontinued when anxiety has been reduced to appropriate levels.

For relief of excessive anxiety adjunctive

Librium® 10 mg
(chlordiazepoxide HCl)
1 or 2 capsules t.i.d./q.i.d.

ROCHE

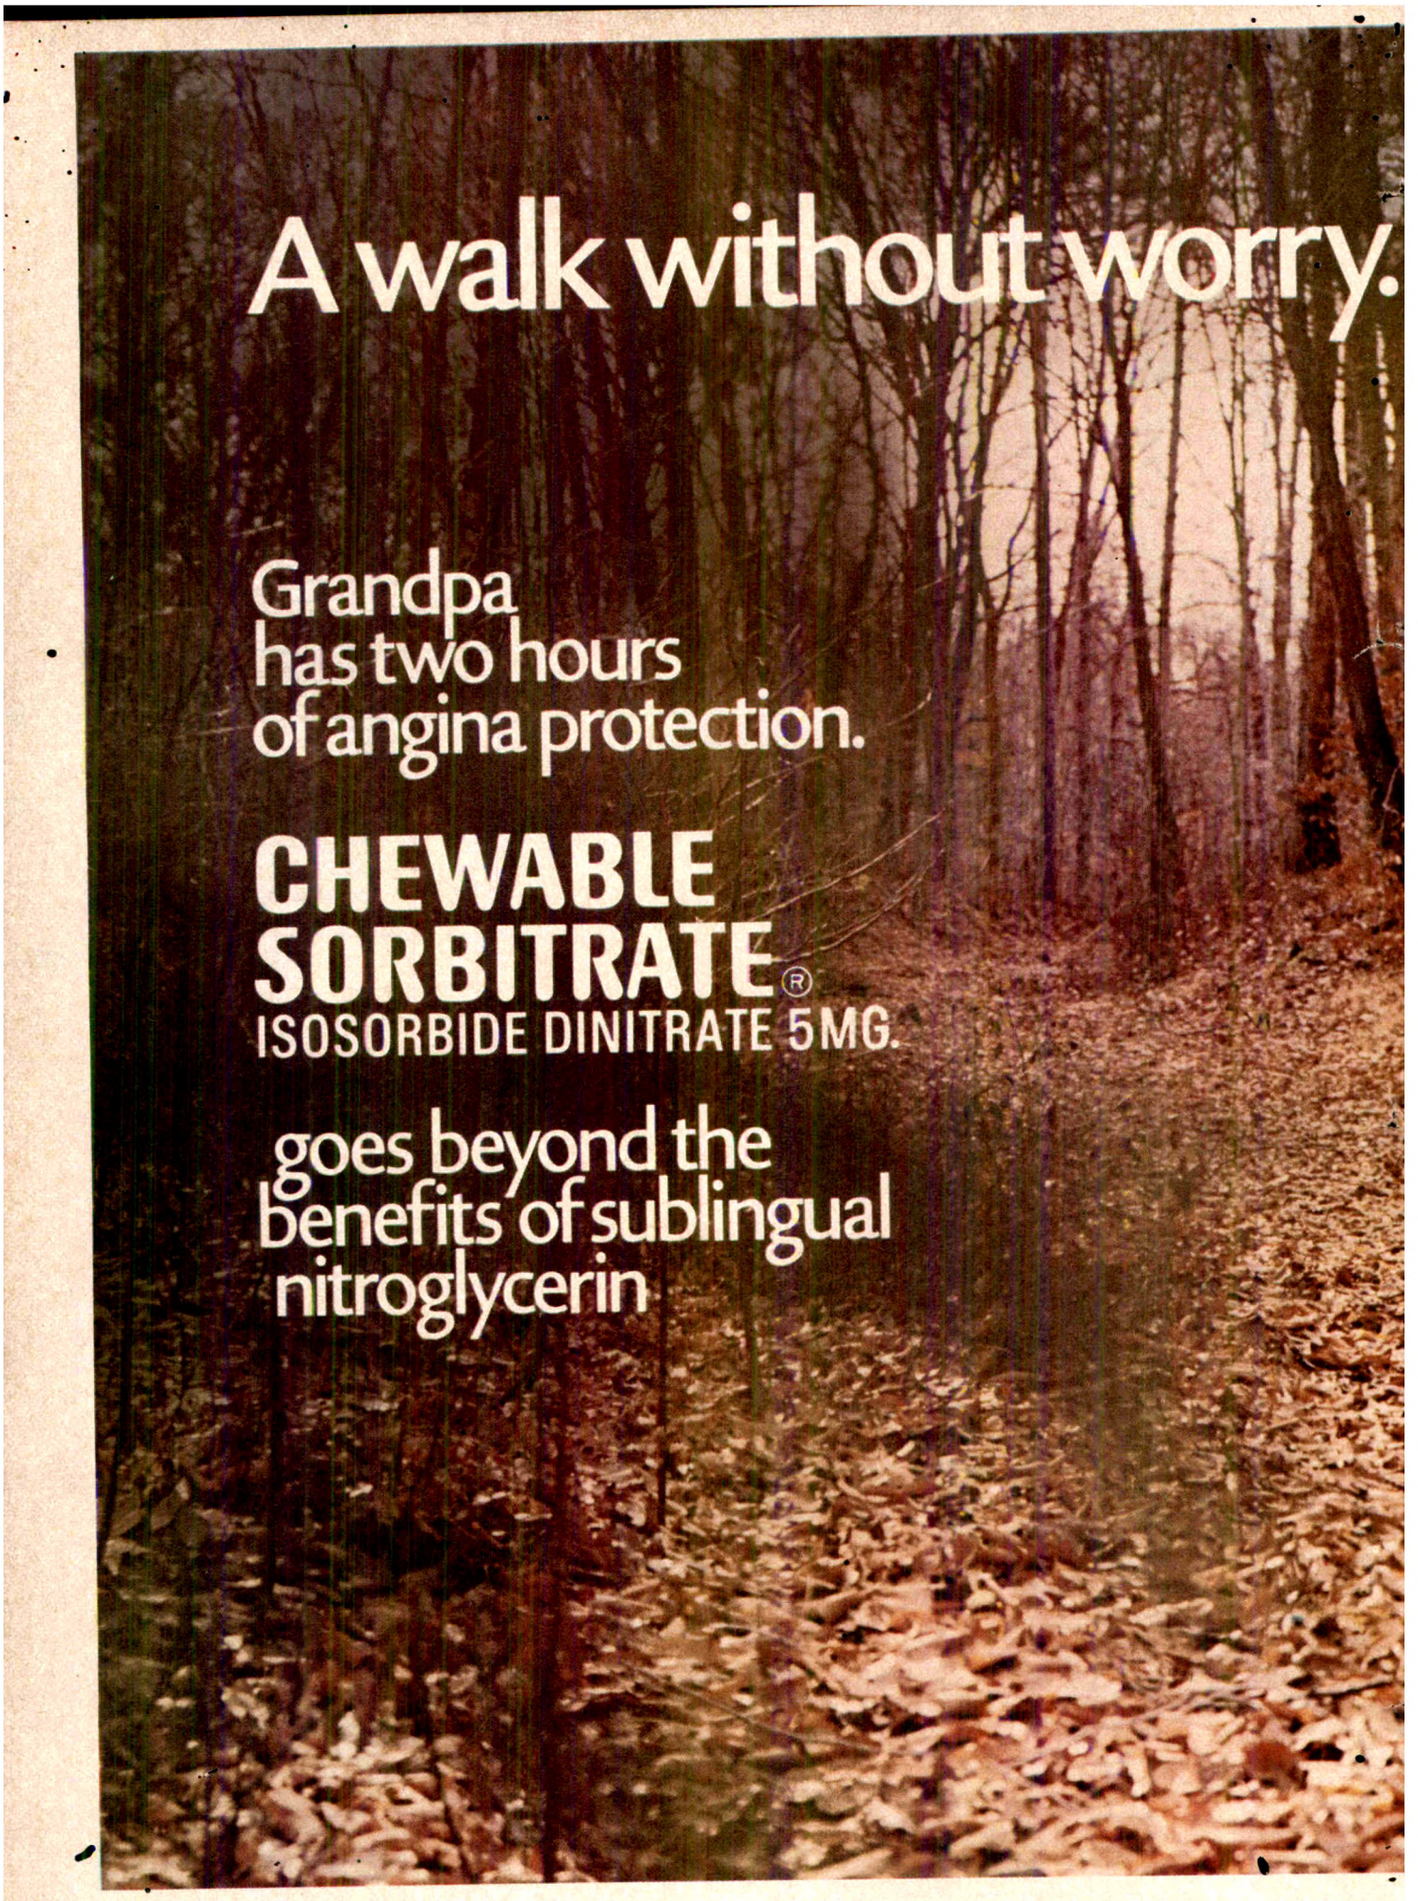
Division of Hoffmann-La Roche Inc.
Nutley, N.J. 07110

---

in presence of impaired renal or hepatic function. Paradoxical reactions (*e.g.*, excitement, stimulation and acute rage) have been reported in psychiatric patients and hyperactive aggressive children. Employ usual precautions in treatment of anxiety states with evidence of impending depression; suicidal tendencies may be present and protective measures necessary. Variable effects on blood coagulation have been reported very rarely in patients receiving the drug and oral anticoagulants; causal relationship has not been established clinically.

Adverse Reactions: Drowsiness, ataxia and confusion may occur, especially in the elderly and debilitated. These are reversible in most instances by proper dosage adjustment, but are also occasionally observed at the lower dosage ranges. In a few instances syncope has been reported. Also encountered are isolated instances of skin eruptions, edema, minor menstrual irregularities, nausea and constipation, extrapyramidal symptoms, increased and decreased libido—all infrequent and generally controlled with dosage reduction; changes in EEG patterns (low-voltage fast activity) may appear during and after treatment; blood dyscrasias (including agranulocytosis), jaundice and hepatic dysfunction have been reported occasionally, making periodic blood counts and liver function tests advisable during protracted therapy.

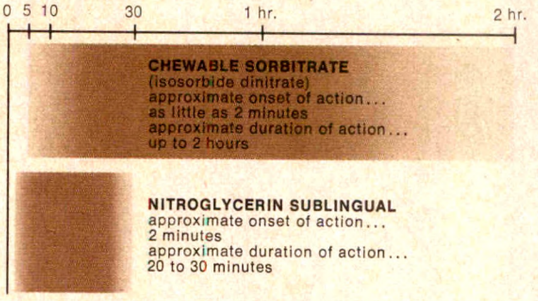
Supplied: Librium® Capsules containing 5 mg, 10 mg or 25 mg chlordiazepoxide HCl. Libritabs® Tablets containing 5 mg, 10 mg or 25 mg chlordiazepoxide.



A walk without worry.
Grandpa
has two hours
of angina protection.
CHEWABLE
SORBITRATE®
ISOSORBIDE DINITRATE 5MG.
goes beyond the
benefits of sublingual
nitroglycerin

For up to two hours of protection, your angina patient needs *more* than sublingual nitroglycerin. And Chewable Sorbitrate provides more.

☐ Acts almost as fast as nitroglycerin... lasts about 4 times as long.



☐ More stable in air than sublingual nitroglycerin: it can be stored or carried with no significant loss of potency.

☐ And when indicated: Sorbitrate® (isosorbide dinitrate) Sublingual 5 mg. and 2.5 mg.

SUMMARY OF PRESCRIBING INFORMATION

Mode of action: The mechanism of action of SORBITRATE (isosorbide dinitrate) is unknown, although the basic pharmacologic action is to relax smooth muscle. Isosorbide dinitrate reduces in number and severity the incidence of angina pectoris attacks, with concomitant reduction in nitroglycerin intake.

Indications: Sublingual and Chewable: For the prevention and treatment of angina pectoris.

Oral: For the relief of angina pectoris. It is not intended to abort the acute anginal episode. SORBITRATE WITH PHENOBARBITAL is indicated for patients in whom the angina pectoris is accompanied by anxiety or its related symptoms.

Contraindications: A history of sensitivity to the drug.

Warnings: Data supporting the use of nitrates during the early days of the acute phase of myocardial infarction are insufficient to establish safety. Phenobarbital may be habit forming.

Precautions: Should be used with caution in patients who have glaucoma. Tolerance and cross tolerance to other nitrates may occur.

Adverse Reactions: Headache which may be severe and persistent. Lowering the dose and using analgesics will help control the headaches which usually diminish or disappear as therapy is continued.

Adverse reactions seen occasionally: Cutaneous vasodilation with flushing; transient dizziness and weakness as well as other signs of cerebral ischemia associated with postural hypotension; individual marked sensitivity to the hypotensive effects of nitrates wherein severe responses can occur even with the usual therapeutic dose (alcohol may enhance this effect); drug rash and/or exfoliative dermatitis.

This drug can act as a physiological antagonist to norepinephrine, acetylcholine, histamine and other agents.

Dosage and Administration: Route: Sublingual, oral and chewable tablets.

Individual Dose: To minimize hypotensive responses, which may occasionally be severe with chewable doses as low as 5 mg., the smallest effective dose should be employed. Chewable tablets are generally given in doses of 5 mg. Sublingually or orally, 5 to 10 mg. is the range commonly used although doses of up to 30 mg. have frequently been employed.

Dosage Scheaule: Smallest effective dose necessary for the prevention and treatment of pain of an anginal attack. Sublingual SORBITRATE may be taken p.r.n. or at 4 to 6 hour intervals; Oral SORBITRATE may be taken 3 to 4 times daily. CHEWABLE SORBITRATE may be taken for prompt relief of anginal pain 3 or 4 times daily. Although the onset and duration of effect of coronary nitrates may vary, following are the generally reported ranges of these values for SORBITRATE:

Onset of Effect: Sublingual and Chewable: 2 to 5 minutes. Oral: 15 to 30 minutes.

Duration of Effect: Sublingual and Chewable: 1 to 2 hours. Oral: Estimated to be 4 to 6 hours.

It is recommended that the oral dosage be taken on an empty stomach.

STUART PHARMACEUTICALS | Div. of ICI America Inc.
WILMINGTON, DEL. 19899

The unique

Kato® Powder

potassium chloride supplement with the natural tomato juice flavor

Description: Spray-dried tomato powder containing 20 mEq potassium (equivalent to 1.5 Gm KCl) per measured dose with natural and synthetic flavors, spices and colors. Benzoic acid and potassium benzoate added as preservatives. When reconstituted as directed, makes a pleasantly flavored, low sodium tomato juice drink.

Indications: The prevention or correction of potassium deficit, particularly when accompanied by hypochloremic alkalosis in conjunction with thiazide diuretic therapy, in digitalis intoxication, or as the result of long-term corticosteroid therapy, low dietary intake of potassium, or excessive vomiting or diarrhea.

Contraindications: Potassium is contraindicated in severe renal impairment involving oliguria, anuria or azotemia; in untreated Addison's disease, adynamia episodica hereditaria, acute dehydration, heat cramps, hyperkalemia from any cause.

Precautions: Kato Powder is a concentrate and should be taken only after reconstituting with water as directed. Do not use in patients with low urinary output or renal decompensation. Administer with caution; it is impossible accurately to assess the extent of potassium depletion, or the daily dose required. Excessive dosage may result in potassium intoxication. Frequent checks of the clinical status of the patient, ECG and/or plasma potassium level should be made. High plasma concentrations of potassium ion may cause death through cardiac depression, arrhythmias or arrest. Use with caution in patients with cardiac disease.

Adverse Reactions: Vomiting, diarrhea, nausea, and abdominal discomfort may occur. Gross overdosage may produce signs and symptoms of potassium intoxication: mental confusion, listlessness, paresthesia of the extremities, weakness and heaviness of legs, flaccid paralysis, hyperkalemia, ECG abnormalities, fall in blood pressure, cardiac arrhythmias and heart block. The characteristic changes in the ECG are disappearance of the P wave, widening and slurring of QRS complex, changes of the S-T segment, tall peaked T waves, etc.

Toxicity: Potassium intoxication may result from overdosage of potassium or from therapeutic dosage in conditions stated under "Contraindications." Hyperkalemia, when detected, must be treated immediately because lethal levels can be reached in a few hours.

Treatment of Hyperkalemia: 1. Dextrose solution 10% or 25% containing 10 units of crystalline insulin per 20 Gm dextrose, given I.V. in a dose of 300cc to 500cc in an hour. 2. Adsorption and exchange of potassium using sodium or ammonium cycle cation exchange resin, orally or as retention enema. 3. Hemodialysis or peritoneal dialysis. 4. Elimination of potassium-containing foods and medicaments. Warning: Digitalis toxicity can be precipitated by lowering the plasma potassium concentration too rapidly in digitalized patients.

Administration and Dosage: Mix with water to make a pleasant tomato juice drink. The unit dose packet and the dose-measure supplied in the can each provide 20 mEq of potassium. Usual adult dose—1 packet or 1 measure of Kato Powder mixed with about 2 ounces of water twice daily—supplies 40 mEq potassium per day. Take with meals or follow with ½ glass of water. Larger doses may be required, but should be administered under close supervision because of the possibility of potassium intoxication.

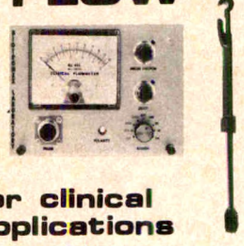
How Supplied:

Carton of 30 unit dose packets, 20 mEq each.

8 oz can (40 doses) with 20 mEq dose-measure.

Ingram Pharmaceutical Company / San Francisco, Ca 94111

BLOOD FLOW



for clinical applications

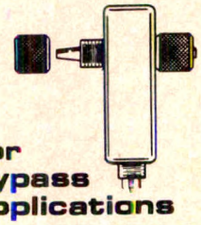
- Designed for clinical O.R. or cath lab use
- Easily applied handle-type probe
- Patient safety assured through isolation circuitry
- Simple to operate - minimum controls - direct meter readout in milliliters per minute

FLOW PROBES

for clinical applications

- Convenient, handle-type probe with positive capture slide
- Designed for O.R. and cath lab use
- For rapid analysis of flow through exposed blood vessels
- Use with Biotronex clinical blood flowmeter

FLOW PROBES



for bypass applications

- Use with heart-lung machine, artificial kidney or similar systems
- Iron core construction provides high sensitivity and accuracy
- Operates with BLI research and clinical blood flowmeters
- Available in sizes to fit most tubing

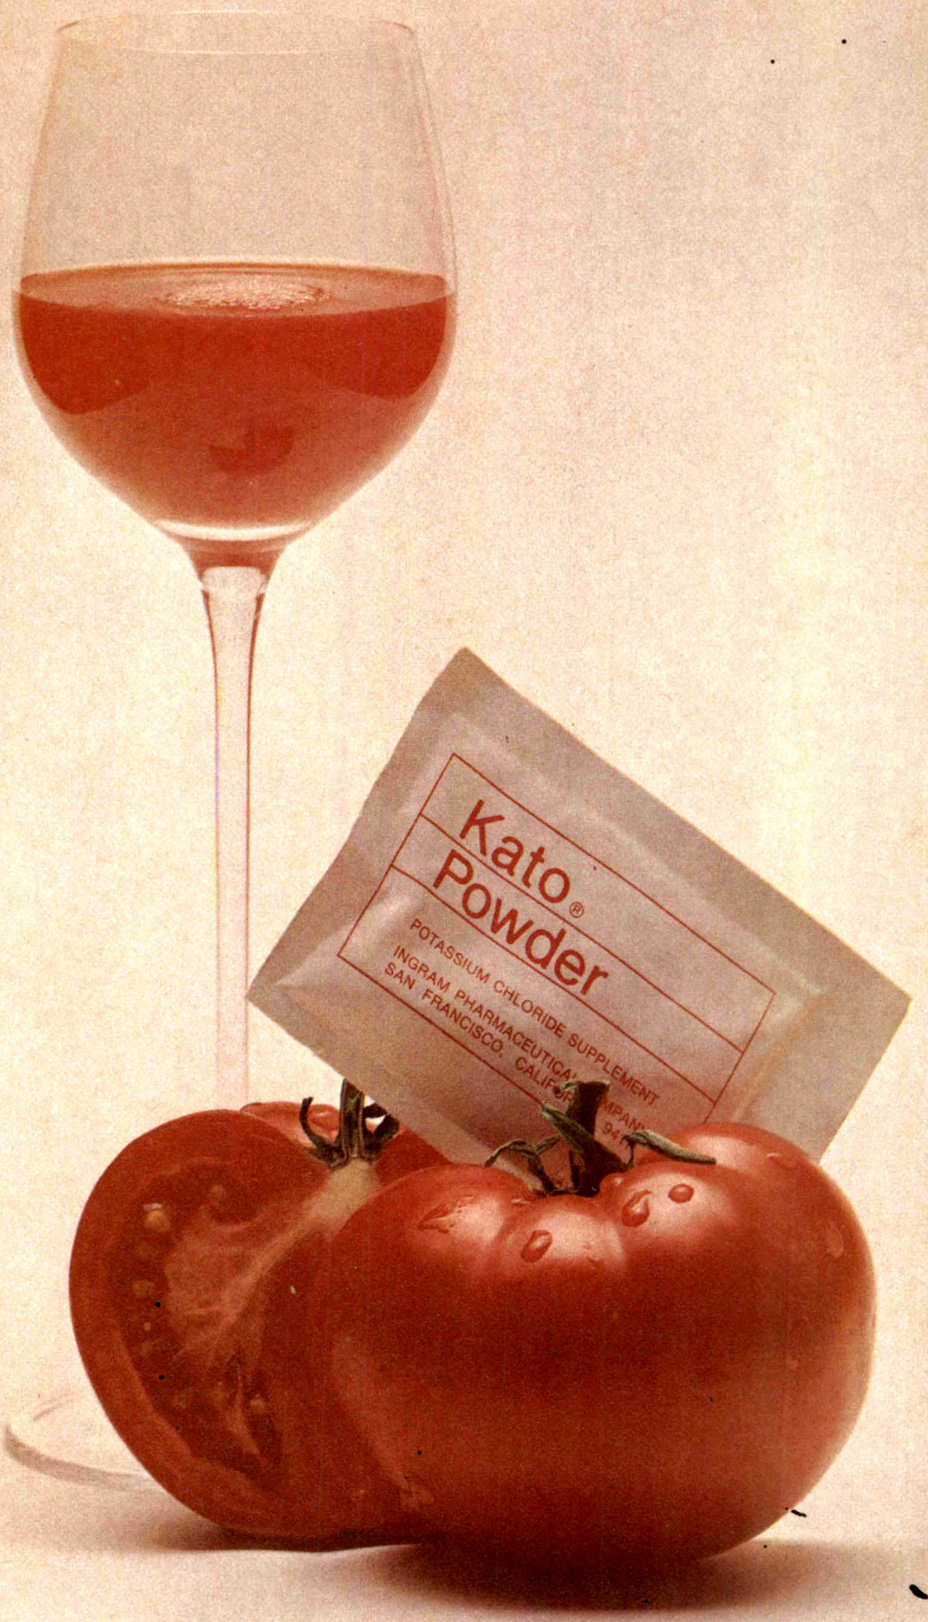
in potassium therapy

Kato is a Natural

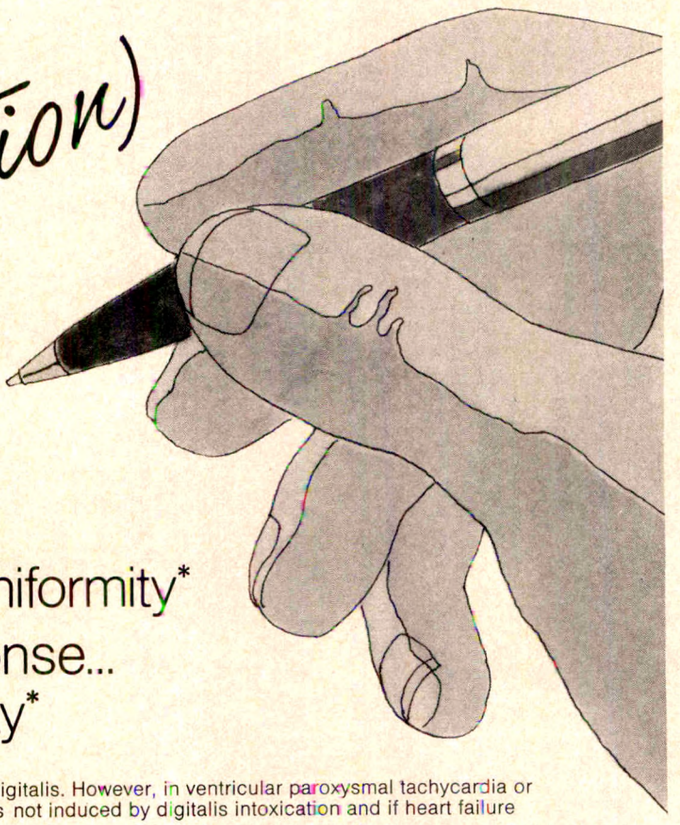


Kato Powder is KCl blended with natural tomato powder and subtle spices. Mixed with a mere 2 ounces of cold water, it provides a dose of potassium chloride in a good tasting low sodium tomato juice drink. Refreshingly different. Patients take it and like it!

Lanoxin

[digoxin]

(no substitution)



write it

precision quality control...

- assured tablet content uniformity*

predictable patient response...

- proven biologic availability*

Contraindications: There are no absolute contraindications to digitalis. However, in ventricular paroxysmal tachycardia or ventricular fibrillation, it should be used *only* in refractory cases not induced by digitalis intoxication and if heart failure has developed.

Precautions: If the patient has been given digoxin during the previous week or any other less rapidly excreted drug of the digitalis group during the previous two weeks, the dose of Lanoxin brand Digoxin must be reduced accordingly. Because of impaired renal function and excretion in elderly patients, they frequently require lower than recommended doses.

Potassium loss in patients sensitizes the heart to digitalis intoxication even with recommended doses. The diuretic agents as well as electrolyte manipulations by the physician are major causes of potassium depletion in cardiac patients. Under these conditions, it may be necessary to reduce the usual dosages of Lanoxin brand Digoxin during digitalization and maintenance.

Digoxin is usually ineffective in cases of cardiac failure due to mechanical causes which are independent of myocardial diseases, e.g., cardiac tamponade, or to disorders not primarily of cardiac origin, as severe anemia. Despite a variable or poor response to digoxin in the presence of active rheumatic carditis, the development of cardiac failure is an indication for its use.

Effects of Overdosage and Treatment: The symptoms of overdosage with digoxin are quite similar to those occurring with other digitalis preparations. The most common toxic manifestations are anorexia, nausea, vomiting and various cardiac arrhythmias, including ventricular extrasystoles and paroxysmal supraventricular tachycardia or fibrillation with A-V block. In general, the gastrointestinal manifestations of toxicity with digoxin precede the cardiac arrhythmias occurring from overdosage. Furthermore, because of the rapid dissipation of digoxin, manifestations of toxicity are of short duration, usually lasting from a few hours to one or two days.

If necessary, potassium chloride may be administered as an intravenous infusion containing (adult dosage) 40 milliequivalents in 500 cc. of 5% dextrose in water, given over the course of 1 hour and repeated, if required, until a total of 120 milliequivalents have been given (1 mEq. KCl = 74.5 mg.). Electrocardiographic monitoring should be conducted and the infusion halted immediately upon the appearance of peaking of the T-waves. For children, the intravenous infusion dosage of potassium chloride would be 5 to 10 milliequivalents in 100 cc. of 5% dextrose in water given over the course of 1 hour, repeated if required, to a total of 15 to 30 milliequivalents. For more serious intoxication with abnormal cardiac rhythms, potassium chloride may be given orally in divided doses totalling 4 to 6 grams per day (adults) or 1 to 2 grams (children) provided renal failure is not present.

LANOXIN® digoxin TABLETS. **0.125 mg.** (yellow) in bottles of 100 and 1,000. **0.25 mg.** (white) scored, in bottles of 100, 500, 1,000 and 5,000; also Unit Dose Pack, strips of 10 tablets, 10 boxes of 100 tablets (1,000). **0.5 mg.** (green) scored, in bottles of 100 and 1,000.

CLINICAL STUDIES

Comparison of Biplane and Single Plane Left Ventriculograms in Patients with Coronary Artery Disease

PETER F. COHN, MD, FACC
RICHARD GORLIN, MD, FACC
DOUGLASS F. ADAMS, MD
ROBERT A. CHAHINE, MD
PANTEL S. VOKONAS, MD
MICHAEL V. HERMAN, MD, FACC

Boston, Massachusetts

Fifty patients with coronary artery disease were studied with biplane left cineventriculography (right and left anterior oblique views). Volumetric analyses were compared with those of 10 normal patients also studied with simultaneous biplane ventriculography. In normal subjects there was good agreement between minor diameters in the right and left anterior oblique views, and between ventricular volumes and ejection fractions determined by single plane and biplane techniques. In patients with coronary artery disease there was more scatter in these values, especially when asynergy was present. Loss of ventricular symmetry probably explains this disparity. By providing visualization of all five zones of the left ventricular wall, the biplane technique allowed a comprehensive evaluation of ventricular asynergy and overall function.

The clinical profile of the 50 patients with coronary artery disease demonstrated that optimal candidates for biplane ventriculography are patients with prior myocardial infarction, left ventricular enlargement and clinical evidence of abnormal hemodynamic status.

The animal experiments of Tennant and Wiggers[1] and the subsequent clinical observations of Harrison[2] have stimulated interest in abnormal ventricular wall motion in coronary artery disease. Investigations using noninvasive techniques have included analysis of precordial pulsations and heart sounds[3-5] as well as more sophisticated measures such as echocardiography,[6] scintiphotography[7] and radarkymography.[8] The most recent standard of reference has been the study of left ventricular wall motion by left cineventriculography.[9-12] Single plane projections have been used in most reported studies. This communication assesses the comparative value of single and biplane ventriculography in detecting abnormal wall motion and determining ventricular volumes and ejection fractions in patients with coronary artery disease.

From the Cardiovascular Division, Department of Medicine and the Department of Radiology, Harvard Medical School and Peter Bent Brigham Hospital, Boston, Mass. This study was supported in part by U. S. Public Health Service Grants PO-1 HE-11306, IT-1 HE-5679, HE-11668, HE-05832 and GM-18674. Manuscript accepted June 27, 1973.

Address for reprints: Peter F. Cohn, MD, Cardiovascular Division, Department of Medicine, Peter Bent Brigham Hospital, 721 Huntington Ave., Boston, Mass. 02115.

Methods

Patient selection: Sixty patients with a syndrome of chest pain were classified in two groups. Group 1 consisted of 10 consecutive patients with

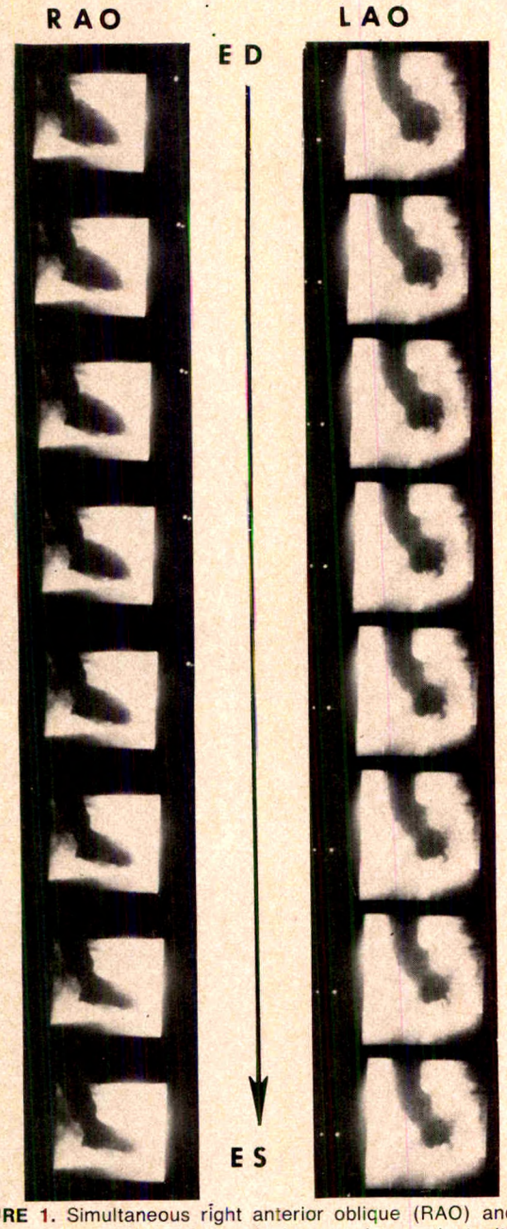

FIGURE 1. Simultaneous right anterior oblique (RAO) and left anterior oblique (LAO) left ventriculograms in a patient with obstructive disease of the right coronary and left anterior descending arteries. The sequence is from end-diastole (ED) to end-systole (ES). Asynergy is most marked in the right anterior oblique view and mainly involves the apical and anterior segments. The left anterior oblique view demonstrates good wall motion, especially in the posterolateral segment. The ejection fraction calculated from volumes determined in the biplane projection was 51 percent, compared to 39 percent when calculated from volumes determined in the right anterior oblique projection.

normal coronary arteriograms, normal hemodynamic status and normal biplane left ventriculograms. They served as control subjects for evaluating left ventricular volumes, ejection fractions and wall motion. Group 2 comprised 50 consecutive patients with demonstrated coronary artery disease. None of these 50 patients had concomitant rheumatic, pericardial or congenital heart disease.

Evidence of prior transmural infarction was determined by standard enzymatic and electrocardiographic criteria.[13] Evidence of left ventricular enlargement was determined from the posteroanterior, lateral and left anterior oblique views of a four position cardiac series, using standard radiologic criteria.[13]

Catheterization and angiographic procedures: Catheterization procedures were similar to those previously reported from our laboratory.[9,10] Left ventricular end-diastolic pressure was measured at high gain (normal value ≤12 mm Hg). Cardiac output was determined by the indocyanine green dye technique (normal value ≥2.5 liters/min per m^2). Selective coronary cineangiograms were obtained by either the Sones or Judkins technique on 16 mm Ilford Pan F or Kodak Plus-X film with General Electric or Siemens 6 to 9 inch dual field, image-intensifier X-ray systems.

Simultaneous left ventricular cineangiograms (at 100 to 200 frames/sec) were obtained with multiple-hole catheters using power injections and 40 to 50 ml of 76 percent meglumine sodium diatrizoate. The biplane projections were 30° in the right and 60° in the left anterior oblique (RAO, LAO) views when the 9 inch mode was used (Fig. 1). All ventriculograms were interpreted by the same two investigators who reached a consensus without knowledge of the patients' coronary anatomic data. The term *asynergy* refers to all localized abnormalities of systolic wall motion (with septal asynergy referring to asynergy of both the anterior and posterior septum), and the method of interpreting these various patterns is that of Herman et al.[10] Ventricular volumes and ejection fractions were calculated from sequential end-diastolic and end-systolic silhouettes (Fig. 2), using a grid calibration technique and single plane (right anterior oblique) and biplane volumetric formulas adapted from those of Dodge et al.[14]: single plane volume = $\pi/6\,DRAO^2 \times LRAO$ with D the calculated minor diameter and L the measured length to base diameter; bi-

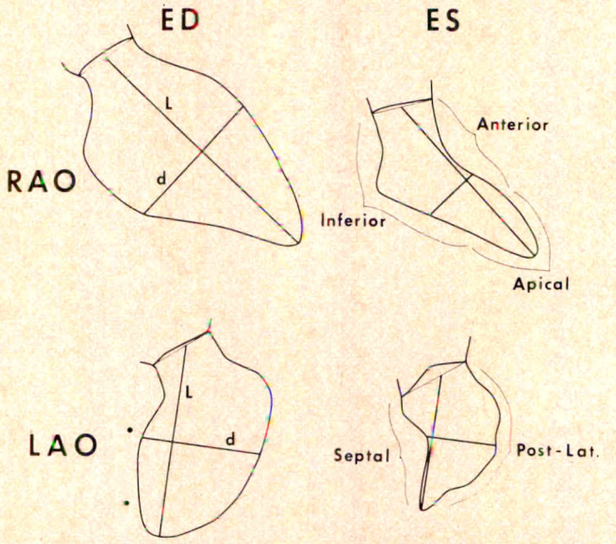

FIGURE 2. End-diastolic (ED) and end-systolic (ES) silhouettes drawn from simultaneous right anterior oblique (RAO) and left anterior oblique (LAO) left ventriculograms. The five segments of left ventricular wall are depicted as well as the method for measuring major (L) and minor (d) ellipsoid diameters. When the minor diameter is calculated, the formula used is D = 4 Area/πL (see text). Post-Lat. = posterolateral.

plane volume = $\pi/6$ DRAO × DLAO × LRAO (unless LLAO longer). In the present study D was calculated from the formula D = 4 Area/πL . L was always measured from the middle of the aortic valve to the apex in both projections and in nearly all cases was the longest major diameter. This technique allowed measurement of a three-dimensional figure in which the minor diameters are perpendicular to each other in the same plane. Analysis was limited to regularly conducted beats occurring no later than four cycles after complete opacification. Because of the frequency of wall motion abnormalities in this study, no attempt was made to correct angiographic volume to true volume by use of barium-filled ventricular casts.

Results

Clinical, hemodynamic and arteriographic variables associated with asynergy: The frequency of asynergy in the patients with coronary artery disease is shown in Table I. Certain variables were more often associated with asynergy than were others: Asynergy was present in 4 of 4 patients (100 percent) with chronic R–ST segment elevation on the electrocardiogram, 22 of 23 (96 percent) with increased left ventricular end-diastolic pressure, 22 of 25 (88 percent) with left ventricular enlargement, 32 of 40 (80 percent) with a prior myocardial infarction and 24 of 32 (75 percent) with multivessel coronary artery disease. Approximately 50 percent of the patients with normal ventricular size, normal left ventricular hemodynamics and single-vessel disease also exhibited asynergy, and asynergy was present in 2 of 10 patients with a completely normal resting electrocardiogram and no history of infarction.

Value of left anterior oblique view in assessing asynergy: Posterolateral wall motion can readily be assessed in the left anterior oblique view, but septal motion is sometimes obscured by overlying apical segments of the left ventricle. This is especially true when angiographic contrast medium is concentrated in an akinetic apex and prevents visualization of the posterior septum. With this reservation, the following observations were made in patients with coronary artery disease (Table II): (1) Fifteen patients (30 percent) had normal wall motion in both views; (2) 35 patients (70 percent) had abnormal motion in the right anterior oblique view, but 10 of these had normal motion in the left anterior oblique view; (3) 10 patients (20 percent) had isolated asynergy in a single zone of the right anterior oblique projection; no patient had isolated asynergy in the left anterior oblique view.

These findings indicate that wall motion in the left anterior oblique view more often appeared to be normal than motion in the corresponding right anterior oblique view. Furthermore, certain patterns of asynergy emerged. Some degree of septal asynergy was present in 25 patients. All of these patients had anterior or apical zone asynergy; similarly, all six patients with posterolateral asynergy had inferior asynergy combined with anteroapical disease (global asynergy). The converse was not true, however. As noted, many patients with anteroapical or inferior asynergy had normal posterolateral motion. Five of six patients (83 percent) with posterolateral asynergy had significant disease of the left circumflex artery. But obstructive disease was generally much less common in the circumflex system than in either the left anterior descending or right coronary arteries.

TABLE I

Clinical, Hemodynamic and Arteriographic Correlations in 50 Patients with Coronary Artery Disease

	Total	Normal Wall Motion	Asynergy
Clinical:	50	15	35
Normal electrocardiogram, no history of MI	10	8	2
History or electrocardiographic evidence of MI	40	8	32
R–ST segment elevation	4	0	4
Left ventricular enlargement	25	3	22
Hemodynamic:			
Increased LVEDP (>12 mm Hg)	23	1	22
Reduced CI (<2.5 liters/min per m²)	12	1	11
Arteriographic:			
3 vessel disease	16	5	11
2 vessel disease	16	3	13
1 vessel disease	18	7	11

CI = cardiac index; LVEDP = left ventricular end-diastolic pressure; MI = myocardial infarction.

TABLE II

Relation Between Zones of Asynergy in the Right (RAO) and Left (LAO) Anterior Oblique Views in 50 Patients with Simultaneous Biplane Ventriculograms

	LAO Ventriculogram

Determination of minor diameters, ventricular volumes and ejection fractions: Minor diameters in both the right and left anterior oblique silhouettes (DRAO and DLAO) were determined by direct measurement (Fig. 2) and by calculation (D = 4A/πL at end-diastole and end-systole) (Table III). There was agreement between minor diameters in the right and left anterior oblique projections (measured and calculated) in the normal subjects. In addition, the measured and calculated values in the *same* silhou-

* Differences in values (DRAO vs. DLAO, calculated vs. measured) were not significant by paired *t* test.

CAD = coronary artery disease; D = diameter; DLAO and DRAO = minor diameters in the left and right anterior oblique views, respectively; normal-sized LV = end-diastolic volume less than 250 cc, as calculated by both biplane and single plane formulas.

ette agreed closely with one another. In patients with coronary artery disease these relations did not hold: (1) minor diameters in the right and left anterior projections were often several millimeters apart, whether these values were directly measured or calculated, with the left anterior oblique value usually larger. This difference was observed at end-diastole and end-systole in both small and large hearts in patients with and without visual evidence of ventricular asynergy. Although these differences existed, they were not statistically significant. (2) Similarly, the measured and calculated values in the *same* silhouette also differed by several millimeters, with the calculated values usually larger than the measured values. (3) The percent change from end-diastole to end-systole was nearly the same in both views, although patients with asynergy had lower absolute values.

The mean differences between minor diameters in the two projections in the control group were 0 and 1 mm at end-diastole and end-systole, respectively. Although these values were 4 and 5 mm, respectively, in patients with asynergy, the differences between the groups were not statistically significant.

End-diastolic and end-systolic ventricular volumes were determined by single plane and biplane formulas. In normal subjects there was close agreement between volumes determined by single and biplane techniques (Fig. 3A). More disparity was observed in patients with coronary artery disease (Fig. 3B), especially those with ventricular asynergy (Fig. 3C). Thus, although significant regression coefficients were present in patients with all three conditions, the widest confidence limits were observed in those with asynergy: The regression equation for patients with asynergy who had an end-diastolic volume of less than 250 ml was $Y = 0.7X + 60 \pm 32$ (standard error of estimate) compared to the overall group value of $Y = 0.8X + 65 \pm 60$.

Ejection fractions determined by biplane and single plane techniques were similar to each other in the normal subjects (68 percent ± 1.8 vs. 70 percent ±2.5) and in the patients with coronary artery disease (without asynergy 75 percent ± 1.3 vs. 78 percent ± 1.7, and with asynergy 47 percent ± 3.0 vs. 44 percent ± 3.3). Average differences were 0.04 in patients without asynergy and 0.08 in patients with asynergy. Nine of the 25 patients with normal wall motion had greater than 0.04 differences between single plane and biplane values. In eight of these nine patients, the ejection fraction in the right anterior oblique projection was larger than the biplane value. By contrast, 12 of the 20 patients with asynergy (and more than 0.08 difference between values for single plane and biplane ejection fractions) had larger biplane values. In these 12 patients there was more end-diastolic to end-systolic shortening in minor diameters in the left than in the right anterior oblique projection (27 ± 3.2 vs. 18 percent ± 2.6, $P < 0.001$).

Discussion

Discussion of the findings in this study focuses on two specific areas: (1) clinical, hemodynamic and arteriographic factors associated with ventricular asynergy, and (2) value of the left anterior oblique view in assessing wall motion and in calculating ventricular volumes and ejection fractions.

Asynergy and Related Findings

Seventy percent of the patients with coronary artery disease had angiographic evidence of left ventricular asynergy. This prevalence is similar to that reported by Bjork et al.[11] but greater than that re-

ported by Cheng.[12] The difference may be explained by the increased frequency of transmural myocardial infarction in our study. History of such an infarction or abnormal Q waves on the electrocardiogram, or both, are relatively specific indicators of asynergy, as is R–ST segment elevation (Table I).

Left ventricular enlargement in a multiview cardiac series is another useful finding. However, the absence of these findings did not necessarily correlate with normal wall motion in our study or those of others.[3,10,11] Thus, left ventricular asynergy was found in more than 50 percent of the patients with a normal chest roentgenogram and in 20 percent of those patients with a completely normal electrocardiogram and no history of infarction.

Hemodynamic abnormalities observed during catheterization were another relatively specific sign of abnormal wall motion. The reduced stroke output may result from derangements in myocardial fiber shortening caused by the altered configuration of the ventricle, with increased left ventricular end-diastolic pressure representing either a Starling effect or increased ventricular wall stiffness.[15] Although patients with asynergy tended to have multivessel disease, many patients with abnormal wall motion had only single vessel disease. The location of arterial lesions has been shown previously to correlate with sites of asynergy.[10] Asynergy was not observed in our series of 10 normal subjects.

The Left Anterior Oblique Projection

The left anterior oblique projection provides information about two zones of the left ventricular wall (septal and posterolateral) that are not visualized in the right anterior oblique view. These zones were not asynergic in the absence of corresponding involvement of the anterior, apical or inferior zones on the latter view (Table II). Thus, the prevalence of asynergy in a given series of patients will not be altered by the addition of the left anterior oblique view. Why there is often less asynergy in the posterolateral region is inadequately understood; the phenomenon may be due in part to the relatively reduced frequency of disease in the left circumflex artery. In previous studies[16–18] ventricular volumes calculated from biplane and single plane silhouettes correlated closely with one another, as did ejection fractions derived from these volumes. These studies did not comment on the presence of localized abnormalities of ventricular wall motion and the left and right anterior oblique projections were used in only one study.[16] A good correlation was observed between measured minor diameters in the two oblique views. Correlations have also been reported between calculated minor diameters in the anteroposterior and lateral views[17] and between volumes determined in the right anterior oblique and anteroposterior projections.[18]

In our study the minor (transverse) diameters in the right and left anterior oblique views were similar in normal subjects whether these values were measured or calculated. In patients with coronary artery

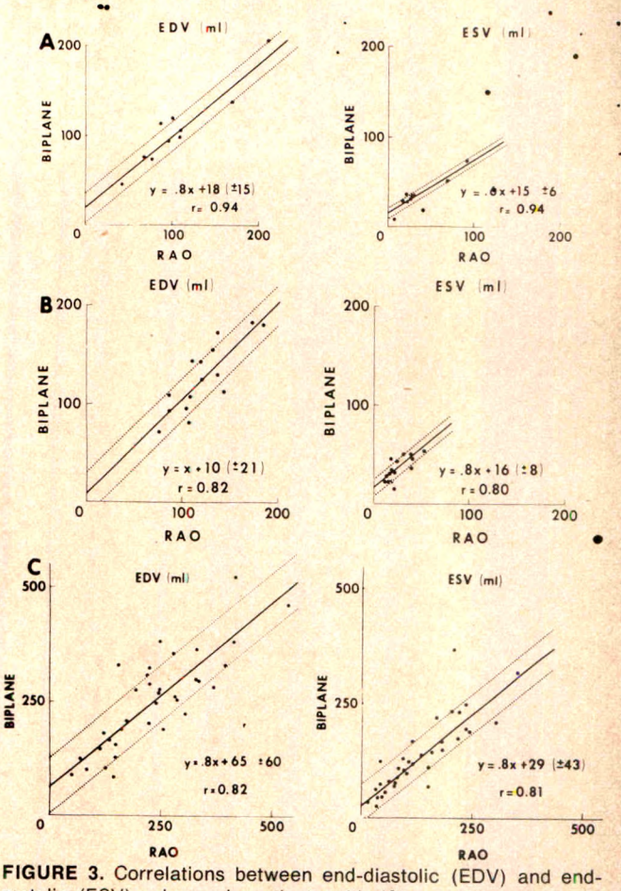

FIGURE 3. Correlations between end-diastolic (EDV) and end-systolic (ESV) volumes in patients with (**A**) normal coronary arteries and wall motion, (**B**) coronary artery disease but no visible asynergy, and (**C**) coronary artery disease and asynergy. In all three groups values for end-diastolic and end-systolic volumes were not significantly different whether biplane or right anterior oblique techniques were used; however, the greatest scatter is seen in patients with asynergy.

disease, calculated values often exceeded measured ones and diameters in the left anterior projection were often larger than the corresponding diameters in the right anterior oblique projection at both end-diastole and end-systole. This was especially true in patients with asynergy and was found in both small and large hearts. The reasons for this disparity in some patients without visible asynergy are not apparent. It is possible that subtle segmental changes in the ventricular wall have made these ventricles less symmetrical. Because the minor diameters in the right and left anterior oblique views are perpendicular to each other in the same plane (unlike those in the anteroposterior and lateral views), asymmetry in cross section is more likely to be detected by this technique, which uses a vertical and horizontal minor diameter. In addition, the left anterior oblique projection is more likely to cause small errors in this type of determination because the view is from the apex of the ventricle rather than perpendicular to the long axis, and tilting in one direction or another may distort the areas and diameters. In patients with visible asynergy, the disparity between calcu-

lated and measured diameters reflects the irregular shape of these ventricles, especially at end-systole. Differences at end-diastole may be caused by asymmetry due to abnormalities of ventricular relaxation.

Since these diameters represent an important factor in the volume equation, it was not surprising to find that the greatest difference between volumes determined in the right anterior oblique and biplane views occurred in patients with asynergy. Even when patients with large ventricles are omitted, the confidence limits of the regression equation are very wide. Thus, a patient with asynergy and an end-diastolic volume of 100 ml by the right anterior oblique calculation might have a corresponding calculated biplane end-diastolic volume ranging from 85 to 205 ml (using ±1 standard deviation of the regression formula), whereas a patient without asynergy would have a biplane volume ranging from 83 to 113 ml. (Since there is no in vivo technique for accurately measuring true ventricular volume, we made no attempt to indicate which technique most closely approximates true volume.)

Ejection fractions determined by methods using the biplane and right anterior oblique views tended to be similar to each other in patients with and without asynergy. The average differences were 0.04 in patients without asynergy and 0.08 in patients with asynergy. When values in individual patients demonstrated greater than average differences, patients without asynergy tended to have larger values in the right anterior oblique projection. (This may reflect technical problems in drawing outer borders of papillary muscles in vigorously contracting ventricles.) By contrast, patients with asynergy tended to have larger biplane values. In these latter patients, shortening in the minor axis in the left anterior oblique view was significantly greater than shortening in the minor axis in the right anterior oblique view. These findings agree with the visual observations that wall motion in the left anterior oblique view is often better than that in the right anterior oblique view when asynergy is present (Table II).

Conclusions

Because biplane ventriculography in the right and left anterior oblique projections provides angiographic documentation of left ventricular wall motion in *all* five zones, it is a useful adjunct in evaluating ventricular asynergy and function. Ventriculograms can be obtained simultaneously or in sequence, with the former method preferred to avoid effects of contrast agent on ventricular function. When both simultaneous biplane and single plane facilities are available, the biplane facility is most efficiently used in patients whose clinical findings suggest asynergy. Such patients often have left ventricular enlargement on chest roentgenogram and historical or electrocardiographic evidence of a prior myocardial infarction. In addition, they may have hemodynamic abnormalities, particularly increased left ventricular end-diastolic pressure. Previous studies have shown a correlation between increased ventricular diastolic pressures, ventricular asynergy and diastolic filling waves and sounds (third or fourth heart sounds, or both).[5,19] Thus, patients with diastolic heart sounds, left ventricular enlargement and prior myocardial infarction are optimal candidates for biplane ventriculography.

Devolutionary Pattern of Coronary Atherosclerosis in Patients with Angina Pectoris

Coronary Arteriographic Studies

DEMETRIOS KIMBIRIS, MD, FACC
PETER LAVINE, MD
HANS VAN DEN BROEK, MD
MOOSA NAJMI, MD
WILLIAM LIKOFF, MD, FACC

Philadelphia, Pennsylvania

The devolutionary pattern of coronary atherosclerosis in patients with angina pectoris was studied in 47 persons cinearteriographically. Two subsets of patients were identified at the initial examination. The first comprised 12 patients who did not have coronary atherosclerosis. In these 12, the cinearteriographic findings remained normal on repeated study 15 to 73 months later. The second subset included 35 patients with severe obstructive coronary atherosclerosis. When coronary visualization was repeated 15 months later, arterial disease remained stable in 11 patients (31.4 percent). Significant progression of the arterial disease was observed in the remaining 24 patients (68.5 percent). The frequency of hyperlipidemia, clinical diabetes, systolic and diastolic hypertension and a positive family history of coronary heart disease was not significantly different in those with stable and progressive disease. Furthermore, the distribution of the initial disease did not distinguish one group from the other. Since collateral channels were more prolific in patients who ultimately were classified as having stable arterial disease, it is possible that the initial severity of disease in this group was greater than in those with progressive disease. None in the latter group noted a reduction in the frequency or severity of angina pectoris. One third of those with stable disease did record such a reduction. However, paradoxically, two patients with stable coronary disease had a new myocardial infarction in the interval between examinations.

Our findings suggest that the devolutionary pattern of coronary atherosclerosis in patients with angina pectoris as observed cinearteriographically is unpredictable and apparently unrelated to commonly cited risk factors. They indicate that the severity of angina pectoris is the most precise guide to progressive coronary artery disease even though progressive disease can occur without affecting angina. The occurrence of myocardial infarction in patients with stable disease underscores the fact that many determinants influencing myocardial perfusion are not identified by cinearteriography.

Although coronary atherosclerosis progresses inexorably, the actual devolutionary pattern of the arterial disease in symptomatic patients is obscure. Additional information on this subject, obtained by repeated visualization of the coronary circulation in patients with angina pectoris, forms the basis of our report.

Material and Methods

The study group comprised 47 patients, 36 men and 11 women, ranging in age from 33 to 65 years (mean 48.6 years). No patient had undergone saphenous vein bypass surgery for coronary heart disease.

Clinical data on each subject included a record of risk factors for coronary atherosclerosis—namely, hypertension, diabetes mellitus, hyperlipidemia, cigarette smoking, stressful life pattern and physical indolence as

TABLE I

Age Distribution, Sex and Interval Between Studies in the Different Groups

Group	Patients (no.)	Sex M	Sex F	Mean Age (yr)	Mean Interval Between Studies (mo)
NCAD	12	6	6	46.7	32.9
CAD	35	31	4	49.6	26.2
SCAD	11	10	1	50.2	20
PCAD	24	21	3	49.2	25.8

CAD = coronary artery disease; NCAD = no coronary artery disease, PCAD = progressive coronary artery disease; SCAD = stable coronary artery disease.

well as the onset, frequency and severity of angina pectoris and details of electrocardiographic abnormalities. Severity of angina pectoris was classified from grade 1 to 3. Each item was reappraised before coronary visualization was repeated.

Coronary arteriography was performed according to the Sones technique utilizing a 6-inch image tube and 35 mm cine film. Obstructing atherosclerosis was estimated as percent of the lumen of the involved vessel. Myocardial contractility was evaluated by ventriculography.

Progression of coronary artery disease was considered significant when obstruction increased 20 percent or more in any single vessel or when an artery became completely occluded.

Results

At the time of initial arteriography, 12 of the 47 patients were observed to have normally patent coronary vessels (Table I). These 12 were classified as having no coronary artery disease. Six patients were men and six were women. Their ages ranged from 33 to 60 years (mean 46.7 years). A positive family history of coronary heart disease was recorded in 5 of these patients (41.6 percent). An equal number had cholesterol values greater than 250 mg/100 ml. None had hypertension or diabetes mellitus (Table II). Angina pectoris was classified as grade 1 or 2 in six subjects and grade 3 in the remaining six patients. Without exception, the electrocardiographic findings were abnormal; however, the results of left ventriculography were uniformly normal.

The remaining 35 patients, 31 of whom were men, had obstructing coronary atherosclerosis and were classified as having coronary artery disease. Their ages ranged from 36 to 65 years (mean 49.6 years) (Table I).

A positive family history of coronary heart disease was obtained in 21 patients in this group (60 percent). Cholesterol values exceeded 250 mg/100 ml in 25 subjects (71.4 percent). Chemical diabetes mellitus was present in 7 persons (20 percent). Abnormal elevations of systolic and diastolic blood pressure levels were observed in six patients (17.1 percent) (Table II). Angina pectoris was classified as grade 1 in three patients (8.5 percent), grade 2 in 22 (62.5 percent) and grade 3 in 10 (28.5 percent).

Only two of the patients in the group with coronary artery disease had single vessel disease (5.5 percent). Five subjects had double vessel disease (14.2 percent), and 28 had triple vessel disease (80 percent). The right coronary vessel was involved in 31 cases (88.5 percent), the left anterior descending coronary artery in 32 (91.4 percent) and the left circumflex artery in 31 (88.5 percent) (Table III). Collateral blood vessels were observed in 17 patients (48.5 percent).

Left ventriculography was performed at the time of each arteriographic study in 25 of the patients with coronary artery disease. During the initial study, myocardial contractility was considered significantly impaired in 15 of these subjects (60 percent).

Group Without Coronary Artery Disease

The interval between cinearteriograms in this group ranged from 15 to 73 months (mean 32.9 months) (Table I). In that interval the severity of angina remained unchanged in six patients (50 percent), decreased in three (25 percent) and increased in the remainder. Without exception, the electrocar-

RCA	9	5	22	5	8	6

LAD = left anterior descending coronary artery; LCA = left circumflex coronary artery; RCA = right coronary artery.

diograms remained stable. The second radiologic examination reaffirmed the presence of normal coronary arteries and myocardial contractility in every member of this group.

Group With Coronary Artery Disease

The interval between examinations in this group ranged from 8 to 50 months (mean 26.2 months) (Table I). In 11 of the 35 patients, the degree of coronary artery disease was unchanged (31.4 percent). These patients were classified as having stable coronary artery disease. A significant increase in the degree of arterial obstruction was observed in 24 patients (68.5 percent). These patients were therefore considered to have progressive coronary artery disease.

Group with stable coronary artery disease: Of the 11 patients in this category, 10 were men. Ages ranged from 40 to 58 years (mean 50.2 years). The interval between arteriograms ranged from 8 to 41 months (mean 20 months) (Table I).

A positive family history for coronary heart disease was presented by eight patients (77.7 percent). Serum cholesterol values exceeding 250 mg/100 ml were recorded in an equal number. Chemical diabetes mellitus and elevated levels of systolic and diastolic pressure were each discovered in two patients (18.1 percent) (Table II).

Angina pectoris was classified as grade 2 in seven patients (63.6 percent) and grade 3 in four patients (36.3 per cent) at the time of initial coronary visualization. When the second examination was performed, angina had decreased in approximately one third of the group, increased in one third and was unchanged in the remaining patients.

Evidence of a transmural myocardial infarction was present in two patients (18.1 percent) when the first examination was performed and developed in two additional patients before the second examination. In the remaining seven subjects (63.6 percent) the electrocardiogram remained unchanged.

All of the patients in the group with stable coronary artery disease had atherosclerotic involvement of left anterior descending coronary artery (Table III). In three subjects the vessel was completely occluded (27.2 percent). The left circumflex artery was involved but not completely obstructed in 10 patients (90.9 percent) (Table III). The right coronary artery was diseased in nine patients (81.8 percent) and completely occluded in five of them (55.5 percent) (Table III). Collateral vessels were present in eight patients (72.7 percent) initially and in one additional patient at the time arteriography was repeated (Fig. 1).

Left ventriculography was performed in both studies in only seven patients of this group (63.6 percent). Impaired myocardial contractility was observed in four patients (57.2 percent) initially and was not diagnosed in any additional patients during the second examination.

Group with progressive coronary artery disease: Of the 24 patients included in this group, 21 were men. Their ages ranged from 36 to 65 years (mean 49.2 years). The interval between the arteriographic studies was 11 to 50 months (mean 25.8 months) (Table I).

A positive family history of coronary heart disease was obtained in 13 patients (54.1 percent). Cholesterol levels exceeded 250 mg/100 ml in 17 patients (70.8 percent); chemical diabetes was noted in 5 (20.8 percent) and elevated levels of systolic and diastolic pressure in 4 (16.7 percent) (Table II). At the time of the initial examination, angina pectoris was considered grade 1 in 3 patients, grade 2 in 15 and grade 3 in 6. On repeat arteriographic study, angina had become significantly worse in half of the group; in no instance did it become less severe.

Electrocardiographic indications of a transmural myocardial infarction were present in 8 patients at the time of the initial arteriography (33.3 percent) and in 10 patients (41.6 percent) when the second examination was performed. However, new transmural infarctions were observed in two patients without previous infarction. Thus, four separate instances of myocardial infarction are believed to have taken place between examinations.

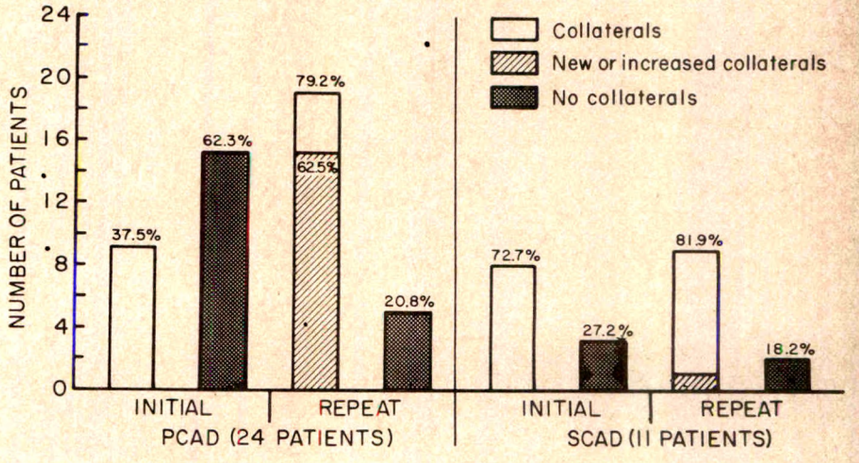

FIGURE 1. Comparison of collateral circulation in the two subgroups of patients with coronary artery disease. PCAD and SCAD = progressive and stable coronary artery disease, respectively.

Initially, the right coronary artery was involved in 22 patients (91.2 percent) and the left anterior descending and left circumflex arteries in 21 subjects each (87.5 percent) (Table III). The right coronary artery was occluded in 5 patients and the left anterior descending artery in 3. Collateral channels were seen in nine patients (37.5 percent) (Fig. 1). Results of left ventriculography were abnormal in 11 of the 18 patients examined (61.2 percent).

Significant progression of disease in the right coronary artery was observed in eight patients (33.3 percent), and complete occlusion was seen in six of these eight. Marked worsening of lesions in the left anterior descending coronary artery was noted in nine subjects (37.5 percent) and resulted in complete occlusion of the artery in five. Progressive involvement of the left circumflex artery was observed in 15 patients (62.5 percent); complete occlusion developed in 5 of these 15. At the time of the second cinearteriographic study, collateral vessels were observed in 19 patients (79.2 percent) (Fig. 1). The left ventriculogram was believed indicative of myocardial dysfunction in 15 subjects (83.3 percent).

Discussion

At the outset of this cinearteriographic study, two subsets of patients with angina pectoris were identified. The hallmark of the first was a normal coronary arteriogram. Subjects with angina and normally patent coronary arteries have been previously described by a number of investigators.[1–8] Accumulated experiences have not yet provided a satisfactory explanation for the chest discomfort simulating ischemic heart disease. Prognosis, like cause, has not been defined. Although some patients have died, most long-term experiences suggest a benign fate. The observations recorded in our survey indicate that coronary arteriograms remain normal although angina pectoris usually persists.

The second subset comprised patients with obstructive coronary atherosclerosis. Approximately 95 percent of these subjects had double or triple vessel disease. Each of the major arteries was equally vulnerable. Homocoronary or intercoronary collateral vessels were visualized in almost half of the patients.

When cinearteriography was repeated approximately 1 to 4 years after the initial examination, significant progression in the arterial obstruction was observed in more than two thirds of the patients included in this group. This frequency of progression is somewhat higher than that recorded by others.[9]

Is it possible to predict progression of coronary artery disease?: Even in retrospect, it is not possible to predict who among the second subset was more likely to have stable or progressive coronary artery disease. The distribution of the initial abnormality does not appear to be a clue since it was remarkably similar in both groups at the outset. However, since collateral channels initially were more prolific in the group with stable disease, more severe obstructions that could not worsen materially may have been more common in these patients. The incidence of risk factors including a positive family history for coronary heart disease, hyperlipidemia, clinical diabetes mellitus and systolic and diastolic hypertension was not higher in the patients with progressive disease and cannot be held responsible for the more rapid increase in arterial atherosclerosis. The mean interval between examinations was somewhat longer for the group with progressive disease, but it is unlikely that this single factor accounts for the differences observed cinearteriographically. From the items available for study, it is reasonable to conclude that it is not possible to predict among patients with angina pectoris the pace at which the arterial disease will worsen.

In observing the cinearteriographic depiction of the devolutionary pattern of coronary atherosclerosis, lesions in the left circumflex artery appeared to mature more rapidly than others. However, complete occlusions developed more frequently in the left anterior descending and right coronary arteries.

New collateral vessels were noted in almost two thirds of patients with progressive but in none of those with stable disease, thus emphasizing the role of progressive arterial disease as the primary stimulus for the development of these channels.[10–15] The protective role of collateral vessels is supported by the observation that none of the subjects with progressive disease who had collateral vessels at the first examination had abnormal myocardial contractility even when complete occlusion of a major artery occurred subsequently.

Severity of angina pectoris: The degree of severity of angina pectoris appeared to be a crude guide to the progress of the arterial disease. One third of the patients with stable coronary disease noted a reduction in the frequency and severity of angina in the interval between arterial visualizations. No one with progressive coronary disease had a reduction in severity of angina and in half of the group the severity had significantly increased. Paradoxically, two patients with stable coronary artery disease had a new myocardial infarction in the interval between examinations.

Clinical implications: Limited conclusions are warranted from this study. The devolutionary pattern of coronary atherosclerosis in patients with angina pectoris as seen cinearteriographically is quite unpredictable, apparently unrelated to risk factors and essentially unheralded by specific clinical manifestations separating those with rapidly progressive disease from those with relatively stable lesions. These observations stress the gap that, in the present state of knowledge, separates anatomic structure from function, and they underscore the many determinants regulating the balance between coronary perfusion and myocardial metabolism that fall beyond the scope of cinearteriography.

Acknowledgment

We thank Ms. Barbara Podliski for her efforts in preparation of this manuscript.

Effects of Factors Predisposing to Atherosclerosis on Formation of Coronary Collateral Vessels

ROBERT A. HEINLE, MD, FACC
ROBERT I. LEVY, MD
RICHARD GORLIN, MD, FACC*

Boston, Massachusetts
Bethesda, Maryland

Two hundred eighteen consecutive patients undergoing selective coronary angiography were studied to determine the effects of underlying predisposing coronary risk factors on the formation of intercoronary collateral anastomoses. The presence or absence of hyperlipoproteinemia, diabetes mellitus, glucose intolerance, hypertension or obesity did not influence the formation of these intercoronary collateral channels. Our findings suggest that there are presently no measurable clinical factors that permit prediction of the presence of coronary collateral channels in an individual patient. Factors predisposing to atherosclerosis have a similar distribution in patients with and without such vessels.

With the advent of techniques capable of demonstrating interarterial coronary anastomosis, several important postmortem and in vivo studies in man have been reported.[1-5] These studies clearly demonstrate that the most important factor in determining the presence of functionally significant collateral vessels is the severity of the coronary arterial stenosis. The presence of these vessels also appears to be related to the presence of myocardial ischemia as demonstrated by abnormal postexercise electrocardiograms and abnormal transmyocardial lactate production.[6] It is generally accepted that coronary collateral vessels are congenitally determined potential channels that function only in response to (1) a pressure difference across or between coronary arteries as a result of obstruction, or (2) myocardial ischemia distal to the obstruction.[7] The response to myocardial ischemia might explain the greater prevalence of these vessels in patients with anemia and arterial unsaturation as reported by Zoll et al.[1] However, the presence of both severe arterial obstruction and evidence of myocardial ischemia in some patients without collateral vessels suggests that additional factors may promote or inhibit collateral development. This report describes a study of the relation between factors predisposing to coronary atherosclerosis and the presence of collateral vessels in patients with documented coronary atherosclerosis.

Material and Methods

Case Material

Two hundred eighteen consecutive patients undergoing selective coronary cinearteriography were studied. In all cases arteriography was performed to evaluate angina pectoris or chest pain of obscure cause or to assess coronary circulation in patients being considered for cardiac valvular surgery. Thus, the group represents some degree of preselection rather than a random sampling of the population at large. One hundred sixty-four patients were male, and 54 were female; the age range was 29 to 69 years (mean 47 years).

Symptoms: The clinical records of all patients in the study were reviewed. At least one of us had assumed primary responsibility for the care of each patient during the current hospitalization. The criteria for the diag-

nosis of angina pectoris and for myocardial infarction were those of the New York Heart Association, Committee on Nomenclature.[8]

Angiography: The degree of coronary atherosclerosis was assessed by selective cineangiography performed at a rate of 60 frames/sec. The angiograms were taken in multiple projections and in many instances after sublingual administration of nitroglycerin. Kemp et al.[9] have shown that this technique accurately defines the degree of disease in vessels up to a size of 300 μ. The angiograms were reviewed independently by two of us and were judged to be of high diagnostic quality in each case. Each patient also underwent diagnostic left and right heart catheterization and cineventriculography.

The degree of atherosclerosis was rated as follows: 0 (indicating no discernible luminal narrowing or irregularity), 50 percent narrowing or less, 75 percent narrowing, or 90 percent narrowing or greater (the latter indicating severe segmental narrowing or complete occlusion of the vessel).

Criteria for the presence of coronary collateral vessels were as previously reported[5]: (1) direct visualization of accessory blood vessels either filling the distal segment of an occluded or severely stenotic artery, or subserving the area of myocardium that would ordinarily be supplied by the severely stenotic vessel; and (2) visualization of a coronary artery after injection of contrast material into the contralateral vessel.

Lactate metabolism: Paired blood samples for lactate determinations were obtained from an indwelling arterial catheter and a second catheter fluoroscopically positioned within the coronary sinus. Measurements were made "at rest" and again during stress to the oxygen delivering systems induced by infusion of isoproterenol.[10] Lactate was analyzed in duplicate,[11] and a gross production of lactate was considered to be abnormal.[12]

Coronary Risk Factors

Lipid determinations: Plasma samples were drawn from each patient after a 12 to 16 hour overnight fast and were shipped at 4° centigrade to the Molecular Disease Branch of the National Heart and Lung Institute for analysis as previously reported.[13] The plasma was analyzed for total cholesterol[14] and triglycerides,[15] and the lipoprotein was fractionated into very low density lipoprotein, high density and low density components and determined in terms of lipoprotein cholesterol by a combination of ultracentrifugation and precipitation procedures.[16] The normal limits of plasma cholesterol and triglyceride and low density lipoprotein cholesterol previously described[16] were used in part to define the hyperlipoproteinemic states. Type II hyperlipoproteinemia was established by the finding of a low density lipoprotein cholesterol value greater than the age-adjusted 95 percentile limit, and type IV by the finding of a pure endogenous hypertriglyceridemia (prebeta lipoproteinemia) with a plasma triglyceride value greater than the age-adjusted 95 percentile limit.[16]

Carbohydrate tolerance: An intravenous glucose tolerance test was performed in all but 16 patients who had clinically overt diabetes mellitus. After an overnight fast, 0.5 g/kg of glucose was infused rapidly and plasma samples were drawn every 10 minutes for 1 hour. The rate of glucose disappearance in percent per minute (IVGTT k) was calculated, and a value of less than 1.0 was considered abnormal.

Hypertension: Hypertension was defined as diastolic blood pressure greater than 90 mm Hg recorded (1) on two separate occasions during the present hospitalization, (2) on at least two previous occasions by a physician, or (3) at the time of cardiac catheterization.

Obesity: Obesity was defined as a body weight 20 percent greater than medium ideal weight according to Metropolitan Life Insurance Company tables.[17]

TABLE I

Relation Between Frequency of Collateral Channels and Severity of Vessel Disease

Degree of Arterial Narrowing	RCA Patients (no.)	RCA With Collateral Channels no.	RCA With Collateral Channels %	LAD and/or LCF Patients (no.)	LAD and/or LCF With Collateral Channels no.	LAD and/or LCF With Collateral Channels %
0	139	0	0	144	0	0
50%	11	1	9.1	7	0	0
75%	8	1	12.5	16	1	6.2
≥90% (or total occlusion)	60	51	85.0	51	42	82.4

LAD = left anterior descending branch of left coronary artery; LCF = left circumflex branch; RCA = right coronary artery.

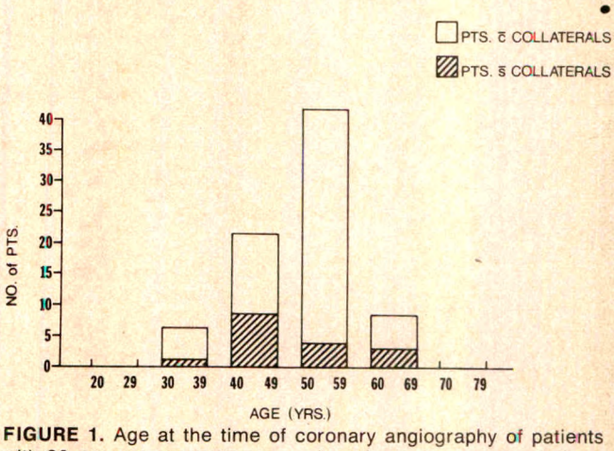

FIGURE 1. Age at the time of coronary angiography of patients with 90 percent or greater narrowing of a major coronary artery. There was no statistical difference between the groups with and without collateral vessels.

Results

For analysis of collateral vessels, the right and left coronary arterial systems were considered independently (Table I). No collateral vessels were visualized in any patient with less than 50 percent narrowing of either coronary arterial system. Intercoronary anastomoses were seen in 1 of 18 vessels with 50 percent narrowing and in 2 of 24 with 75 percent narrowing. However, in 93 of 111 vessels with 90 percent narrowing or greater, collateral channels were present and filled the distal portion of the vessel beyond the obstruction. There were no significant lesions of the main left coronary artery.

Since the stimulus for collateral vessel formation, as defined by these methods, appeared to be the presence of severe obstruction of a vessel, compari-

son was made between patients with 90 percent or greater narrowing of the coronary artery *with* collateral vessels and patients with 90 percent narrowing or greater *without* collateral vessels. Fifteen patients had severe obstruction of both the right coronary and the left anterior descending arterial systems; and all 15 had collateral channels supplying both vessels. Of 81 patients with severe single vessel disease, 65 had collateral channels and 16 did not. There were, therefore, 80 patients with significant narrowing of one or two vessels and collateral channels and 16 patients with severe obstruction and no collateral channels. These 96 patients are the basis for the remainder of the study. There was no significant difference in the age of patients with and without collateral vessels at the time of study (Fig. 1).

Symptoms: Angina pectoris was the presenting complaint in all but 2 of the 96 patients. The other two patients had hemodynamically significant aortic stenosis and both had coronary collateral vessels (Table II). There was no statistical difference between patients with and without collateral vessels in regard to the initial symptom of the coronary artery disease or history of previous acute myocardial infarction.

TABLE II

Frequency of Clinical Abnormalities in Patients With and Without Collateral Channels

	Collateral Channels		
	Present (80 patients)	Absent (16 patients)	*P* Value
Angina pectoris	78 (97%)	16 (100%)	NS
History of infarction	44 (55%)	6 (38%)	NS
Initial symptom			
Angina	61 (76%)	13 (81%)	NS
Infarction	17 (21%)	2 (12%)	NS

NS = not significant; *P* = probability.

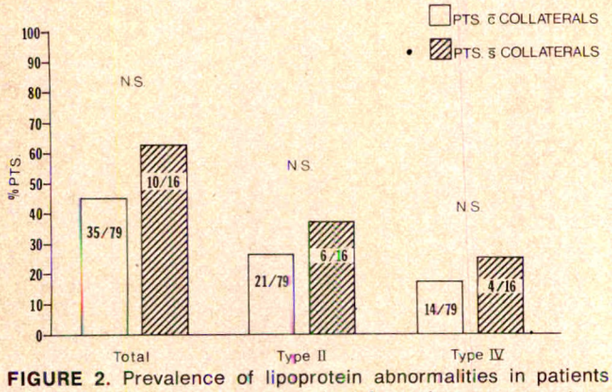

FIGURE 2. Prevalence of lipoprotein abnormalities in patients with 90 percent or greater narrowing of a major coronary artery. The presence of a lipoprotein abnormality did not influence the occurrence of collaterals. N.S. = not significant.

Lipoprotein abnormalities: Figure 2 shows the distribution of abnormal lipoprotein patterns in patients with and without collateral vessels. One patient with visible intercoronary collateral channels did not have adequate lipoprotein studies and is not included in this evaluation. Thirty-five of 79 patients with collateral vessels and 10 of the 16 patients without such vessels had a lipoprotein abnormality; this difference was not statistically significant. Of the five types of lipoprotein abnormality identified by Frederickson, only the type II and the type IV abnormalities occurred in this series. Figure 2 also shows the distribution of these two lipoprotein abnormalities in the patients with and without collateral vessels. There was no significant difference between the groups.

Glucose intolerance: Figure 3 shows the distribution of overt diabetes mellitus or glucose intolerance in the patients with and without collateral vessels. Forty-nine of the 80 patients with collateral vessels and 12 of the 16 without collateral vessels demonstrated this metabolic abnormality. This difference was not statistically significant.

Hypertension and obesity: Figure 3 also shows the frequency of hypertension and obesity in the two

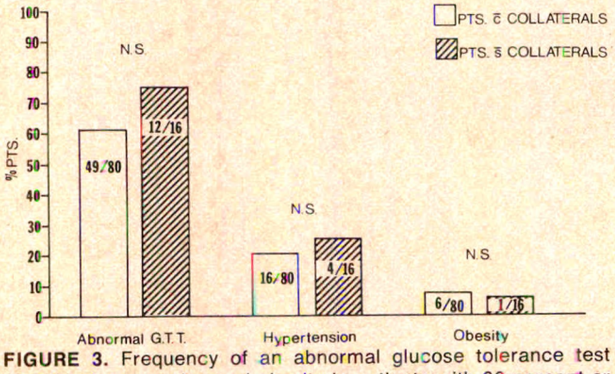

FIGURE 3. Frequency of an abnormal glucose tolerance test (G.T.T.), hypertension and obesity in patients with 90 percent or greater narrowing of a major coronary artery. These factors did not influence the occurrence of collateral vessels.

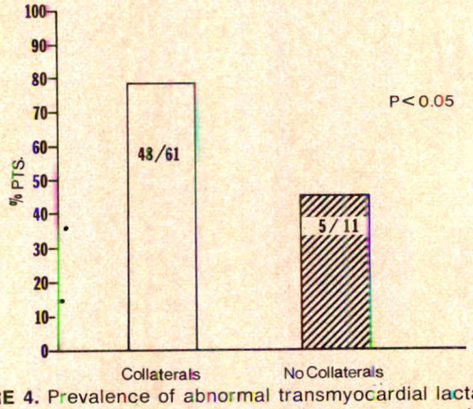

FIGURE 4. Prevalence of abnormal transmyocardial lactate production in patients with 90 percent or greater narrowing of a major coronary artery. This abnormality occurred more frequently in the group with collateral vessels than in the group without these vessels.

groups of patients. There were no differences between the groups, in regard to the presence of increased diastolic blood pressure or obesity. Since the number of patients with obesity was quite small, statistical analysis of group comparison may not be meaningful for this variable.

Lactate metabolism: Transmyocardial lactate studies were completed in 72 of the 96 patients with severe obstruction of the coronary arteries. The prevalence of abnormal lactate extraction was significantly greater in the patients with collateral vessels than in those without such vessels (Fig. 4).

Discussion

The analysis in this unselected group of patients with symptomatic documented coronary artery disease indicates that the formation of intercoronary collaterals is not affected by the presence of lipoprotein abnormalities, glucose intolerance, diastolic hypertension or obesity. Although glucose intolerance and hypertension are known to have effects on the vascular tree, these underlying abnormalities did not inhibit the formation of coronary collateral vessels. This finding is not completely unexpected since hypertension and diabetes mellitus have effects on small arteries (especially intramyocardial vessels) and perhaps even smaller vessels, but the collateral channels usually represent large epicardial vessels that do not appear to be influenced by these two factors.

A previous report from this laboratory[13] concluded that the atherosclerotic pattern of the coronary artery as demonstrated by selective coronary angiography was similar regardless of the underlying factor predisposing to formation of the atherosclerosis. The frequency of single and multiple vessel disease, isolated stenosis and multiple narrowings of the same vessel, long areas of narrowing and complete obstruction were not different in the groups with lipoprotein abnormalities, glucose intolerance, hypertension or obesity. These factors thus appear to be important only in creating susceptibility to development of coronary atherosclerosis; they apparently do not directly influence the anatomic location of the obstructive lesions or affect the opening of intercoronary connections.

This study of consecutive patients confirms the observation that the presence of severe coronary arterial stenosis is extremely important in the formation of functionally significant intercoronary anastomosis. Although anemia and arterial unsaturation may contribute to the formation of collateral vessels,[1] the presence of coronary atherosclerosis is clearly the most significantly finding in patients with these vessels. We believe that ischemia causes local vasodilatation which then causes a reduction in distal coronary arterial pressure; this reduction accentuates the gradient across the obstruction in a manner that sets the stage for enlargement of preexisting collateral channels. The increased frequency of lactate production under stress supports this concept.

It is possible that, in the patients without collateral vessels, the severity of the arterial lesion was "overread" and that the narrowing was actually less than 90 percent. However, 7 of the 16 patients had complete occlusion of the coronary artery, and this type of lesion is not easily misinterpreted. In addition, all patients had angina pectoris, and six had evidence of previous myocardial infarction. These two clinical features were also found in the group with collateral vessels.

The clinical findings and assessment of myocardial metabolism under stress to the oxygen delivery system were included in our study to show that our patients were not different from those in previously reported series. A prior history of angina pectoris or myocardial infarction could not be used to predict the presence of coronary collateral vessels. The greater frequency of lactate production by the myocardium under stress demonstrates that the coronary collateral channels do not necessarily protect a person from myocardial ischemia. However, the value of these channels in the general population is completely unknown, and the data available are from patients who have been studied mainly because they have symptoms of myocardial ischemia.

A shortcoming of our study is its comparison of data in a large group of patients with collateral channels with findings in a much smaller group without such channels. However, in a consecutive clinical study in which the anatomic appearance of atherosclerosis cannot be predicted, disparity in the size of the groups is unavoidable and not surprising. In spite of this disparity, our study has value as a consecutive study of patients who were not preselected except for the original indication for arteriography. Our findings indicate that the formation of coronary collateral vessels in patients with symptomatic coronary artery disease does not seem to be influenced by some of the major factors predisposing to the development of atherosclerosis.

Hemodynamic Observations in Patients with Unstable Angina Pectoris

DAVID S. CANNOM, MD
DONALD C. HARRISON, MD, FACC
JOHN S. SCHROEDER, MD, FACC

Stanford, California

Brachial and pulmonary arterial pressures were monitored for 48 hours in 26 patients with unstable angina pectoris and documented occlusive coronary artery disease. The circulatory response during 56 episodes of spontaneous anginal pain permitted the division of responses into three distinctive hemodynamic subsets. Patients in group I had an increased heart rate only with the spontaneous attack of angina; patients in group II had associated increases in brachial arterial pressure and slight increases in heart rate during the episodes of pain; patients in group III demonstrated increases in both brachial and pulmonary arterial diastolic pressures with minimal changes in heart rate. Resting hemodynamic data during pain-free periods were normal in 25 of 26 patients. Patients in all groups who had more than one episode of pain had similar hemodynamic responses to the first and later episodes. Although myocardial hypoxemia appears to be responsible for the spontaneous attack of angina, the hemodynamic responses to the attack varied but were highly specific for any one patient.

Our observations suggest that there may be various pathogenic mechanisms for "spontaneous" or resting angina in patients with occlusive coronary artery disease but that the mechanism and associated hemodynamic changes may be specific for individual patients.

The widespread application of aortocoronary artery saphenous vein bypass surgery for the relief of angina pectoris has resulted in a renewed interest in the hemodynamic alterations accompanying anginal attacks. A number of techniques, including drug administration,[1] right atrial pacing[2,3] and exercise,[4] have been used to induce angina and permit monitoring of the accompanying hemodynamic changes. More sophisticated analyses of left ventricular function, including examination of changes in compliance occurring with myocardial infarction[5] and angina,[6] have expanded understanding of altered left ventricular function. However, little attention has been focused on the hemodynamics of the spontaneous or apparently unprovoked anginal attack. This report presents the results of hemodynamic study during 56 episodes of spontaneous angina in 26 consecutive patients hospitalized with unstable or "preinfarction" angina.

Materials and Methods

Patients: Twenty-six patients admitted to Stanford University Hospital were accepted for this study of unstable angina on the basis of the following criteria:

1. History of one or more episodes of ischemic cardiac pain judged clinically severe enough to warrant admission to the coronary care unit because of suspected impending myocardial infarction.

2. Admission electrocardiograms with Q waves diagnostic of prior myocardial infarction by World Health Organization criteria, or depressed S-T segments with pain typical of myocardial ischemia. Although S-T segment

TABLE I

Clinical Profile of 26 Patients

Age (yr)	52.2 (average); 36–67 (range)
Sex	24 men, 2 women
Duration of angina (yr)	2.4 (mean); 1 day–20 years (range)
Duration of crescendo angina (mo)	<1 (25 patients)
Prior myocardial infarction	Present (10 patients); absent (16 patients)
Abnormal electrocardiogram	Present (26 patients)

elevation with pain typical of Prinzmetal's angina would not have excluded a subject from the study, such changes were not noted in our patient population.

•3. Initial values for serum enzymes (lactic dehydrogenase [LDH] and serum glutamic oxaloacetic transaminase [SGOT]) were within normal limits. Elevations of serum creatinine phosphokinase (CPK) levels to 100 international units/liter did not exclude a patient from the study.

4. Subsequent documentation by coronary arteriography of occlusive coronary disease with greater than 70 percent narrowing in at least one major coronary artery.

Each patient was seen by one of us on the day of admission and formally admitted to the study on the basis of clinical findings. The purposes of the study were explained to the patients, and their informed consent was obtained.

Protocol: The following protocol was carried out in each case: 1. Initial instrumentation was performed on admission. A catheter was positioned in the pulmonary artery to record both pulmonary arterial and pulmonary arterial wedge pressures. The Swan-Ganz thermodilution catheter was used in some cases. A 50 gauge, short polyethylene catheter was inserted into the brachial artery percutaneously. Both catheters were attached to Microdot transducers and Hewlett-Packard pressure preamplifiers. A Honeywell strip-chart recorder was utilized to record all the hemodynamic measurements. Early in the series in 11 patients the left ventricle was catheterized and pressure measured with the use of a no. 7F Cook catheter, which was then replaced by the short polyethylene catheter inserted in the brachial artery for continuous monitoring. Both brachial and pulmonary arterial pressures were recorded at least hourly and during any episode of chest pain at a paper speed of 25 mm/sec. Patients were carefully instructed to call the coronary care unit nurse immediately during any episode of substernal discomfort. During pain-free periods, the brachial arterial catheter was used for continuous pressure recording at a paper speed of 0.25 mm/sec. The pulmonary arterial catheter was not kept continuously attached to the pressure transducer because of the possibility of thrombus formation. Thus, pulmonary arterial pressures were recorded only during chest pain. Lead II of the electrocardiogram was continuously monitored.

2. The patient's cardiac output was measured initially using either standard dye-dilution or thermodilution techniques. In addition, measurement was made of the arterial oxygen saturation and arteriovenous oxygen difference on admission and on at least a daily basis thereafter.

3. After 48 hours of hemodynamic monitoring, coronary arteriography was performed by the Judkins technique. This procedure was followed by left ventricular angiography performed with use of a no. 7F Cook pigtail catheter.

TABLE II

Hemodynamics During Unprovoked Anginal Episodes

	Prior to Pain	At Onset of Pain	After Nitroglycerin	*P* Value
Group I (5 episodes of pain)				
BA pressure (mm Hg)	120/63	122/69	120/70	
PA pressure (mm Hg)	18/9	17/10	19/10	
Heart rate (beats/min)	72 ± 1.4	85 ± 4.7	70 ± 2	<0.05
a-v O_2 difference (vol %)	4.6	...	...	
Cardiac output (liters/min)	5.6	...	...	
Group II (23 episodes of pain)				
BA pressure (mm Hg)	123/69	152/89	124/80	
PA pressure (mm Hg)	23/10	26/13	21/12	
Heart rate (beats/min)	79 ± 1.7	88 ± 2.8	84 ± 1.5	<0.01
a-v O_2 difference (vol %)	4.8	...	...	
Cardiac output (liters/min)	5.3	...	...	
Group III (28 episodes of pain)				
BA pressure (mm Hg)	126/70	166/95	119/70	
PA pressure (mm Hg)	21/12	36/20	19/14	
Heart rate (beats/min)	77 ± 1.7	78 ± 1.8	83 ± 2.2	NS
a-v O_2 difference (vol %)	4.7	...	...	
Cardiac output (liters/min)	5.2	...	...	

a-v O_2 = arteriovenous oxygen difference; BA = brachial arterial; NS = not significant; PA = pulmonary arterial.

4. A decision was made on the day of arteriography regarding the patient's subsequent management. If surgery was recommended, it was performed within 48 hours of the arteriography, or usually 72 hours after admission to the study.

Medical treatment during the period of hemodynamic monitoring was limited to sedation and administration of sublingual nitrates during anginal attacks. Propranolol, anticoagulant agents and long-acting nitrates were not given.

Results

Clinical Data

The clinical profile of the study patients is presented in Table I. The majority (24 of 26) were male patients with a background of stable exertional angina that, on exacerbation, prompted admission to the hospital. Typically, the change in ischemic chest pain was quite abrupt, occurring days to weeks before admission, and frequently it represented the onset of resting or nocturnal angina. Only two patients admitted to the study had experienced their first attack of anginal pain on the day of admission. Ten patients had prior myocardial infarction by standard criteria on the admission electrocardiogram; all 26 patients had ST-T wave abnormalities on admission suggestive of ischemia. Transient and reversible ST-T wave changes occurred during anginal episodes in most patients.

Hemodynamic Measurements

The 48 hour monitoring period provided data that allowed hemodynamic characterization of this patient population. During initial instrumentation, measurements were made of the brachial, pulmonary arterial and pulmonary arterial wedge pressures. Normal values were considered to be less than 12 mm Hg (mean) for the pulmonary arterial wedge, less than 35/10 mm Hg for the pulmonary artery and less than 140/90 mm Hg for the brachial artery. A cardiac index of 2.5 to 4.5 liters/min per m^2 was considered normal.

Initial hemodynamic data demonstrated normal values for the three pressure measurements and cardiac output in 25 of 26 patients during pain-free periods. The 26th patient, a 53 year old man, had an initial resting left ventricular end-diastolic pressure of 17 mm Hg. His daily serum enzyme determinations were consistent with the evolution of myocardial infarction but were not associated with electrocardiographic changes.

Hemodynamics during anginal episodes: Seventeen of the 26 study patients continued to have episodes of anginal pain at rest during the 48 hour monitoring period. Only those episodes of sufficient severity to require sublingual nitrates were included. The frequency of attacks ranged from 1 episode in each of five patients to a maximum of 13 episodes documented in one patient. There was an average of 2.6 anginal episodes per patient during the monitoring period.

The hemodynamic data obtained during the 56 episodes are summarized in Table II. Three types of hemodynamic abnormalities could be distinguished during pain. These changes represent observations made at the onset of pain. While the heart rate and brachial arterial pressure were continuously moni-

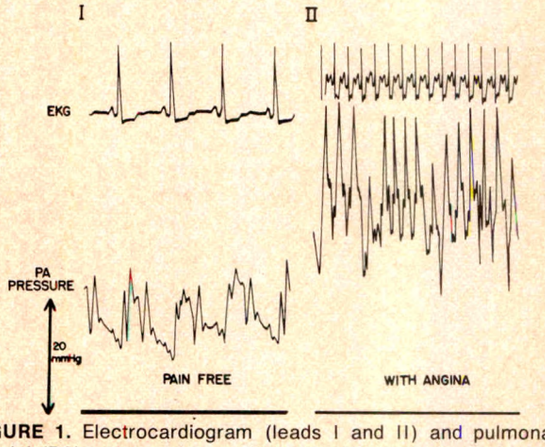

FIGURE 1. Electrocardiogram (leads I and II) and pulmonary arterial (PA) pressure in a patient in group III during a pain-free period and during angina. At the onset of pain, the pulmonary arterial pressure has increased from 23/10 to 53/23 mm Hg. Note the ischemic S-T segments during pain. Paper speed on the left is 25 mm/sec; that on the right is 10 mm/sec.

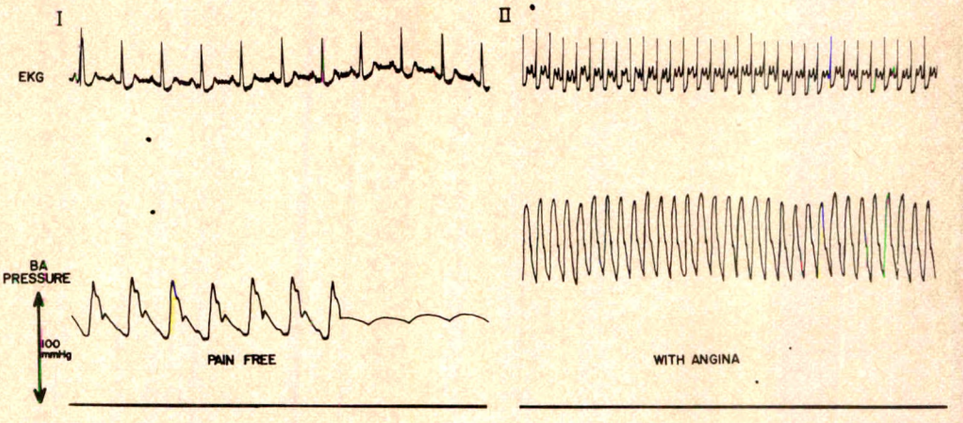

FIGURE 2. Brachial arterial (BA) pressure for the same patient during the same episode of pain. The pressure has increased from 110/50 mm Hg during an angina-free period to 200/110 during pain. Paper speeds as in Figure 1.

tored, notation was made of pressures at the onset of pain, typically less than 30 seconds after the start of pain. After the heart rate and brachial and pulmonary arterial pressures were determined, nitroglycerin was given and the response noted. Usually within 2 to 5 minutes the pain had subsided and the baseline condition was restored. In three patients (group I) there were no changes other than an increase in heart rate, averaging 15 beats/min. The brachial, pulmonary arterial and pulmonary arterial wedge pressures remained unchanged before and during pain. Another discrete subset of seven patients (group II) typically had an increase in brachial arterial pressure and heart rate before and during pain. A third group of seven patients (group III) had increased brachial, pulmonary arterial and pulmonary arterial wedge pressures before or during anginal attacks, or both. The latter group did not have an increase in heart rate with pain comparable to that observed in group I or II. The average increase in brachial arterial pressure for the latter two groups was 28 mm Hg systolic and 20 mm Hg diastolic. Patients who had increased pulmonary arterial pressure during pain had an average increase of 15 mm Hg systolic and 8 mm Hg diastolic. No patient had clinical evidence of pulmonary vascular congestion with these increases in pulmonary arterial pressure. In no case did an increase in pulmonary arterial or pulmonary arterial wedge pressure precede an increase in brachial arterial pressure or heart rate. Examples of pressure changes noted in one patient during pain are shown in Figures 1 and 2. In all patients who had more than one period of chest pain, the hemodynamic responses during later episodes of pain were similar to those of the first episode.

In five patients a significant increase in brachial arterial pressure preceded the subjective awareness of anginal pain by 5 to 10 minutes (Fig. 3). Four of these five patients were in the group in which both brachial and pulmonary arterial pressures increased with pain.

Coronary Arteriography

The coronary arteriographic and left ventriculographic findings in the 25 patients studied are shown in Table III. Eighty percent of the patients (20 of 25) had double or triple vessel occlusive coronary disease with greater than 70 percent narrowing. More than 50 percent (14 of 25) had associated contractile abnormalities on review of the left ventriculogram. All these studies were completed without complication.

Clinical Course

The subsequent clinical course for the study group is outlined in Table IV. Three of the patients experienced myocardial infarction during the observation period, as diagnosed by a rise in serum glutamic oxaloacetic transaminase (SGOT) levels to more than 50 percent above normal. There was no characteristic hemodynamic pattern before infarction in these three patients, except in the previously mentioned patient with increased left ventricular end-diastolic pressure at rest. None of the infarctions were transmural as defined by the development of Q wave patterns on the electrocardiogram, and all were diagnosed by enzyme changes alone. All patients survived. Four patients were not operated upon for nonmedical reasons, typically because of reluctance by the patient or his referring physician to consider surgery. The remaining 19 patients had cardiac operations on either day 3 or 4 of their hospitalization. Seven patients had a single saphenous vein bypass graft; 12 had a double graft. In addition, two patients had associated right coronary gas endarterectomy. All survived operation and were discharged from the hospital. During operation, two patients had new Q waves diagnostic of myocardial infarction; both of these patients did well clinically postoperatively.

Discussion

Although an extensive literature has recently emerged concerning the indications and results of aortocoronary artery saphenous vein bypass surgery for the patient with unstable angina, few studies have reported the hemodynamic status of these patients during both pain and pain-free periods.[7-13] An important feature in understanding the success or failure of this surgical procedure is the analysis of the hemodynamic status of the patient with unstable angina in three conditions: during pain-free periods, during episodes of unprovoked angina pectoris, and

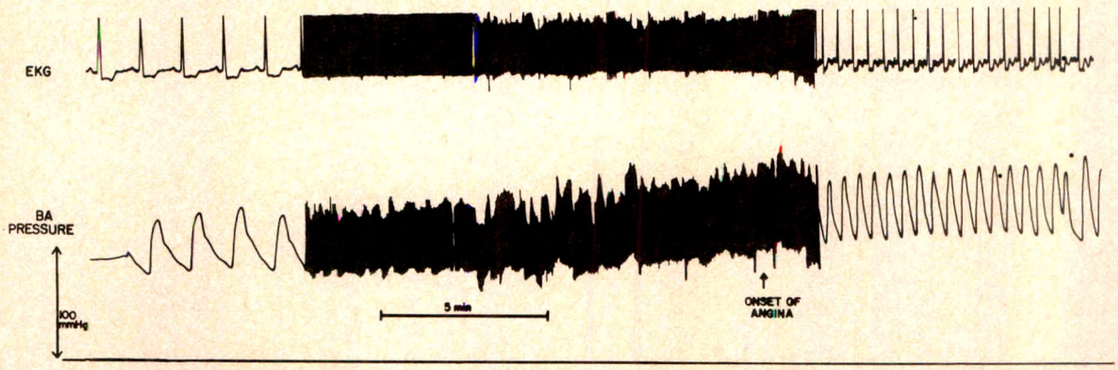

FIGURE 3. A continuous recording of brachial arterial (BA) pressure before and during angina. To the far left the brachial arterial pressure is 120/80 mm Hg at a paper speed of 25 mm/sec. The paper speed has been reduced to 0.25 mm/sec in the center section of the illustration. Note that the brachial arterial pressure began to increase 15 minutes before the patient was aware of chest pain. With the onset of angina the brachial arterial pressure increased to 180/110 mm Hg. Paper speed at the far right is 10 mm/sec.

after operation. This report summarizes our experience with 26 consecutive, carefully selected patients having unstable angina and confirmed severe occlusive coronary artery disease. Significant coronary artery disease (greater than 70 percent narrowing of at least one vessel on coronary arteriograms) was mandatory for inclusion in this study. Such arteriographic documentation is important, since four additional patients (not included in our series) initially underwent monitoring because their clinical presentation and electrocardiograms suggested unstable angina, but arteriograms showed either normal or only minimally diseased coronary arteries. The questionable statistical validity of studies reporting the clinical course of large series of similar patients without arteriographic confirmation of coronary disease makes comparison among patient series difficult.[14]

The normal resting, pain-free hemodynamic measurements contrast sharply with those of patients having established acute myocardial infarction; many of the latter patients demonstrate gross hemodynamic alterations, including abnormalities in arteriovenous oxygen difference, cardiac index and left ventricular end-diastolic pressure.[15,16] The extent of these abnormalities relates to the severity of left ventricular failure, or changes in compliance secondary to the acute infarction. In patients with acute myocardial infarction but without clinical heart failure, Ramo et al.[15] observed abnormalities including widened arteriovenous oxygen differences in 45 percent of patients, and reduced cardiac index (less than 3 liters/min per m^2) in 51 percent. The only abnormality noted among our patient population was increased left ventricular end-diastolic pressure (17 mm Hg) in one patient who was later demonstrated to have had a subendocardial infarction.

Robinson[17] has discussed in detail the relation of heart rate and systolic blood pressure to the onset of anginal pain. All 17 patients having spontaneous angina had changes in one or both of these variables, leading to an increase in cardiac work and increased myocardial oxygen demand. These changes apparently accompanied or, in some cases, preceded the pain, although a component of this hemodynamic response may well be a response to the pain itself. Five patients had a well documented increase in brachial arterial pressure 5 to 15 minutes before the onset of subjectively recognized chest pain. Four of these patients were classified in group III and one in group II. This small number suggests that angina at rest is precipitated by an autonomically mediated sympathetic discharge, with consequent increases in systemic vascular resistance and heart rate, resulting in increased cardiac work.[18] Administration of nitroglycerin was uniformly effective in relieving the chest pain; however, the decrease in systolic blood pressure usually occurred before the patient experienced relief of the angina. Blood catecholamine levels were not measured during anginal attacks.

Any given patient showed the same accompanying hemodynamic abnormalities during each episode of pain, and systolic blood pressure and heart rate product were closely correlated during each episode. These results are comparable to the observations of Scheidt et al.[19] and Roughgarden,[20] who found hemodynamic changes consisting of increased brachial arterial pressure or abnormal left ventricular function preceding subjective angina in a small number of patients. We were unable to correlate the type of associated hemodynamic changes with the location or severity of occlusive coronary artery disease, absence or presence of abnormalities of contraction by left ventricular angiography, or number of previous myocardial infarctions.

Hemodynamic basis for angina pectoris: The hemodynamic monitoring methods used in our study do not allow definitive comment on the sequence of physiologic events antedating the onset of pain in these patients with angina at rest. Continuous monitoring of left ventricular and pulmonary arterial pressures with serial determination of cardiac index during pain will be necessary if the true sequence of

causal factors is to be determined. Our data support Gorlin's thesis that angina at rest may be caused by an episode of acute peripheral vasoconstriction, perhaps related to release of catecholamines.[18] This thesis would explain the increased heart rate in the patients in group I. The patients in group III whose pulmonary arterial and pulmonary arterial wedge pressures increased with angina are of importance, since the altered pulmonary arterial diastolic pressures suggest that left ventricular dysfunction is a feature, if not the primary cause, of the anginal attack. Altered left ventricular compliance as a response to the ventricular hypoxia would be one explanation for this observation.[6] Alternatively, the development of reversible acute heart failure due to alterations in both left ventricular pressure and volume could also explain the results obtained in patients in group III. Scheidt et al.[19] described three patients who had six episodes of pain preceded by an increase in left ventricular end-diastolic pressure without associated changes in arterial pressure or heart rate, but the mechanism of this change is unclear. Only a critical sequential analysis of the hemodynamic events will allow more careful cause and effect analysis of the unprovoked anginal attack in the patient with unstable angina. Such studies are currently underway.

Prognostic significance of hemodynamic findings: The subsequent clinical course of the 26 patients could not be predicted from the presence or absence of continued angina at rest or the type of hemodynamic abnormalities associated with resting angina. Three patients had myocardial infarction as demonstrated by serum enzyme changes. None of these patients had subsequent pain in the hospital, possibly because of infarction of the ischemic area. Nineteen patients had coronary bypass surgery without any hospital mortality. These 19 were equally distributed among those patients having no pain at rest in the hospital in groups I, II and III. We thus conclude that the resting and pain-associated hemodynamic status was not helpful in distinguishing the high risk patient for early myocardial infarction or operative death in this small group.

The abnormal hemodynamic status, particularly changes in left ventricular compliance, may well be an important cause of the unstable nature of the angina or a precipitating factor in myocardial infarction. The high percentage of patients who had early coronary bypass surgery did not permit further analysis of this point. Continuing accumulation of hemodynamic data on patients with unstable angina should provide more comprehensive information regarding this problem.

Maximal Cardiac Output During Exercise in Patients with Coronary Artery Disease

JOHN R. McDONOUGH, MD, FACC
RUTH A. DANIELSON, BA
ROBERT E. WILLS, MD
DONALD L. VINE, MD

Seattle, Washington

Cardiac output, determined by the direct Fick method, was measured each minute during multistage treadmill testing in which patients exercised to the point of exhaustion. Twenty-nine tests and 183 measurements of cardiac output during exercise were performed in 16 patients with coronary artery disease. Maximal cardiac output paralleled the maximal oxygen intake and was reflected by a plateau during the final minutes of exercise. Significant decreases in stroke volume and increases in mean pulmonary arterial pressure suggest that acute left ventricular dysfunction is the mechanism limiting the maximal cardiac output in these patients. Maximal cardiac output is a sensitive and fundamental indicator of the degree of impairment resulting from coronary disease, and has potential value in defining the role of various methods of treating this disease.

This report describes the results of assessment of cardiac output during exercise in patients with coronary artery disease who underwent treadmill stress testing to the point of exhaustion.

Methods

Patients: Fifteen men and one woman with coronary artery disease, observed in an academic cardiology service, were selected for study. Three had prior transmural myocardial infarction diagnosed by typical pain syndrome, enzyme changes and evolving electrocardiograms that were diagnostic during the patients' admission to the coronary care unit and while they were under our supervision. The remaining 13 patients had angina pectoris and had undergone selective coronary arteriography and left ventricular angiography. Since several patients had repeat hemodynamic tests on different days, this report provides an analysis of 29 studies. Anthropometric, clinical and angiographic data on the 16 patients are shown in Table I.

Ergometry: Studies were performed with patients in the basal fasting state after completion of a physical examination and 12 lead electrocardiogram and after giving informed consent. Initial tests were carried out using the multistage continuous treadmill methods of Bruce et al.[1,2] and Doan et al.[3] Monitoring of pressures, heart rate and electrocardiogram during exercise and the first few minutes of recovery was performed by one or more physicians; a defibrillator, ventilator, oxygen and drugs[4] for emergency use were always available. The second (hemodynamic) test was performed days to weeks later and consisted of the multistage treadmill test of Bruce et al., with the addition of a less strenuous 3 minute initial stage with the patient walking at 1.7 miles/hour at zero elevation. Each 3 minute work load was followed by a step increase to the next stage without intervening rest, and the patient was asked to continue until exhausted. After exercise the patient was monitored in the supine position until the electrocardiogram, pressures and heart rate returned to preexercise levels.

Catheterization: A balloon flow-directed soft polyvinyl catheter (Swan-Ganz no. 7F) was advanced to the pulmonary artery by way of a cutdown procedure on the median basilic vein during monitoring of pressure. Ectopic beats seldom occurred and were never a problem. The catheters were

+ = present; — = absent; ... = not studied; % = percent narrowing of vessel diameter on arteriogram.

easily and rapidly (15 to 60 seconds) advanced to the pulmonary artery without fluoroscopy as described by Swan et al.[5]

A systemic artery, either the radial or brachial, was entered percutaneously using direct needle puncture with a short catheter advanced over the needle or over a guide wire using the Seldinger technique (Bardic 18.5 g, Jelco 16 g or Longdwell 16 g) and fixed to the skin by suture.

Pressure measurements: Transducers (Kulite P5L-125-6) were applied directly to the ends of the catheters and connected to carrier amplifiers (Brush Instrument RD 4212); pressure was obtained on a Brush Instruments Mark 240 recorder.

After balancing, the transducers were calibrated against a mercury column immediately before each test. The transducers were leveled at the mid-axillary line with the patient in the supine position and at the fourth interspace anterior axillary line with the patient upright. During standing and exercise, the catheterized arm was supported by an adjustable cradle fastened to the support bars of the treadmill to maintain the relation of transducers to the fourth interspace during changes in grade of the walking platform. Phasic and mean systemic and pulmonary arterial pressures were measured under the following conditions: supine and standing rest, exercise and supine recovery. Pulmonary wedge pressures were measured during supine rest and again during supine recovery. Wedge pressure determinations were not attempted during exercise. Sensitivity was 5 mm Hg/mm for systemic arterial pressure recording and 1 mm Hg/mm for pulmonary arterial pressure recording. Recording speeds were 5 and 25 mm/sec.

Oxygen intake: Exhaled air was collected in 120 liter neoprene bags at 1 minute intervals, with volume measured by spirometer and oxygen and carbon dioxide content by the Scholander technique, using standard formulas for calculation of oxygen intake ($\dot{V}O_2$). Paramagnetic (Beckman E-2) analysis of gas samples was also carried out after water vapor was removed and before and after removal of carbon dioxide; as expected, results of the two methods were in close agreement. The standard error of the difference (SEd)* of 17 samples calculated by both methods in $\dot{V}O_2$ liters per minute was 0.022.

Blood oxygen content: Blood, drawn anaerobically into heparinized syringes, was analyzed on the same day with use of the van Slyke manometric method. Samples from the pulmonary and systemic arteries were obtained simultaneously and timed to the mid-period of exhaled air collection. The relatively large lumen of the Swan-Ganz no. 7F catheter enabled removal of 5 to 7 ml samples in 9 to 12 seconds. Precision of measurement by van Slyke was assessed in duplicate aliquots from 41 consecutive samples, and by single measurements of 32 pairs of samples drawn in two syringes in immediate sequence from either arterial or mixed venous blood. Standard error of the difference of oxygen content in milliliters per liter for aliquots was 0.95, and for consecutive samples 2.25. During the exercise studies, single rather than paired samples were drawn simultaneously from pulmonary and systemic arteries to allow for more frequent sampling.

Cardiac output: Cardiac output was calculated by the direct Fick method on the basis of the measurements described, with use of standard formulas. Heart rate was measured from the continuously recorded electrocardiogram. Stroke volume was calculated in standard manner as the ratio of cardiac output and heart rate.

*SEd = $\sqrt{\frac{\Sigma d^2}{2k}}$, where d = difference between replicates of k pairs.[6]

FM = final minute of exercise; NS = not significant. −1 to −4 = minus 1 to minus 4 minutes of exercise. Other abbreviations as in Table II.

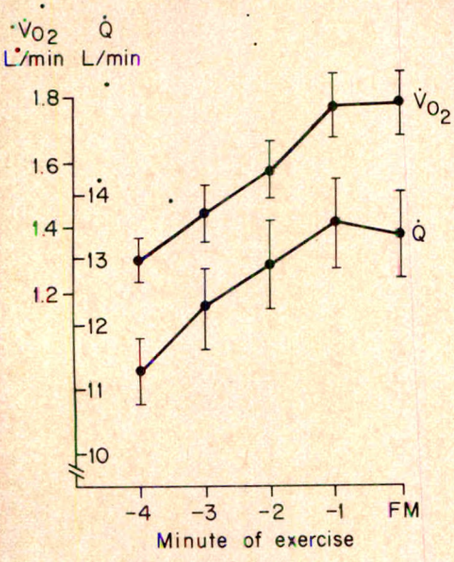

FIGURE 1 (left). Oxygen intake ($\dot{V}O_2$) and cardiac output ($\dot{Q}$) during exercise in patients with coronary artery disease. Plateau levels indicate maximal values. Mean values (liters/min) ±1 standard error are presented. FM = final minute of exercise.

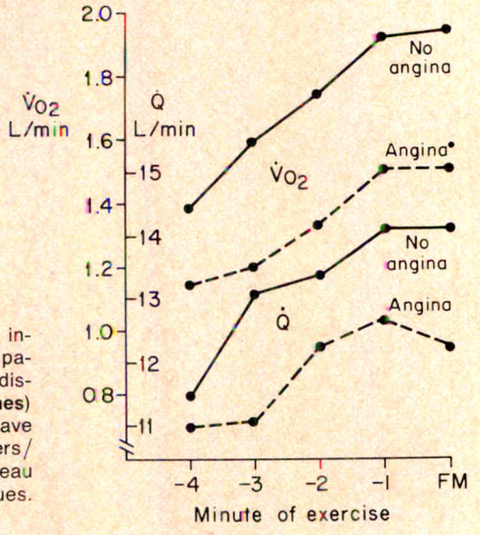

FIGURE 2 (right). Oxygen intake and cardiac output in patients with coronary artery disease who did (**broken lines**) and did not (**solid lines**) have angina. Mean values (liters/min) are presented. Plateau levels indicate maximal values. Abbreviations as in Figure 1.

ing exercise. Table II contains mean values for the various indexes of oxygen transport during the final minute of symptom-limited exercise and the preceding 4 minutes. The cardiac output and oxygen intake data are shown in Figure 1. Both indexes increased significantly during exercise until the final minute of exercise when both leveled off without further significant change (Table III). The data were analyzed further, comparing the results in patients with angina and those with healed myocardial infarction, patients given nitroglycerin sublingually immediately before exercise and those not so treated, and patients who experienced anginal pain during exercise and those who did not. All groups showed an increase of cardiac output and oxygen intake with increasing exercise and a leveling off of both variables during the final minute (Table IV). In one analysis (Fig. 2), the results of the 29 tests were divided into those of 11 patients who had anginal pain during exercise and 18 patients who did not. The results in both groups plateaued at the final minute of exercise, but the lower values in the group with chest pain reflected the greater impairment of oxygen transport in these patients.

Arteriovenous oxygen difference: Blood oxygen content data (Tables II and III, Fig. 3) demonstrated the marked changes in blood oxygen levels between the conditions of supine rest and maximal exercise. A slight but significant increase in systemic arterial oxygen content was associated with a marked reduction in pulmonary arterial oxygen, which reached a nadir of 47 ml/liter during the final minute of exercise. Progressive widening of the arteriovenous oxygen difference occurred with exercise up to a mean level of 134 ml/liter in the final minute.

Arterial pressures: During exercise, systemic pressure showed a marked increase during systole but only slight changes during diastole. Pulmonary arterial mean pressure also increased slightly during exercise. Pulmonary wedge pressures decreased significantly between the conditions of supine rest before exercise and the early supine recovery period (30 to 90 seconds after termination of exercise) (Table V).

TABLE IV

Mean Oxygen Intake and Cardiac Output in Patients with Coronary Artery Disease Classified According to Presence of Angina During Exercise, Prior Myocardial Infarction or Use of Nitroglycerin Before Exercise

	Oxygen Intake (liters/min)						Cardiac Output (liters/min)					
Minute of Exercise	AP (11)	No AP (18)	MI (8)	No MI (21)	NG (14)	No NG (15)	AP (11)	No AP (18)	MI (8)	No MI (21)	NG (14)	No NG (15)
Minus 4	1.148	1.383	1.584	1.184	1.228	1.361	10.99	11.46	13.06	10.67	10.79	11.75
Minus 3	1.194	1.594	1.806	1.306	1.361	1.519	11.02	13.09	14.21	11.59	11.55	13.03
Minus 2	1.332	1.737	2.006	1.420	1.479	1.672	12.26	13.37	14.61	12.32	12.50	13.37
Minus 1	1.502	1.916	2.228	1.584	1.637	1.899	12.71	14.08	15.24	12.87	13.08	14.03

Figures in parentheses indicate number of subjects. AP = angina pectoris during exercise; FM = final minute of exercise; MI = healed myocardial infarction; NG = nitroglycerin, 0.4 mg sublingually before exercise.

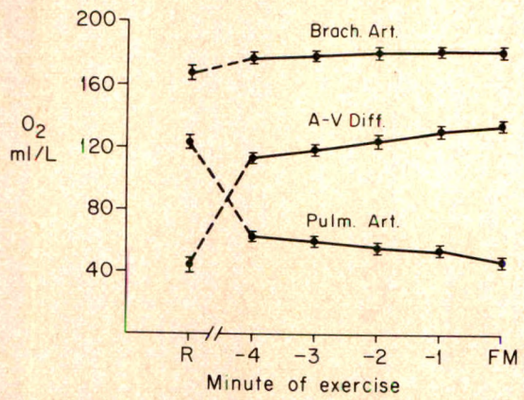

FIGURE 3. Blood oxygen content during exercise in patients with coronary artery disease. Mean values (ml/liter) ±1 standard error are presented. A-V Diff. = arteriovenous oxygen difference; Brach. Art. = brachial artery; FM = final minute of exercise; Pulm. Art. = pulmonary artery; R = rest.

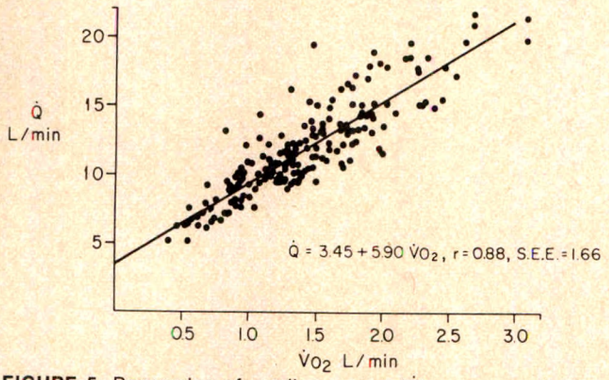

FIGURE 5. Regression of cardiac output ($\dot{Q}$) on oxygen intake ($\dot{V}O_2$) in 183 measurements obtained during exercise in patients with coronary artery disease. r = coefficient of correlation; S.E.E. = standard error of the estimate.

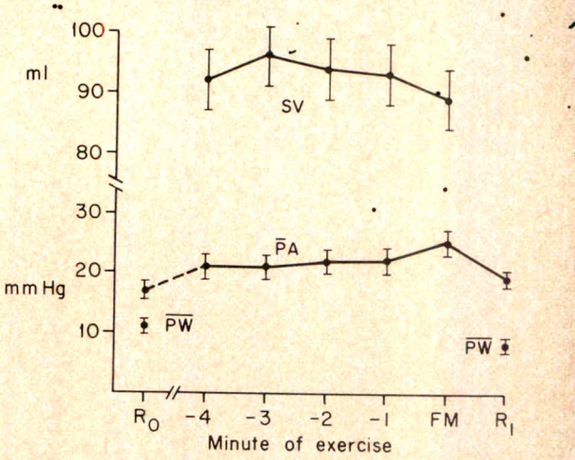

FIGURE 4. Stroke volume (SV) and mean pulmonary arterial pressure ($\bar{P}A$) during exercise in patients with coronary artery disease. Mean values ±1 standard error are presented. FM = final minute of exercise; $\overline{PW}$ = pulmonary wedge pressure; R_0 = rest; R_1 = early recovery.

Stroke volume: Stroke volume increased slightly but significantly between the conditions of supine rest and upright exercise. The differences in stroke volume were not significant with increasing exercise until the final minute, when a highly significant decrease in stroke volume occurred (Table III). The increase in mean pulmonary arterial pressure between the minute preceding the final minute of exercise (22 mm Hg) and the final minute (25 mm Hg) was also significant (t = 2.11, P <0.05). The sequential data on stroke volume and mean pulmonary arterial pressure are shown in Figure 4.

Regression and prediction: A regression analysis of cardiac output on oxygen intake was carried out for the 183 measurements made during exercise

TABLE V

Brachial and Pulmonary Arterial Pressures (means and standard deviations)

	Brachial Arterial Pressure (mm Hg)			Pulmonary Arterial Pressure (mm Hg)		
	Systolic	Diastolic	Mean	Mean	Wedge	HR × SBP

HR × SBP = product of heart rate and brachial arterial systolic pressure divided by 100.

(Fig. 5). The regression equation found for these patients with coronary artery disease was $\dot{Q} = 3.45 + 5.90\ \dot{V}O_2$ ($r = 0.88$, standard error of the estimate [SEE] = 1.66).

Predictors of maximal cardiac output are listed in Table VI. The maximal heart rate and double product of heart rate and maximal systolic pressure proved disappointing predictors. Test duration, although better, was not a good predictor. Maximal oxygen intake showed the highest correlation, but the high standard error precludes its use as a good predictor. Maximal stroke volume (SV_{max}), although somewhat better ($\dot{Q}_{max} = 1.91 + 0.13\ SV_{max}$ [$r = 0.87$, SEE = 1.83]), offers no advantage since it requires the measurement of cardiac output for its derivation.

TABLE VI

Predictors of Maximal Cardiac Output in Patients with Coronary Artery Disease

Predictor	Correlation Coefficient (r)
Maximal oxygen intake ($\dot{V}O_2$)	0.89*
Test duration	0.57
Maximal heart rate (HR max)	0.26
Product of HR max and maximal brachial arterial systolic pressure	0.22

* Maximal cardiac output = 2.52 + 6.09 $\dot{V}O_2$ max, standard error of the estimate = 3.68.

Discussion

In 1955, Taylor et al.[7] demonstrated the maximal oxygen consumption of normal subjects as a fundamental measure of circulatory performance. They combined increasingly strenuous treadmill exercise with serial measurements of oxygen intake and observed that the obligatory increase in oxygen consumption with increasing treadmill work reached a plateau that defined the capacity of the oxygen transport system and usually corresponded to subjective feelings of extreme exhaustion.

Similar patterns reflecting the maximal oxygen intake and maximal cardiac output were found for our patients with coronary artery disease. Maximal cardiac output occurred both in patients with angina and in those with healed infarction, and in patients who experienced anginal pain during exercise as well as those who did not.

The decreasing stroke volume and increasing pulmonary arterial pressure that occurred during the final minute of exercise would appear to reflect acute left ventricular impairment or failure, which is rapidly reversed during the initial seconds of recovery after exercise. Acute reduction in left ventricular performance thus seems to be the mechanism responsible for limiting the maximal cardiac output in these patients.

Comparison of normal men and those with coronary disease: Analysis of the regression of cardiac output on oxygen consumption is of interest when compared to findings in normal men of similar age. Granath et al.[8] using submaximal bicycle exercise found a value of $\dot{Q} = 3.01 + 6.00\ \dot{V}O_2$; whereas Grimby et al.[9] found the relation in nine endurance athletes to be $\dot{Q} = 8.3 + 5.2\ \dot{V}O_2$ and noted the higher intercept in physically trained than in untrained persons. The regression equation for men with coronary artery disease (Fig. 5) is nearly identical to that seen for normal men. One might have anticipated a smaller slope for the patients with coronary disease, reflecting more oxygen extraction to compensate for less cardiac output, and thus to conserve the work of the heart, but this was not so. It is there-

a–v O_2 = arteriovenous oxygen difference (ml/liter); Hgb = hemoglobin (g/100 ml); HR = heart rate (beats/min); NA = not available; $\dot{Q}$ = cardiac output (liters/min); SV = stroke volume (ml); Syst. Art. Press. (SDM) = systemic arterial pressure, systolic, diastolic, mean (mm Hg); $\dot{V}O_2$ = oxygen intake (liters/min); Wt = weight (kg).

fore reasonable to infer from these data that acute left ventricular dysfunction, which occurs in the final minute of exercise and limits the maximal cardiac output, is preceeded by a normal response of the cardiac output at all submaximal levels of exercise.

A further comparison of maximal oxygen transport variables is seen in Table VII.[9,10] Hemodynamic variables in normal men in two contrasting age groups selected to compare trained athletes with untrained average men are compared with data in men with coronary artery disease. Several of the contrasts are of interest. Male athletes, young or old, typically have a high level of stroke volume and cardiac output; in younger but not older athletes, the maximal arteriovenous oxygen difference can be widened in excess of 170 ml/liter, thus allowing a proportionately greater maximal oxygen consumption in younger athletes. Physically trained men also show less deterioration of the maximal oxygen intake with advancing age than untrained men.[11]

A 33 percent reduction of maximal cardiac output of men with coronary disease compared to findings in older untrained men is accounted for by a 25 percent reduction in maximal stroke volume and an 8 percent reduction in maximal heart rate. The maximal arteriovenous oxygen differences are similar.

Other hemodynamic studies of exercise in cardiac patients include several in subjects without coronary artery disease[12-15] and others using submaximal tests in patients with coronary disease.[16-19] Detry and Bruce[20] demonstrated the effect of nitroglycerin on increasing maximal oxygen intake, and Detry et al.[21] demonstrated significant improvement in maximal oxygen intake after exercise training in patients with coronary artery disease. Murray et al[22] performed graded treadmill exercise studies in five patients with severe angina, and noted abnormalities in oxygen transport, depressed cardiac output and stroke volume, and widened arteriovenous oxygen difference before the onset of angina. Blackmon et al.[23] studied hemodynamic responses to maximal exercise in patients with tight mitral stenosis.

Our study appears to be the first to present data on maximal cardiac output in patients with coronary artery disease. This is rather surprising since this variable is a sensitive and fundamental indicator of the degree of impairment resulting from coronary disease. The studies appear to be safe since no serious complications or sequellae (such as ventricular fibrillation or myocardial infarction) occurred during these 29 tests in patients with coronary artery disease or in 14 additional tests in other patients with cardiac disease and a few normal subjects.

UNIVERSITY COLLEGE OF MEDICINE LIBRARY

Effects of Submaximal Isometric Handgrip on Left Ventricular Size and Wall Motion

PHILIP LUDBROOK, MB, MRACP, MRCP (UK)
JOEL S. KARLINER, MD, FACC
ROBERT A. O'ROURKE, MD, FACC

San Diego, California

To evaluate the effects of sustained submaximal isometric handgrip exercise on the left ventricle in patients with previous myocardial infarction, we utilized the noninvasive techniques of radarkymographic video tracking, measurement of the left heart dimension and calculation of systolic time intervals to assess alterations in wall motion and left ventricular size and function during handgrip exercise performed at a tension level of 15 percent of maximal voluntary contraction. In 9 of 12 patients with dyskinesis or asynchrony at rest the mean amplitude and velocity of systolic outward movement increased during handgrip exercise ($P < 0.05$), whereas in 11 patients with initially hypokinetic areas mean amplitude and velocity decreased ($P < 0.05$); in 3 patients dyskinesis was produced de novo. In all 12 patients both amplitude and velocity decreased in areas of normal wall motion ($P < 0.05$); similar changes occurred in 5 normal control subjects. Alterations in systolic time intervals during handgrip exercise were variable, and no consistent patterns were observed in either patients or control subjects. In seven patients whose left heart dimension increased during handgrip exercise, wall motion abnormalities were more severe at rest than in the five patients whose left heart dimension decreased. The five control subjects showed a decrease in left heart dimension during handgrip exercise.

We conclude that the normal response to submaximal isometric handgrip exercise at 15 percent of maximal voluntary capacity is a decrease in left ventricular size and a reduction in both the amplitude and velocity of left ventricular wall motion. Furthermore, in patients with previous myocardial infarction sustained isometric handgrip exercise is a useful maneuver for the intensification or induction of left ventricular wall motion abnormalities. By contrast, no consistent alterations in systolic time intervals were observed during handgrip exercise either in normal subjects or in patients with previous myocardial infarction. Thus, systolic time intervals do not appear to be useful for evaluating the left ventricular response to submaximal handgrip exercise in individual patients.

Little information is available on alterations in left ventricular size and wall motion induced by submaximal handgrip exercise, although it would be desirable to have reliable, noninvasive methods for comparing the response of the left ventricle to a standardized stressful intervention in normal subjects and patients with heart disease. Accordingly, we evaluated the effects of sustained submaximal handgrip exercise on left ventricular wall motion, using radarkymographic video tracking for continuous analysis of the movement of selective segments of the left ventricular wall[1,2] in normal subjects and in patients with coronary artery disease. In addition, we assessed the influence of handgrip exercise on the external left heart dimension[3] and externally recorded systolic time intervals.

				Asynchrony	Mid lateral

Methods

Case material: Twelve patients (mean age 53.5 years, range 30 to 73) with documented myocardial infarction but no history of angina pectoris and five subjects without cardiovascular disease (mean age 41.6 years, range 35 to 69) were studied in the supine basal state between 8:00 AM and 12:00 noon (Table I).

In six patients receiving digoxin, the last dose was taken 48 hours before study. On the day of study, none of these patients had evidence of cardiac decompensation such as tachycardia, pulmonary rales or a third heart sound. In all six patients, digoxin had been given for treatment of disorders occurring in association with acute myocardial infarction: transient atrial arrhythmias (four patients), mild left ventricular dysfunction (mean pulmonary capillary wedge pressure 15 mm Hg) (one patient) and pulmonary rales and quadruple rhythm (one patient). None of these patients subsequently had been limited by exertional dyspnea while taking digitalis. One of the six patients had received three 10 mg doses of propranolol before administration of this drug was discontinued 36 hours before study. This time span was chosen so that propranolol, which has a half-life of 3.2 hours after oral administration,[4] would be completely dissipated at the time of study. Propranolol had been instituted for therapy of ventricular premature contractions first noted 5 months after infarction. No patient had been receiving either quinidine or procainamide before study. A base-line scalar electrocardiogram was recorded; arterial blood pressure obtained by cuff sphygmomanometer and heart rate were monitored throughout the procedure. No patient had systemic arterial hypertension or electrocardiographic evidence of left or right bundle branch block.

Wall motion video tracking: This procedure was performed as previously described[2,5] using the commercially available Biotronix Heart Motion Video Tracker. The frequency response of this device, tested by means of a generated sine wave display, decreased to 75 percent of maximal response at a frequency greater than 15 to 16 Hz. With use of a 23 cm image intensifier, the fluoroscopic cardiac image was displayed on a Plumbicon television camera and recorded on video tape for later analysis or tracked directly during fluoroscopy. The analog video signal also was recorded on a Honeywell Visicorder photographic system for subsequent data analysis. After a standard inspiration, recordings were made of the left ventricular free wall at selected high, mid and low sites in the posteroanterior and left anterior oblique projections. Inferior and posterior wall movements were similarly recorded in the left anterior oblique and left lateral projections. In each patient the amplitude and velocity of wall motion were calculated at these selected sites before and after each intervention (Fig. 1). For each value of amplitude and velocity in each patient the average of at least three beats in which satisfactory recordings were obtained was used. Correction of these values for heart rate did not significantly alter them. Abnormal wall motion was defined according to a modification of the terminology of Herman and Gorlin[6]: Dyskinesis was defined as paradoxical systolic expansion; asynchrony as disturbance of the temporal sequence of contraction, early inward movement being followed by late paradoxical expansion or vice versa; and hypokinesis as diminished wall motion (Table I).

Measurements of systolic time intervals: These determinations were made from simultaneous recordings of a high-frequency phonocardiogram, the indirect carotid arterial pulse and the electrocardiogram on a multichannel recorder (Elena-Schonander Mingograf) at a paper speed of 100 mm/sec. Calculations of mean intervals were derived from measurements of 10 satisfactorily recorded car-

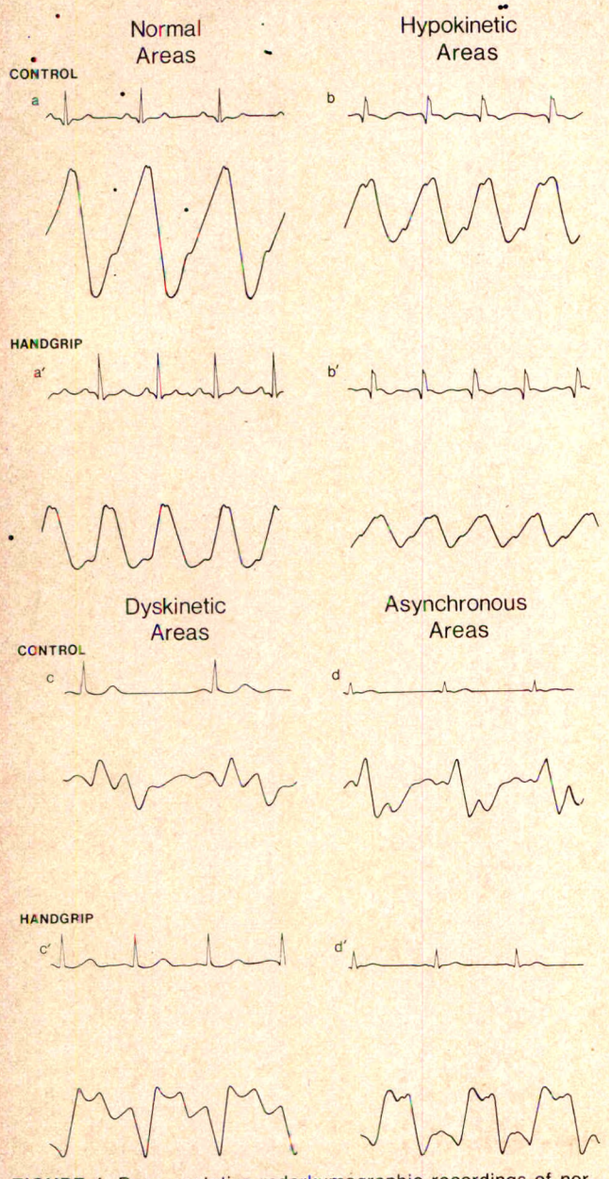

FIGURE 1. Representative radarkymographic recordings of normal **(a)**, hypokinetic **(b)**, dyskinetic **(c)** and asynchronous **(d)** areas of wall motion, before and during sustained handgrip exercise performed at a tension level of 15 percent of maximal voluntary contraction.

diac cycles. Observed time intervals were corrected for heart rate and sex according to the regression equations of Weissler et al.[7] and were expressed as indexes. The ratio of preejection period (PEP) to left ventricular ejection time (LVET) was obtained by dividing the observed preejection period by the uncorrected left ventricular ejection time since this ratio is independent of heart rate.[8]

Left heart dimension: This value was utilized as an index of left ventricular size[3] and was obtained by measuring the distance from the midline to the widest point on the left heart border on a standard chest roentgenogram exposed precisely at end-diastole by means of an electrocardiographic triggering device after a measured inspiration of 1,000 ml from functional residual capacity. It has previously been shown that the external left heart dimension correlates well with cineangiographic measurements of left ventricular cavity size.[3]

Isometric handgrip exercise: In the 12 patients and the 5 normal subjects control measurements were obtained of systolic time intervals, left heart dimension and amplitude and velocity of left ventricular wall motion at the selected sites indicated earlier. After giving informed consent, each subject was studied at the conclusion of a 3 minute period of sustained isometric handgrip exercise, performed at a tension level of 15 percent of the subject's previously determined maximal voluntary contraction, using a calibrated dynamometer.[9,10] In addition, 10 other normal subjects (mean age 34, range 25 to 42) had measurements of systolic time intervals before and at the end of a similar period of sustained handgrip exercise. Each patient was carefully instructed to avoid a Valsalva maneuver during the handgrip exercise.[10] No adverse effects such as angina pectoris or arrhythmias were noted during or after any of the studies.

Results

During handgrip, the average heart rate for the 12 patients increased by 18 percent from 63.8 ± 3.3 (standard error) to 75.4 ± 3.6 beats/min (P <0.001); in the 5 normal subjects, heart rate increased by 16.0 percent from 63.8 ± 5.2 to 74.0 ± 12.5 beats/min (P <0.01). In each patient systemic systolic arterial pressure increased by an average of 10 to 15 mm Hg during handgrip exercise.

Studies on left ventricular wall motion: In all 12 patients with coronary artery disease, some form of abnormal wall motion was observed in the base-line recording. In six patients who had sustained either isolated or combined anterior, lateral or apical infarction, areas of dyskinetic wall motion were recorded at those sites (Fig. 1c). In four patients prominent asynchrony was recorded, manifested by initial inward movement followed by early relaxation, and in three of these four a delayed paradoxical outward bulge followed the initial inward movement or vice versa (Fig. 1d). In 11 cases areas of hypokinesis were prominent (Fig. 1b).

Of nine patients who had either dyskinesis or asynchrony at rest, six demonstrated an increase in amplitude, and eight an increase in velocity of outward movement during handgrip. In three other cases, dyskinesis was produced de novo. For all of these nine patients the mean amplitude of outward dyskinetic movement increased during handgrip from 1.4 ± 0.31 to 2.2 ± 0.50 mm (68 percent increase, P <0.01) (Fig. 2), whereas mean velocity increased from 15.1 ± 2.7 to 18.4 ± 3.4 mm/sec (22 percent increase, P <0.05) (Fig. 3).

In initially hypokinetic areas observed in 11 patients, mean amplitude was reduced by 31 percent from 3.2 ± 0.42 to 2.2 ± 0.53 mm (P <0.01) and average velocity by 26 percent from 19.3 ± 3.1 to 14.2 ± 2.0 mm/sec (P <0.05) although an increased velocity was recorded in three patients (Fig. 2 and 3). Similarly, in areas of normal contraction noted in

each of the 12 patients, mean amplitude was reduced by 31 percent from 5.6 ± 0.53 to 3.9 ± 0.53 mm (P <0.01) and average velocity by 20 percent from 29.8 ± 3.9 to 23.9 ± 4.0 mm/sec (P <0.05) during handgrip (Fig. 2 and 3). However, in 3 of the 12 patients, velocity increased.

In the five normal subjects, the mean amplitude of wall motion was reduced by 34 percent from 6.3 ± 1.2 to 4.2 ± 0.3 mm (not significant), one subject demonstrating an increased amplitude. Mean velocity decreased by 51 percent from 57.4 ± 9.4 to 28.2 ± 2.02 mm/sec (P <0.05).

Studies on left ventricular size: Mean left heart dimension (uncorrected for body surface area) for all 12 patients increased during handgrip from 93.5 ± 12.6 (standard deviation) to 94.6 ± 13.2 mm (not significant); in the 5 normal subjects it decreased from 81.9 ± 2.67 to 79.5 ± 2.64 mm (P <0.05). However, in a subgroup of seven patients mean left heart dimension increased from 93.9 ± 14.4 to 97.7 ± 14.6 mm (P <0.005) while in the remaining five patients it decreased from 92.9 ± 10.5 to 90.26 ± 11.1 mm (P <0.01). Although initial heart size did not differ significantly in the two subgroups, in the seven patients whose left heart dimension increased wall motion abnormalities were notably more severe at rest, four displaying dyskinesis and the remaining three demonstrating severe diffuse hypokinesis or asynchrony, or both; in the five whose heart size decreased during handgrip, dyskinesis was observed in two and only mild hypokinesis was seen in the remaining three.

Studies on systolic time intervals: During handgrip mean preejection period index decreased in the 12 patients but this change was not significant (Fig. 4). There was no significant alteration in left ventricular ejection time index in the patient group. The average ratio of preejection period to left ventricular ejection time declined in the patient group, but this change was not significant.

In the 10 other normal subjects studied during handgrip exercise, mean preejection period index was unchanged (132.3 ± 4.6 to 131.1 ± 3.7 msec), 4 of the 10 values increasing, whereas left ventricular ejection time index increased in all cases, from a mean of 408.0 ± 4.0 to 422.1 ± 5.1 msec (P <0.001) (Fig. 4). Mean ratio of preejection period to left ventricular ejection time was reduced by 10 percent from 0.357 ± 0.013 to 0.323 ± 0.013, a change which was not significant since the same four subjects whose preejection period index rose after handgrip showed an increased value.

Discussion

Previous investigations of the effects of stressful interventions on the left ventricle have utilized measurements requiring invasive techniques such as cardiac catheterization. For example, abnormal left ventricular function curves have been observed in patients with coronary artery disease in response to sustained isometric handgrip exercise,[11] and atrial

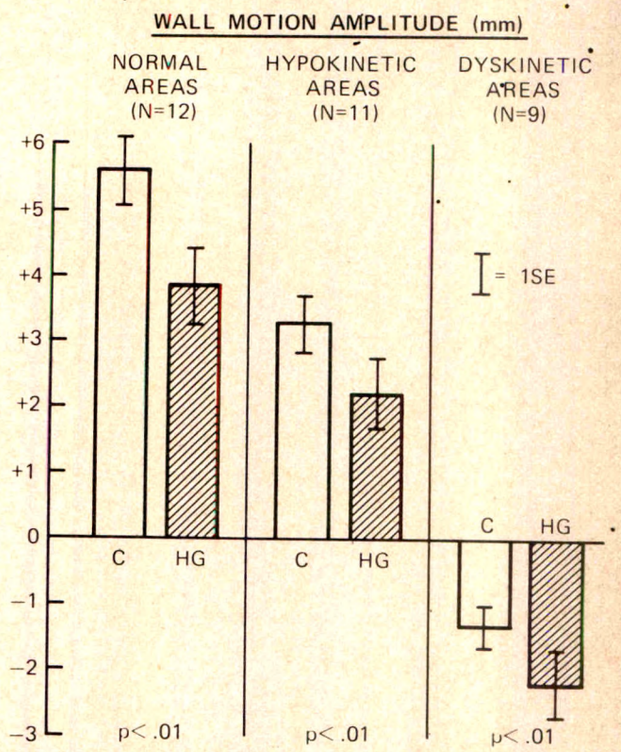

FIGURE 2. Average wall motion amplitude of normal and abnormal areas during control (C) measurements, and during sustained handgrip (HG) exercise. 1SE indicates 1 standard error of the mean.

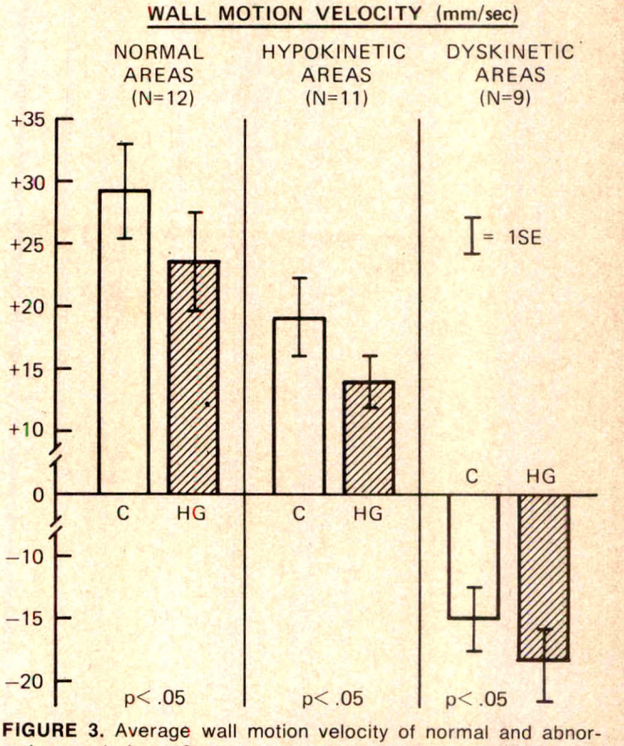

FIGURE 3. Average wall motion velocity of normal and abnormal areas before (C) and during sustained handgrip (HG). 1SE indicates 1 standard error of the mean.

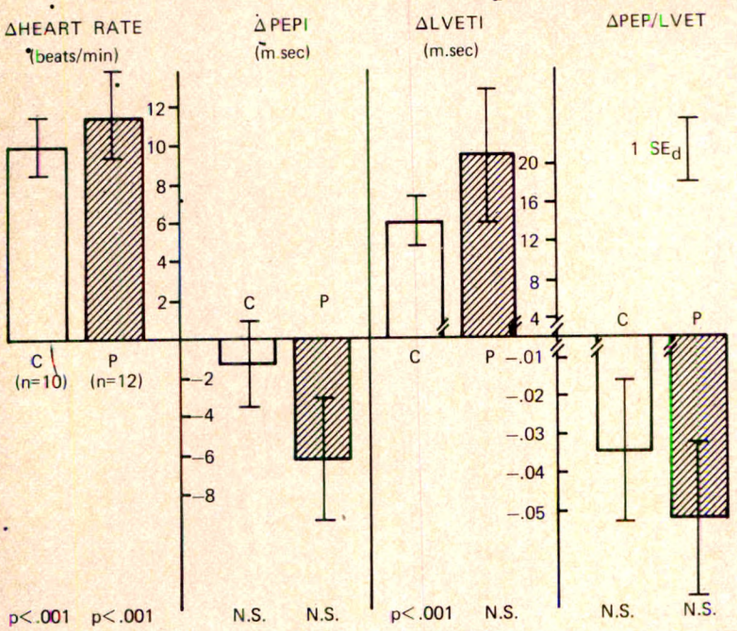

FIGURE 4. Changes (Δ) in heart rate, preejection period index (PEPI), left ventricular ejection time index (LVETI), and PEP/LVET during sustained handgrip in the 10 normal control subjects (C) and in the 12 patients (P). N.S. = not significant; SE_d indicates the standard error of the difference.

pacing during cardiac catheterization has been used to induce or exacerbate dyskinesis as evaluated by left ventriculography.[12] In this study we used three totally noninvasive methods, radarkymographic video tracking, measurement of the left heart dimension and calculation of systolic time intervals in order to assess the response of the left ventricle to a standardized stressful intervention in normal subjects and in patients with previous myocardial infarction.

Changes in wall motion: The results utilizing radarkymographic video tracking revealed that the normal response to submaximal isometric handgrip exercise is a reduction in both the amplitude and velocity of left ventricular wall motion. This reduction was observed in all locations in the normal subjects as well as in areas of normal wall movement in the patients with previous myocardial infarction. However, the response to handgrip in initially abnormal areas of wall motion was quite different. In six of nine patients the amplitude of initially paradoxical wall motion increased and, in three others, dyskinesis appeared de novo. These observations differ somewhat from those of Flessas et al.,[13] who noted only hypokinesis by cineangiography during handgrip in 8 of 10 patients with coronary artery disease. Our results correlate with the frequently observed appearance or accentuation of atrial gallop sounds[14,15] and the development of palpable precordial dyskinesis[15] during or after handgrip exercise. On the basis of these observations, serial noninvasive evaluation of dyskinetic areas after a standardized, stressful intervention is now possible. Prospective assessment of such areas before and after drug therapy and coronary revascularization procedures should provide useful information on the efficacy of such treatment.

Changes in left heart dimension: The normal response of the left heart dimension to handgrip exercise performed at a tension level of 15 percent of maximal voluntary contraction appears to be a reduction in heart size; this reduction was seen in all five control subjects. In the patients with coronary artery disease, the changes in heart size were variable. In the seven patients whose left heart dimension increased during handgrip, wall motion abnormalities were more severe and diffuse at rest and control heart size was slightly greater than in the five patients whose left heart dimension decreased. These observations suggest that in patients with severe wall motion abnormalities heart size tends to increase in response to isometric stress. This reaction is abnormal and may serve to increase myocardial oxygen consumption even further in these patients.

Mechanism of changes in left ventricular wall motion and size: Previous studies have indicated that the overall response to isometric exercise is complex and variable, depending in part on the age and cardiovascular status of the subject, and particularly on the level of tension maintained.[9,10,16] During handgrip performed at a tension level of 15 percent of maximal voluntary contraction, there is a progressive but slow increase in blood pressure, cardiac output and heart rate. Upon release of handgrip these measurements promptly return to control levels. At 20 to 30 percent of maximal voluntary contraction, blood pressure, cardiac output and heart rate continue to increase steadily during handgrip; upon release, these variables increase further.[9,10] Therefore, to prevent excessive myocardial oxygen

demand, we used a tension of 15 percent of maximal voluntary contraction.

At the level of submaximal handgrip exercise used in this study, there is little change in systemic vascular resistance or stroke volume in younger subjects. However, in older subjects, especially in those with cardiovascular disease, a significant increase in systemic vascular resistance[16] and a decrease in stroke volume is often observed. Each level of tension produces a different "steady state"; hence, minor differences in the fraction of maximal voluntary contraction maintained will produce significant differences in the degree to which these physiologic variables are affected. These considerations help to explain the variability of the observed changes in wall motion, heart size and systolic time intervals.

Thus, the wall motion changes induced by handgrip exercise in patients with coronary artery disease are the net result of several influences: (1) augmented myocardial contractility, mediated by the sympathetic nervous system[17]; (2) increased systemic vascular resistance, especially in older patients (these two factors result in increased intraventricular systolic pressure and increased outward distending force acting on the critical area) and; (3) increased myocardial oxygen consumption, presumably mediated by changes in systemic arterial pressure, heart rate and adrenergic influences.

The reduction in wall motion amplitude in normal areas that we observed during handgrip may simply be the result of decreased stroke volume and stroke excursion associated with tachycardia produced by the maneuver. Variable changes in heart size might also be expected after handgrip exercise for similar reasons, depending on the relative contributions made by sympathetic stimulation and increased systemic vascular resistance. These responses, particularly the latter, vary greatly from patient to patient.[9,10]

Systolic time intervals as index of left ventricular function: There is little information on the effect of sustained submaximal isometric handgrip exercise on systolic time intervals in patients with documented coronary artery disease. In our patients both preejection period index (PEPI) and the PEP/LVET ratio decreased during isometric exercise. However, the results were not uniform since increases in preejection period index occurred in four patients and a rise in the PEP/LVET ratio was observed in five patients. A similar variability was noted in the normal control subjects and is in accord with the observations of Frank and Haberern,[18] who concluded that left ventricular ejection time shortens with mild to moderate increase in arterial pressure and lengthens when the arterial pressure increases further. The inconsistent changes in left ventricular ejection time index, preejection period index and PEP/LVET observed in some of our patients are compatible with the wide spectrum of physiologic responses to handgrip mentioned previously. This is particularly true of the role of alterations in systemic vascular resistance and adrenergic influences reported by others in both normal and abnormal subjects.[9,10,17] Although mild or supine or upright exercise can induce abnormalities in systolic time intervals in patients with coronary artery disease, analyses of the changes in such intervals comparing rest with exercise using each patient as his own control have failed to provide an improved separation of patients with normal and those with abnormal hemodynamics.[19] Moreover, McConahay et al.[19] could not predict reliably minor abnormalities of left ventricular function in individual patients with coronary artery disease.

Our results differ somewhat from those recently reported by Siegel et al.,[15] who observed no significant alterations in preejection period index or PEP/LVET in patients with coronary artery disease undergoing maximal handgrip exercise. Thus, although systolic time intervals may not be useful in detecting minor abnormalities in left ventricular function at rest or after isotonic or isometric exercise, we have previously demonstrated[20] that serial assessment of such intervals in the same patient correlates well with changes in clinical status and in some instances may even precede deterioration of left ventricular function. Whether serial studies of systolic time intervals during isometric exercise stress in patients with coronary artery disease will prove useful requires further investigation.

Possible influence of previous drug therapy: Finally, the possible influence of previous drug therapy on our results requires consideration. Of the three patients who developed dyskinesis de novo, one was receiving no medication and two had been receiving digoxin. Of the seven patients whose left heart dimension increased, four had been taking digitalis and three had not. Of the five patients whose left heart dimension decreased during handgrip exercise, one had been receiving propranolol and digoxin, two had been taking digoxin alone and two had been receiving no medication. Two of the four patients who had an increased PEP/LVET ratio during handgrip exercise were receiving digoxin; in the eight patients who had a decrease in this ratio, four had received no prior medication, three had been taking digoxin and one digoxin and propranolol. Although it is likely that heart size, systolic time intervals and abnormalities of left ventricular wall motion would tend to be altered by acute congestive cardiac failure, all our patients appeared to have good compensation both clinically and hemodynamically at the time of study. Thus, previous medication appeared to produce no consistent effects, and our results can be attributed directly to the intervention of isometric handgrip exercise.

The hemodynamic effects of phentolamine (Regitine) were evaluated in nine patients with increased left ventricular filling pressure and clinical left ventricular failure (Group A) and five patients with normal left ventricular filling pressure and an uncomplicated course (Group B) within 48 hours of an acute myocardial infarction. Decreased afterload was noted in both groups after administration of phentolamine. Improved left ventricular performance was noted only in Group A and was manifested by a decrease in left ventricular filling pressure (from 23.9 to 13.6 mm Hg), increase in cardiac index (from 2.1 to 2.9 liters/min per m^2), increase in stroke volume index (from 22.5 to 29.3 cc/beat per m^2), and little change in heart rate (from 94.2 to 99.8 beats/min). In contrast, a decrease in stroke volume index (32 to 26 cc/beat per m^2) and a greater increase in heart rate (77 to 94 beats/min) were noted in Group B. Reduction of preload, which accompanies a reduction in afterload with administration of phentolamine, may have caused a greater decrease in end-diastolic volume in Group B, resulting in the reduced stroke volume index and compensatory increase in heart rate. Our findings suggest that afterload reduction induced by administration of phentolamine enhances depressed left ventricular function in patients with increased left ventricular filling pressure after myocardial infarction. Careful monitoring to prevent complications is required.

Treatment of impaired left ventricular function after an acute myocardial infarction often presents a therapeutic dilemma. Traditionally, severe left ventricular dysfunction, manifested by decreased cardiac output or pulmonary venous congestion, or both, has been treated with inotropic or diuretic agents. Inotropic agents such as digitalis have been reported to cause little change in cardiac hemodynamics in acute infarction,[1,2] and recent experimental data suggest that they may increase the area of myocardial ischemia.[3] Diuretic agents, although effective in reducing pulmonary venous congestion, do not enhance left ventricular performance.[4]

Agents that reduce afterload have significant effects on ischemic heart disease. Thus, sodium nitroprusside, an agent that causes peripheral vasodilatation, has enhanced left ventricular performance in patients with acute myocardial infarction,[5] and phentolamine (Regitine®), which also reduces afterload, has been reported effective in treating chronic refractory heart failure.[6] Phentolamine has also been said to have a positive inotropic effect that might be beneficial in some circumstances. In this study we evaluated the hemodynamic effects of phentolamine in acute myocardial infarction to assess the potential clinical application of this drug.

CI = cardiac index (liters/min per m²); HR = heart rate (beats/min); LVFP = left ventricular filling pressure (mm Hg); MAP = mean arterial pressure (mm Hg); MPAP = mean pulmonary arterial pressure (mm Hg); NS = not significant; Post = after administration of phentolamine; Pre = before administration of phentolamine; PVR = peripheral vascular resistance (dynes sec cm^{-5}); SEM = standard error of the mean; SVI = stroke volume index (cc/m²); SVR = systemic vascular resistance (dynes sec cm^{-5}); SWI = stroke work index (g-m/beat per m²).

Material and Methods

Fourteen studies were performed in 13 patients (3 women and 10 men, aged 42 to 73 years) with historical, electrocardiographic and laboratory evidence of an acute myocardial infarction within 48 hours of the onset of symptoms (Table I). Infarction was located in the anterior wall in nine patients and in the inferior wall in three; an additional patient had only historical and enzyme evidence of acute myocardial infarction. Two patients had cardiogenic shock at the time of the study, nine had clinical manifestations of left ventricular failure with physical and radiologic signs of pulmonary venous congestion, and four had clinically uncomplicated infarction. One patient (Cases 3 and 14, Table I) was studied twice, once when he had signs of pulmonary venous congestion and again when he was free of congestion. Phentolamine was administered intravenously by a constant infusion pump (Harvard) over a 1 hour period in all patients. A dose of 5 mg was administered in the first minute; then an infusion rate was selected that would decrease left ventricular filling pressure significantly or reduce mean arterial pressure by approximately 20 mm Hg. In several mildly hypotensive patients the initial bolus dose was not given. The actual infusion rate ranged from 0.1 to 2 mg/min; the usual rate required was 0.5 to 1 mg/min. After control measurements were obtained, data were recorded 5, 15, 30 and 60 minutes after infusion.

Arterial pressure (AP) was measured directly through a 20 gauge cannula inserted in the radial artery. Right atrial (RA), pulmonary arterial (PA) and pulmonary capillary wedge (PCW) pressures were recorded at the bedside through a balloon-tipped triple lumen catheter. Cardiac output (CO) was measured by the thermodilution technique with the same catheter.[8]

Derived hemodynamic variables were calculated as follows: stroke volume index (SVI) = SV/BSA (cc/m^2); stroke work index (SWI) = SVI × $\overline{AP}$ × (0.0144) (g-m/m^2); systemic vascular resistance (SVR) = 80($\overline{AP}$ − RA)/CO (dynes sec cm^{-5}); and pulmonary vascular resistance = ($\overline{PA}$ − PCW/CO) × 80 (dynes sec cm^{-5}) where SV = stroke volume, BSA = body surface area and 0.0144 and 80 are conversion factors.

Results

The hemodynamic results in all patients are summarized in Table I. The post-phentolamine values listed represent the maximal response to the drug. These responses were usually observed after administration of the first 5 mg dose and were then maintained over the 1 hour period of infusion. In several cases the initial response was assessed as inadequate, and the infusion rate was increased until an adequate response was elicited.

The response in all 14 studies in the 13 patients was characterized by a decrease in left ventricular filling pressure, mean arterial pressure and systemic and pulmonary vascular resistance levels. However, improved left ventricular performance was noted only in patients whose left ventricular filling pressure (pulmonary capillary wedge or pulmonary arterial end-diastolic pressure) was initially increased. Nine patients had an initial left ventricular filling pressure greater than 15 mm Hg and were classified in Group A. They demonstrated an increase in stroke volume with a concomitant significant decrease in left ventricular filling pressure (Fig. 1). Cardiac index increased in all nine patients. In seven of these nine patients there was no significant change in heart rate.

In two patients, who also had the greatest decrease in mean arterial pressure, heart rate increased by 25 and 26 beats/min, respectively. The changes noted in calculated stroke work index were not consistent because of the variable decrease in mean arterial pressure. In contrast, although the five patients with a normal initial left ventricular filling pressure (Group B) also showed a reduction in left ventricular filling pressure, the stroke volume was reduced during drug infusion (Fig. 1). An increase in heart rate was also noted in four of these five patients.

Discussion

Our study demonstrates that effective left ventricular performance can be significantly improved by administration of phentolamine in patients with depressed left ventricular function and pulmonary vascular congestion due to an acute myocardial infarction. This improvement was indicated by prompt re-

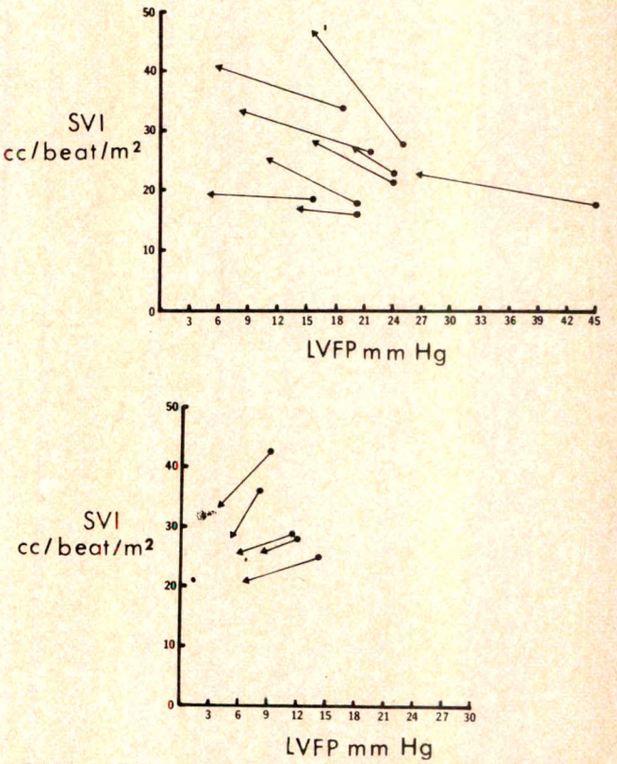

FIGURE 1. Effect of afterload reduction with phentolamine in nine patients with increased left ventricular filling pressure (LVFP) (**top panel**) and five patients with normal filling pressure (**bottom panel**) after acute myocardial infarction. An increase in stroke volume index (SVI) (mean change 6.8 cc [+30 percent]) and decrease in left ventricular filling pressure (mean change 10.3 mm Hg) was noted in all patients with an initially increased filling pressure. In contrast, all patients with an initially normal filling pressure had a further decrease in this variable (mean change 4.8 mm Hg) and an associated decrease in stroke volume index (mean change 6 cc [−18 percent]).

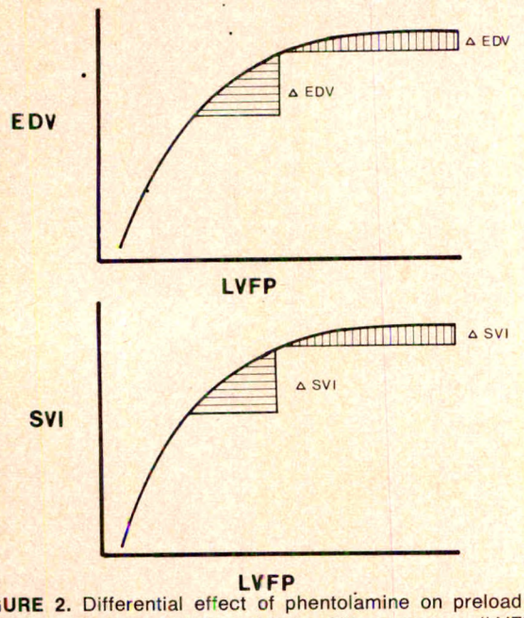

FIGURE 2. Differential effect of phentolamine on preload with normal and increased left ventricular filling pressure (LVFP): a hypothesis. Left ventricular compliance, shown in the **top panel** as end-diastolic volume (EDV) on the vertical axis and left ventricular filling pressure on the horizontal axis, is assumed to be equal for both groups and unchanged by pharmacologic intervention. Reduction of an increased filling pressure to normal (**vertical bars**) is associated with a minimal change in end-diastolic volume with a resultant minimal change in stroke volume index (SVI). In contrast, decrease of a normal filling pressure to a lower value (**horizontal bars**) is associated with a much larger decrease in end-diastolic volume and a concomitant large decrease in stroke volume index. This greater reduction in stroke volume index may be sufficient to counterbalance any increase in this variable due to an increased ejection fraction associated with afterload reduction.

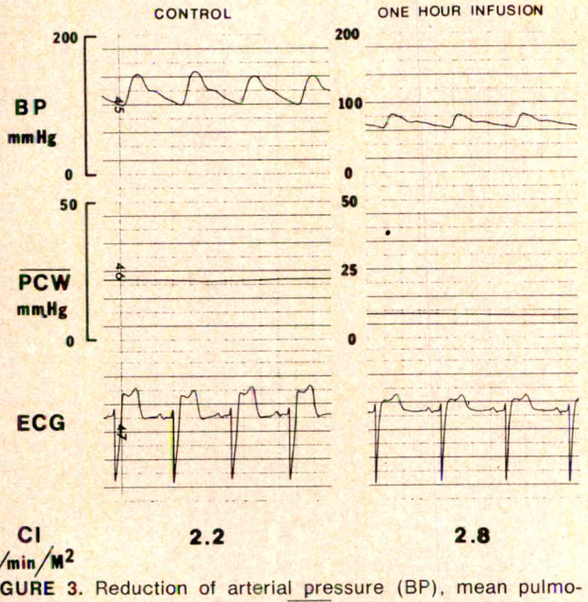

FIGURE 3. Reduction of arterial pressure (BP), mean pulmonary capillary wedge pressure ($\overline{PCW}$) and current of injury on the electrocardiogram (ECG) during phentolamine infusion in acute myocardial infarction. CI =. cardiac index.

duction in left ventricular filling pressure and a concomitant increase in stroke volume. The reduction in left ventricular filling pressure was probably related both to an increase in venous capacitance[9] and to an increase in ejection fraction due to the reduced afterload. Similar improvement in left ventricular performance has been reported after administration of nitroprusside.[5] However, in our patients with normal left ventricular filling pressure, administration of phentolamine resulted in reduced stroke volume, concomitant tachycardia and a further decrease in left ventricular filling pressure.

Mechanisms of hemodynamic effects of phentolamine: The precise mechanism of these disparate hemodynamic responses is not clear, but the interaction of changes in afterload and preload may be partly responsible (Fig. 2). Reduction in afterload decreases impedance to left ventricular ejection, which in turn increases stroke volume. In contrast, reduction in preload to values substantially less than 15 mm Hg decreases stroke volume as a result of shorter end-diastolic fiber length. In our study changes in end-diastolic volume could not be measured directly and could only be inferred from the measured changes in left ventricular diastolic pressure, extrapolated to the curvilinear relation between left ventricular diastolic pressure and volume.[10] In the presence of increased left ventricular end-diastolic pressure, a reduction in preload to 15 mm Hg will presumably cause only a small decrease in diastolic volume, and the reduction in stroke volume due to decreased preload will be small. The concomitant reduction in left ventricular impedance caused by phentolamine may therefore result in a significant increase in stroke volume. In contrast, if left ventricular filling pressure is initially normal, a further reduction of this variable is associated with a greater decrease in end-diastolic volume. In turn, this decrease may cause a reduction in stroke volume, which may be greater than the increase expected from reduction of afterload. The net result may be reduction in stroke volume with a compensatory increase in heart rate.

Other pharmacologic effects of phentolamine: Although the major factors in the hemodynamic improvement noted appear to be related to the interactions between altered afterload and preload, other pharmacologic effects of phentolamine may also be active. Enhanced release of insulin or reversal of catecholamine-induced suppression of insulin, which may enhance aerobic myocardial metabolism, has been described.[11] Inhibition of the bronchoconstriction noted after administration of histamine has been documented and may decrease airways resistance noted during periods of left ventricular failure.[12] Several investigators have claimed that phentolamine has a direct positive inotropic effect on the heart. However, Rabinowitz et al.[13] in a recent study utilizing the isolated cat papillary muscle, demonstrated no direct positive inotropic effect of phentolamine on the myocardium and found no evidence of

an indirect effect produced by release of catecholamines. They also noted that phentolamine had no effect on the adenyl cyclase activity of the myocardium, suggesting that there were no direct effects on the beta receptor. Nevertheless, the tachycardia produced in some of our patients suggests that there was a reflex increase in sympathetic tone, related to a reduction in intravascular pressure.

Clinical implications: The documented immediate improvement in left ventricular pump function in patients with acute myocardial infarction after administration of phentolamine has potential long-term benefits. Reduction in both preload and afterload without change in heart rate or inotropic state should result in a decrease in myocardial oxygen demand. Such an effect could reduce ultimate infarct size and, by relieving myocardial ischemia in peripheral zones, further improve ventricular performance. In one of our patients a decreased amplitude of the current of injury on the electrocardiogram was noted after 60 minutes of phentolamine infusion (Fig. 3) although it cannot be stated whether this was related to the effect of phentolamine or was coincidental. However, recent experimental data have demonstrated that in the depressed, infarcted heart an increase in afterload exacerbates ischemic injury.[14] The electrocardiographic changes we observed are consistent with these data.

Precautions during phentolamine infusion: Because our study was designed to assess the short-term hemodynamic effects of phentolamine in acute myocardial infarction, serial hemodynamic measurements were not carried out beyond 1 hour. However, in two patients infusion was continued beyond 1 hour and, in both patients, periodic adjustment of the infusion rate was required to maintain the hemodynamic response. The dose of phentolamine was then gradually reduced, and the drug was discontinued as base-line hemodynamics and clinical status improved. There was no evidence of tachyphylaxis or delayed adverse response.

Although no adverse reactions occurred after administration of phentolamine in our patients, it is pertinent to note that our studies were performed in a setting in which it was possible to monitor left ventricular filling pressure, systemic arterial pressure and cardiac output. Since patients with a normal left ventricular filling pressure derive no benefit from afterload reduction, it is mandatory to measure this variable before administering drugs that may decrease afterload. Careless administration of such agents may reduce arterial pressure precipitously to a level at which adequate coronary perfusion might not be maintained. In such circumstances, left ventricular function may be seriously depressed as a result of increased myocardial ischemia. Continuous monitoring of left ventricular filling pressure and arterial pressure is thus a prerequisite for determining the appropriate rate of administration of these afterload-reducing agents; otherwise an apparently beneficial therapeutic agent may turn out to be a hazardous one.

GUMERSINDO BLANCO, MD
ALBERTO ADAM, MD
BERNARD L. SEGAL, MD, FACC

Philadelphia, Pennsylvania

The results of direct myocardial revascularization using aortocoronary artery saphenous vein bypass grafting in 100 consecutive patients with ischemic heart disease are evaluated. Twelve patients died at operation or early thereafter. Of 88 patients surviving, 72 had severe angina pectoris before operation, 15 had moderate angina and 1 mild angina. After operation, only 10 patients had severe angina, 6 had moderate angina and 72 were free of angina. Thirty-seven patients underwent an exercise stress test in the upright position using a bicycle ergometer 3 to 5 days before operation. Angina pectoris developed in 33 patients during exercise and was accompanied by significant S–T segment depression. The exercise study was terminated in four patients who experienced shortness of breath. Three to four months postoperatively, 20 of these 37 patients underwent exercise at similar and higher work load levels. No pain or S–T segment depression was noted in 18 of the 20 patients. Two of the 20 patients had positive exercise responses similar to their preoperative responses. Seventeen of the 37 patients did not undergo exercise testing after operation: Four died; eight showed clinical improvement but were not available for repeat exercise studies; the remaining five showed no clinical improvement and did not undergo repeat exercise studies.

Left ventricular function was determined by measuring ejection fraction and mean velocity of circumferential fiber shortening per circumference in 51 patients. The preoperative ejection fraction of patients who manifested clinical improvement after operation was greater than that of patients whose condition did not improve; however, there was considerable overlap of data.

The success or failure to achieve a good clinical result correlated with flow through the bypass, measured at the time of operation. Flow through the saphenous bypass was directly related to the state of the distal coronary arterial system.

Direct myocardial revascularization by aortocoronary artery saphenous vein bypass grafting has been developed successfully by Favaloro et al.,[1] Johnson et al.[2] and others[3–7] in the past several years. This method of direct myocardial revascularization has gained wide acceptance and is being used in many medical centers. Regrettably, since the reported clinical results have not been analyzed in detail, the criteria for selection of patients are not well established.

This report describes (1) clinical results of coronary artery bypass surgery immediately and 4 to 12 months after operation, (2) determination of flow established through the bypass graft and the relation of flow to the status of the distal coronary arteries determined by coronary arteriography, and (3) determination of left ventricular function before surgery and its relation to the clinical results after coronary artery bypass surgery.

Clinical Material and Methods

From April to October 1971, a total of 100 consecutive patients received single or multiple aortocoronary artery bypass vein grafts at the Hahnemann Medical College and Hospital. There were 88 men, whose ages ranged between 31 and 65 years (average age 49 years). The 12 women were 38 to 65 years of age (average age 52 years). Before operation, all patients were evaluated clinically and subjected to left heart hemodynamic studies including left cineventriculography and selective coronary cinearteriography. Angina pectoris was the most prominent and frequent symptom, and was graded mild, moderate or severe. Angina was considered mild if it occurred with severe and vigorous effort, moderate if it occurred during routine and sedentary activities, and severe when it occurred with minimal effort or at rest. The patients with severe angina did not respond satisfactorily to medical therapy, and aortocoronary bypass surgery was performed. Those with mild or moderate angina were subjected to surgery on the basis of significant obstructive lesions demonstrated by coronary arteriography.

Left ventricular function was determined from the left cineventriculogram. Ejection fraction[8] and mean velocity of circumferential fiber shortening per circumference[9] were also measured in 51 patients. The left ventriculogram was obtained in the right anterior oblique projection. The silhouette of the left ventricular cavity was drawn in outline at the end of diastole and at the end of systole. The long axis of the left ventricle was measured from the aortic cusp to the left ventricular apex. The minor diameter of the left ventricular circumference was measured from each outline drawing perpendicular to and at the midpoint of the long axis. The left ventricular end-diastolic and end-systolic volumes were calculated by the following formula:

$$\pi/6 \times L \times D^2(CF)^3$$

where L is long axis, D is the minor diameter and CF is the X-ray magnification factor. Stroke volume was found by subtracting end-systolic from end-diastolic volume. The ejection fraction was calculated from the systolic volume divided by the end-diastolic volume. The mean velocity of circumferential fiber shortening per circumference at the minor diameter was calculated by the following formula and is expressed in centimeters per seconds:

$$\pi D - \pi D_1/SEP \times \pi D \text{ or } D - D_1/SEP \times D$$

where SEP is the systolic ejection period and D_1 is the minor diameter at end-systole. The cine magnification factor was obtained from the image of the Lehman catheter diameter divided by the actual diameter of the catheter. The coronary arteriograms were obtained by the Sones technique. Distal runoff was termed good when the distal arteries beyond the major proximal obstructive lesions appeared normal or showed only minimal luminal irregularities. Distal runoff was termed poor when the lumen of the distal arteries beyond the major proximal obstructive lesions was compromised by at least 30 percent or more, with significant diffuse luminal narrowing.

Graded exercise stress tests were performed by 37 patients in an upright position using a bicycle ergometer. Each patient started at a work load of 25 watts; every three minutes the work load was increased by 25 watts. The patients rested for 10 minutes after each six minute exercise period. Exercise was terminated with the occurrence of (1) chest pain associated with S–T segment depression of at least 0.5 cm, or (2) severe shortness of breath. After operation, 20 of these patients underwent repeat exercise tests performed in the same manner.

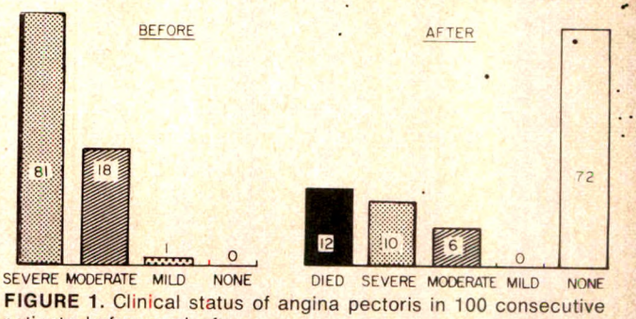

FIGURE 1. Clinical status of angina pectoris in 100 consecutive patients before and after aortocoronary artery saphenous vein bypass graft surgery.

The graft blood flow at operation was measured with a North Carolina electromagnetic flowmeter in 86 aortocoronary grafts in 50 patients. The measurements were made at the termination of cardiopulmonary bypass and at least 5 to 10 minutes after stabilization of blood pressure and heart rate. All patients had sinus rhythm. The probes were precalibrated by means of both blood and saline solution flowing through a segment of the femoral artery of a dog. The size of the probes used was determined by the size of the bypass vein graft. Average flow was calculated from at least two measurements from each bypass.

Results

Clinical Response: Angina Pectoris

The effects of aortocoronary artery saphenous vein bypass grafting on angina pectoris are shown in Figure 1. Of the 88 patients who survived operation, 72 became symptom-free. The patients were classified in five groups to permit further analysis of the results of surgery in relation to the number of vessels diseased and bypassed (Fig. 2).

Group I: In this group (14 patients) with single vessel disease and one bypass, all survived. Angina

pectoris was not alleviated in two patients, both women; both had occlusion of the graft and deterioration of ventricular function, as shown by postoperative cineangiography. In both women, the bypass was made to the left anterior descending coronary artery and there was good distal runoff. The flow through the graft in one patient was 160 cc/min. Of the remaining 12 patients in this group whose condition improved, 8 had a single bypass to the left anterior descending artery, 1 had a bypass to the circumflex artery and 3 had a bypass to the right coronary artery.

Group II: In this group of 54 patients with two vessel disease and two bypasses, 5 patients had no alleviation of angina and all 5 had poor distal runoff postoperatively. One of these five patients had an acute anteroseptal myocardial infarction 4 weeks after operation. Upon restudy, we found that the proximal obstructive lesion of the left anterior descending artery had progressed to complete occlusion and that the bypass graft to the vessel was also occluded. In this group of 54 patients, 6 died, 3 in the operating room after prolonged cardiopulmonary bypass and 2 within 24 hours because of massive myocardial infarction; 1 died 5 days after operation. Autopsy study showed that the latter patient had an occlusion of the graft to the left anterior descending coronary artery. The three patients who died after operation had poor distal runoff demonstrated by arteriography.

Group III: In this group of eight patients with two vessel disease but only one bypass, bypass to the other artery could not be accomplished because of diffuse disease involving its distal portion. Four patients manifested clinical improvements, and four did not. The four patients without angina had good distal runoff. The four patients who continued to experience angina had poor distal runoff of the bypassed vessel.

Group IV: Of this group of nine patients with three vessel disease and three bypasses, four patients died, one in the operating room after prolonged bypass, and three from postoperative acute anteroseptal wall infarction. Angina was alleviated in the five patients who lived. Two of the four patients who died had poor distal runoff demonstrated by arteriography.

Group V: Of this group of 15 patients with three vessel disease and two vessels that could be bypassed, 5 had no alleviation of angina and 2 died. All five patients whose condition did not improve also had poor distal runoff. Of the two who died, one had poor runoff and one died with pump failure associated with acute anteroseptal wall infarction.

Mortality and Prevalence of Myocardial Infarction

Deaths: Twelve of the 100 patients did not survive (Table I). Three patients died in the operating room during prolonged cardiopulmonary bypass. Autopsy in these cases disclosed patency of the saphenous vein bypass grafts, no evidence of acute myocardial infarction, and pulmonary edema due to "pump" failure. Seven other patients died with cardiac failure within 24 hours after operation; autopsy was performed in five of these. Acute anteroseptal myocardial infarction was found in all five; the saphenous vein bypass graft to the left anterior descending artery was patent, but the runoff was poor as demonstrated by arteriography and at necropsy. Another patient died 5 days postoperatively with ventricular fibrillation. At autopsy an acute anteroseptal myocardial infarction was found; the bypass graft to the left anterior descending coronary artery was patent but the distal runoff of this vessel was poor. One patient died 11 days after operation. Autopsy demonstrated a thrombus in the bypass graft

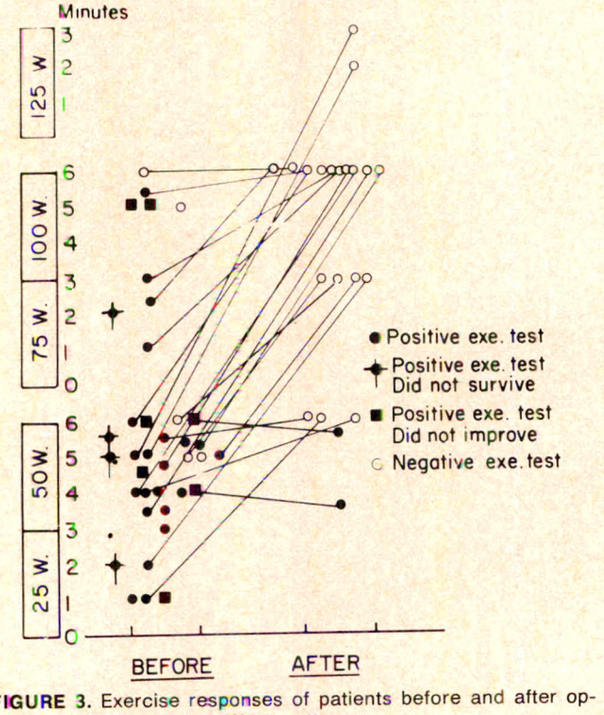

FIGURE 3. Exercise responses of patients before and after operation. exe. = exercise; W. = watts.

to the left anterior descending artery, poor distal runoff of this artery and anterior wall myocardial infarction. Thus, autopsy was performed in 10 of the 12 patients who died, and acute myocardial infarction was the cause of death in 7 of these 10.

Surviving patients: The 88 patients who survived were followed up for 4 to 12 months. Ten patients had electrocardiographic patterns of myocardial infarction within 24 hours after operation; of these 10 patients, 3 manifested clinical improvement and the remaining 7 showed no improvement and persistent angina pectoris. Postoperative coronary arteriography was not performed. The seven patients with persistent angina had poor distal runoff.

Two additional patients had an anteroseptal wall myocardial infarction and clinical deterioration 6 to 12 weeks after operation. The postoperative coronary arteriogram in these patients revealed (1) progression of the proximal obstructive lesions to complete obstruction of the left anterior descending artery; and (2) occluded bypass grafts to this artery. The prevalence rates for postoperative myocardial infarction in the 88 surviving patients were 11 percent for early infarction and 2 percent for delayed infarction (Table I).

Exercise Tolerance

Thirty-seven patients were studied by graded exercise stress tests before operation; 33 had angina pectoris and S–T segment depression of at least 0.5 cm during exercise, and four patients experienced only shortness of breath. Three to 4 months after operation, only 20 patients underwent repeat exercise testing; 18 had a negative response to exercise at a work load similar to or greater than the preoperative work load; 2 had a positive response postoperatively at a level similar to that of the preoperative work load. Seventeen of the 37 patients did not undergo exercise testing after operation: 4 died; 8 with a previous positive exercise study showed improvement after operation but were not available for repeat exercise studies; the remaining 5 patients in this group had recurrent angina pectoris and did not undergo repeat exercise studies (Fig. 3).

Clinical Results in Relation to Flow and Ventricular Function

Ventricular function: Ejection fraction and mean velocity of circumferential fiber shortening per circumference before operation were correlated with the presence or absence of angina pectoris after operation. The ejection fraction of patients whose condition improved ranged from 28 to 75 percent (average 54 ± 11.5 percent [standard deviation]). The ejection fraction of patients who did not show improvement or who died ranged from 10 to 78 percent (average 46 ± 15.5 percent). The difference between ejection fractions in these two groups was significant (P value = 0.05) (Fig. 4). One patient with severe impairment of left ventricular function, as manifested by an ejection fraction of 10 percent, had severe diffuse disease of all three coronary arteries; he did not survive. The mean velocity of circumferential fiber shortening per circumference of patients whose condition improved ranged from 0.37 to 1.47 cm/sec (average 0.89 ± 0.26). The mean velocity of circumferential fiber shortening per circumference of patients who had no improvement or who died ranged from 0.1 to 1.58 cm/sec (average 0.79 ± 0.26). The difference between these two groups was not significant (Fig. 4).

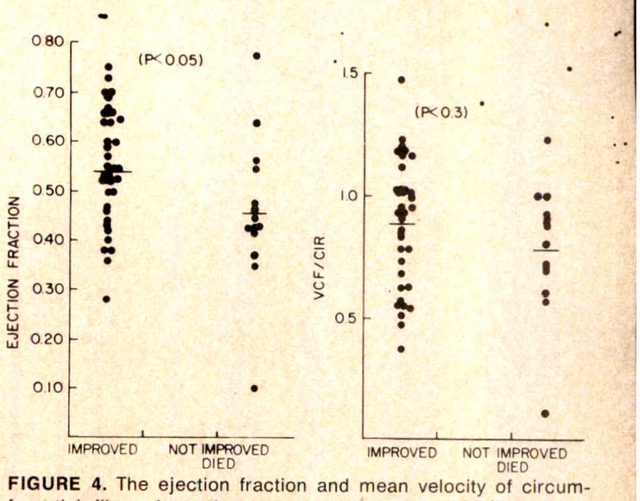

FIGURE 4. The ejection fraction and mean velocity of circumferential fiber shortening per circumference (VCF/CIR) measured in 51 patients preoperatively.

Bypass graft flow: Flow was measured from 86 saphenous vein grafts in 50 patients (Fig. 5). Flow through the bypass to the left anterior descending coronary artery ranged from 20 to 160 cc/min (average 70 ± 38.8 cc) when runoff was good and from 20 to 35 cc/min (average 25 ± 6.1) when runoff was poor. The difference was significant (P value =

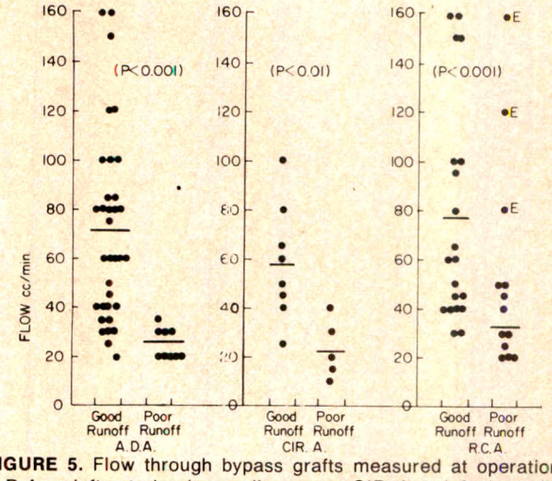

FIGURE 5. Flow through bypass grafts measured at operation. A.D.A. = left anterior descending artery; CIR. A. = left circumflex artery; E = endarterectomy, then bypass graft; R.C.A. = right coronary artery.

0.001). Flow through the bypass graft to the circumflex artery ranged from 25 to 100 cc/min (average 58 ± 23.7) when runoff was good, and from 10 to 40 cc/min (average 23 ± 12) when runoff was poor. This difference was significant (P value = 0.01). Flow through the bypass to the right coronary artery ranged from 30 to 160 cc/min (average of 77 ± 45) when runoff was good, and from 20 to 50 cc/min (average 33 ± 12.3 cc/min) when runoff was poor. This difference was significant (P value = 0.001). In three patients who had poor runoff and who underwent endarterectomy in the distal right coronary artery before bypass grafting, flow was more than 80 cc (Fig. 5). When the coronary arteriogram revealed good distal runoff, flow was greater than 40 cc/min in 79 percent of the bypass grafts to the left anterior descending artery, 75 percent of grafts to the circumflex artery and 70 percent of grafts to the right coronary artery.

Discussion

Clinical Results of Surgery

Relief of angina pectoris: Despite the fairly high surgical mortality rate in our series of patients (12 percent), the clinical results were impressive. Most of the 88 survivors had experienced severe, recurrent angina pectoris before saphenous vein bypass surgery and the operation had been advised because of crippling angina pectoris. After operation, 72 of the surviving patients (82 percent) were completely free of angina pectoris; a great majority have returned to work and are enthusiastic about the relief that they have experienced. Nevertheless, the relief from angina pectoris and the improvement in the quality of life do not constitute proof that the operation is changing the disease process. In many patients vigorous, optimal medical management can accomplish similar results. Regrettably, an untreated control group of similar patients was not available for comparison in terms of long-term survival and their response to medical therapy. The placebo effect must also be considered. Since any surgical procedure unquestionably has a stronger placebo effect than medicine, relief of angina pectoris, although highly desirable, cannot in itself suggest that the disease process has been altered.

The relief of angina pectoris after operation may be due to several important factors. These include (1) reestablishment of adequate blood flow to the ischemic myocardium, (2) possible improvement of left ventricular function, (3) infarction of ischemic areas during and after operation, (4) reduced level of activity, and (5) placebo effect. After operation and during convalescence and rehabilitation, patients are often told to reduce their level of activity.

The operation is designed to improve and reestablish coronary blood flow to ischemic areas. If the shunts are patent and the distal runoff is adequate, then myocardial blood flow should be augmented. In the absence of infarction of ischemic tissue, increased myocardial blood flow should be the primary reason for the impressive relief of angina obtained in this series. Obviously, patency of the graft is necessary for such increased blood flow. Unfortunately, postoperative coronary arteriography was not performed in the symptom-free patients to demonstrate the frequency of graft patency. In the patients who did not show clinical improvement, coronary arteriography after operation demonstrated occlusion of the saphenous vein graft.

Causes of surgical mortality and lack of clinical improvement: Most of the patients who did not survive operation had poor distal runoff demonstrated by coronary arteriography and at necropsy. One patient died because of poor myocardial function, as evidenced by a reduced ejection fraction of 10 percent. Six of the 12 patients who died had myocardial infarction in the anteroseptal area demonstrated at autopsy, resulting in power failure and cardiogenic shock. Although the shunts were patent, distal runoff was poor. Ten other patients experienced myocardial infarction immediately after operation; seven of these showed no clinical improvement and had manifestations of cardiac failure and recurrent angina pectoris.

Sixteen patients continued to have angina pectoris after operation. Poor runoff was noted in 14 of these patients before operation. In only two patients with good runoff, the persistence of angina was attributed to closure of the graft, shown by coronary arteriography. In nine patients with double or triple vessel disease, all the obstructed coronary vessels could not be adequately bypassed because of significant distal atherosclerosis.

Other clinical evidence of improvement: In our experience, the combination of relief of angina pectoris correlated well with improvement in exercise tolerance. The objective findings of left ventricular ischemia on the electrocardiogram were certainly less conspicuous after operation. Again, it is important to emphasize that there were no control subjects. The life cycle of ischemic heart disease is extremely variable, and in a control group properly managed similar improvement in the electrocardiogram may be noted in serial exercise studies. Investigators[10-12] have observed improvement in ventricular function as assessed by exercise hemodynamics, atrial pacing hemodyanmics and cineventriculography after aortocoronary artery bypass grafting.

Patients with overt cardiac failure and large dyskinetic or akinetic areas of the left ventricle were excluded from operation. One patient who had severe hypokinesia of the entire left ventricle with an ejection fraction of 10 percent and a left ventricular end-diastolic pressure of 28 mm Hg did not survive the operation. Seven patients who had severe obstruction of the coronary vessels and a left ventricular end-diastolic pressure of 24 to 30 mm Hg showed postoperative improvement.

Factors Influencing Success of Operation

Graft patency and distal runoff: The success or failure of this operation is determined by the patency

of the graft. Patency ranges from 65 to 90 percent at the end of the first year and, if the grafts are patent then, they generally remain patent for some time thereafter.[14] Many factors influence the patency rate. Perhaps the most important is the size of the distal vessels into which the bypass is directed. The smaller these vessls, the greater the likelihood of occlusion because the flow is reduced. In our experience, patients who did poorly after operation also had poor distal runoff demonstrated by coronary arteriography. Grondin and his associates[15] correlated the patency of aortocoronary artery saphenous vein bypass graft with the amount of flow measured through the bypass at the time of surgery. They found that bypass grafts with a flow greater than 45 cc/min remain patent; bypass grafts that had a flow rate of 20 cc/min or less and that failed to respond to injection of papaverine hydrochloride were closed. They did not correlate the rate of flow with the status of the distal coronary arteries. In our study, there was a striking correlation between the flow measured at the time of surgery and the degree of distal coronary atherosclerosis. It is our impression that distal runoff of these vessels is a major factor in clinical improvement. In our study, only two patients with good distal runoff had a poor result; their angina pectoris was not alleviated. Postoperative coronary arteriograms showed occlusion of the bypass grafts with deterioration of ventricular function, as evidenced by impaired ventricular contraction and reduced ejection fraction. The proximal obstructed lesions in the coronary vessels had progressed to occlusion. Competitive flows are perhaps responsible for the rapid progression of the lesions in the proximal coronary vessels.

The importance of good distal runoff was also evident in the necropsy findings in our patients who died shortly after operation. Five of the seven patients had acute anteroseptal myocardial infarction, with diffuse distal disease of the left anterior descending coronary artery. The bypass grafts were patent in four of these patients who did not survive operation. Death was attributed to complications of postoperative myocardial infarction caused by poor distal runoff. It is our impression that when distal runoff is poor, complications of operative myocardial infarction may ensue and the grafts may eventually close. We therefore believe that the success of the operation is determined by the distal runoff in the presence of adequate ventricular function.

Ventricular function: Values for ejection fraction were compared in patients whose condition improved after operation and those who did not. The left ventricular ejection fraction was significantly higher in the patients whose condition improved, but there was a considerable overlap of data. The ejection fraction reflects the state of myocardial contraction as determined by ventriculography. Most patients with a markedly reduced ejection fraction also had severe distal coronary artery disease. The comparison of mean velocity of circumferential fiber shortening per circumference between these two groups of patients was not statistically significant.

Our studies indicate that the best results of bypass grafting will be obtained in patients with adequate ventricular function and good distal runoff. It is also clear that the operative mortality is greater in patients with impaired ventricular function. Improving blood supply to an area of dyskinesia or akinesia, if it can be accomplished, will be of little or no benefit. Overt cardiac decompensation and conspicuous abnormalities of ventricular function are important factors that increase the risk of operation and the rate of failure. Rea et al.[16] compared the left ventricular function of patients who survived with that of patients who did not survive aortocoronary artery bypass surgery. They found a significant difference in left ventricular function between these two groups: Those who did not survive had greater impairment of ventricular function.

Myocardial infarction: Poor distal runoff may result in no clinical improvement, decreased exercise tolerance, myocardial infarction at operation or progressive shunt closure with myocardial infarction after operation. Myocardial infarction may occur at operation or may be delayed. Delayed myocardial infarction occurs with rapid progression of the original lesion of the coronary artery or closure of the shunt to this artery.

These patients who did poorly after operation generally had poor distal runoff, determined by coronary arteriography or at surgery or necropsy, and their ejection fraction was markedly reduced. Patients who did well with relief of angina pectoris and increased exercise tolerance had good distal runoff and a higher ejection fraction.

It is still not possible to determine whether aortocoronary artery saphenous vein bypass will alter the natural history of coronary artery disease. There are no convincing data that the operation prevents myocardial infarction or alters the mortality rate. Careful randomized studies of patients after coronary arteriography and follow-up for 5, 10 and 15 years may answer this question. A follow-up study of 1 year is reported by Sehapayak and his associates[13]; they found that the mortality at the end of 1 year was similar in the surgically and medically treated groups.

A new closed chest animal technique permits selective intracoronary balloon occlusion and measurement of hemodynamic and regional metabolic function before and during occlusion and reperfusion. The distal end of the double lumen balloon catheter provides information about the nature and extent of flow distal to the occlusion and permits blood sampling or administration of pharmacologic agents directly into the ischemic zone. Independent blood sampling from the great cardiac vein by means of a specially designed balloon catheter and from the coronary sinus by cannula allows simultaneous biochemical and regional blood flow measurements from the occluded and nonoccluded segments of the heart. Simultaneous intracoronary epicardial electrocardiograms permit electrophysiologic correlation with regional hemodynamic and metabolic events. The administration of oxygen by tracheal airway can increase partial oxygen tension in the circulation distal to coronary occlusion. When intracoronary pressures distal to occlusion are markedly reduced, the frequency of ventricular fibrillation is much greater.

The study of progressive alterations in mechanical and metabolic cardiac function subsequent to coronary occlusion or reperfusion requires complex measurements in an animal model that simulates conditions in man. The development of a reversible model of coronary occlusion could accelerate understanding of the mechanisms of segmental myocardial ischemia, revascularization, cardiac arrhythmias and sudden death, and permit local administration of therapeutic agents into an ischemic segment of the heart. Because a better preparation could provide vital information about the nature of myocardial ischemia, the development of new models for studying mechanisms of coronary occlusion and its life-threatening complications has been given a high priority.[1]

Most assessments of the effects of coronary occlusion on cardiac metabolic and mechanical function are based on measurements that do not distinguish between the contributions of ischemic and nonischemic myocardium, although the two segments respond differently. It is believed a myocardial segment subjected to coronary occlusion will convert to anaerobic metabolism and cease contracting whereas increased demands on the nonoccluded segment may overtax its energy supply, resulting in secondary alteration of mechanical and metabolic function.[2] It has also been postulated that the arteries adjoining the occluded area compensate by increasing flow, and that this increase tends to enhance function of the nonoccluded segment.[3] Therefore, to understand fully the individual effects of occlusion, measurement of function from both ischemic and nonischemic segments must be conducted independently and simultaneously. FIGURE 1. Modified double lumen Swan-Ganz balloon catheter. The catheter tip is magnified at **lower right.** The tip protrudes 1 cm beyond the balloon, and its three side holes and end hole are utilized for measuring distal arterial pressure, blood sampling, and inserting intracoronary electrocardiographic electrodes and miniature strain gauges.

new model of experimental coronary occlusion described in this study provides for independent and comprehensive investigations of cardiac function in ischemic and nonischemic myocardium.

Methods

Mongrel dogs weighing 30 to 40 kg were anesthetized with morphine (2 mg/kg intramuscularly) followed 20 to 30 minutes later by pentobarbital (15 mg/kg intravenously). A Harvard respirator provided artificial respiration through a cuffed endotracheal tube. An initial dose of heparin (5 mg/kg) was administered, and further doses of 2 mg/kg were given at 1 hour intervals during the experiment. Supplemental doses of the anesthetic agents were administered whenever necessary to maintain a continuous state of light anesthesia. The amount of fluid lost was estimated and replaced by infusion of physiologic saline solution at a rate of 75 to 100 cc/hour. All the instrumentation and placement of balloon catheters were accomplished in the closed chest preparation.

Instrumentation: A double lumen balloon catheter was adapted for simultaneous occlusion of a coronary artery, sampling of blood and determination of pressure distal to the occlusion. This new intracoronary catheter (Edwards Laboratories, Santa Ana, Calif.), a modification of a Fogarty or Swan-Ganz no. 4F catheter (1.35 mm outer diameter), provides an open lumen extending 15 mm beyond the balloon; the latter can be inflated by air or fluid up to a diameter of 8 mm (Fig. 1). The intracoronary catheter is maneuvered under fluoroscopic control through an angiographic cannula positioned in the left coronary artery. The balloon of the catheter is inflated with Hypaque® sodium 50 percent (weight/volume) (supplied by Winthrop Laboratories) to permit observation of the exact location and control the size of the inflated balloon. This procedure is designed to prevent overdistension of the coronary artery, which may cause epicardial hemorrhage. Occlusion of any specific artery or its branches can be readily achieved by this method. The completeness of occlusion can be demonstrated by coronary angiography[4] and by a sharp reduction in coronary pressure distal to the point of occlusion (Fig. 2). The coronary circulation cut off by the balloon occlusion can be outlined by injection of Hypaque through the central lumen of the intracoronary catheter (Fig. 3). This central lumen is also used to measure retrograde arterial flow, sample blood from the region distal to

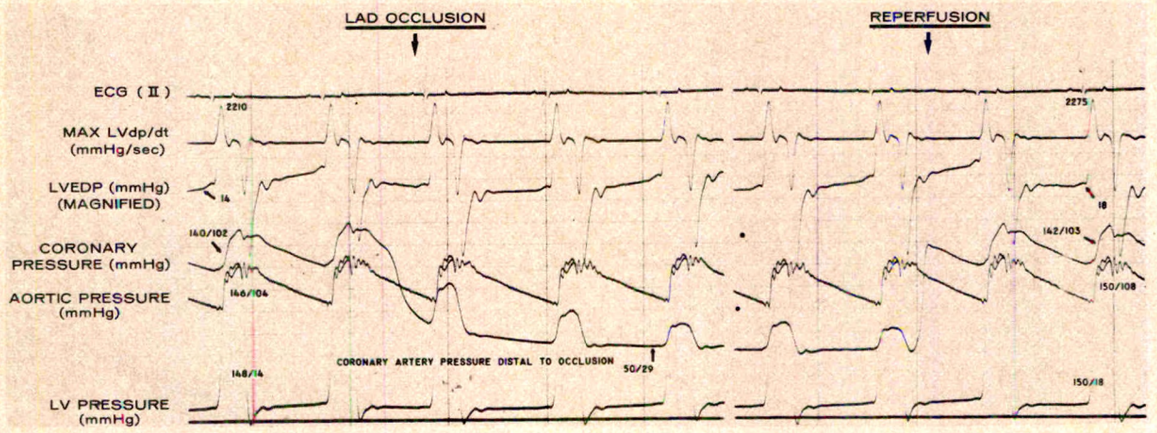

FIGURE 2. Tracings demonstrating that inflation of the intracoronary balloon has occluded the left anterior descending artery. A marked reduction in the distal intracoronary pressure **(arrow)** from 140/102 to 50/29 mm Hg resulted. Deflation of the balloon (REPERFUSION) caused complete restoration of intracoronary pressure. LAD = left anterior descending coronary artery; LV = left ventricular; LVEDP = left ventricular end-diastolic pressure; MAX = maximal.

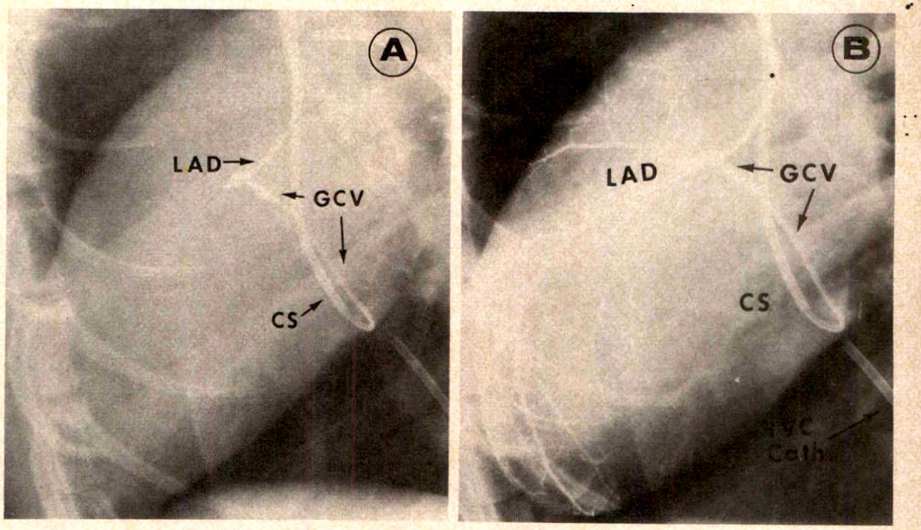

FIGURE 3. Roentgenograms. **A,** demonstrating an intracoronary arterial catheter in the proximal left anterior descending artery (LAD). A great cardiac vein (GCV) catheter has been threaded through the coronary sinus (CS) cannula to approach the balloon occlusion of the left anterior descending artery. **B,** demonstrating distribution of Hypaque® injected into the central lumen of the catheter in the occluded artery to visualize the arterial segment occluded by inflation of the balloon.

the occlusion and assess local mechanical stress and strain. Intracoronary electrocardiograms are recorded by means of a platinum wire protruding through the central lumen of the intracoronary catheter. Reperfusion of the previously occluded area of myocardium can be instituted by gradual or sudden deflation of the balloon (Fig. 2).

A Ganz thermistor catheter is passed into the coronary sinus to obtain blood samples and measure coronary sinus flow by thermodilution.[5] A second double lumen balloon catheter is advanced through a larger guide cannula by way of the coronary sinus until the tip is located deep within the great cardiac vein close to the site of occlusion of the left anterior descending coronary artery (Fig. 3). The central lumen of this catheter is used to collect blood from the great cardiac vein. The balloon near the tip of this catheter is inflated 10 to 15 seconds before sampling. This procedure facilitates separation of blood samples from the coronary sinus and great cardiac vein and allows determination of regional myocardial oxygen consumption as well as lactate, potassium and enzyme balance in both ischemic and nonischemic regions. Thus, simultaneous measurements of regional myocardial blood flow and metabolism may be obtained before and during coronary balloon occlusion, and after reperfusion (Fig. 4).

Hemodynamic and metabolic measurements: Heart rate and cardiac rhythm were determined from the precordial electrocardiogram (lead V_4). A tip transducer catheter (Bio-Tech Instruments, Pasadena, Calif.) was passed from the right femoral artery into the left ventricle to provide measurement of left ventricular pressure and left ventricular end-diastolic pressure. By means of electrical differentiation, the maximal rate of left ventricular pressure rise (dP/dt) was obtained. A Statham P23Db pressure transducer was connected to the central lumen of the intracoronary balloon catheter to measure pressures distal to the point of coronary occlusion (Fig. 2). A similar transducer, connected to a catheter passed through the left femoral artery, was used to measure aortic root pressure and, specifically, peak systolic pressure.

Cardiac output was determined using a Swan-Ganz thermodilution catheter.[6] Stroke work and systemic vascular resistance were computed. Total coronary sinus flow was determined by the Ganz thermodilution technique with the balloon deflated.[5] Regional coronary sinus flow measurements were obtained by temporary inflation of the balloon within the great cardiac vein. Retrograde coronary arterial blood flow could be assessed by direct collection through the central lumen of the intracoronary balloon catheter and this provided samples for measurement of PO_2, lactate and potassium beyond the point of occlusion (Fig. 4).

Control hemodynamic and metabolic data were measured during a 30 minute stable period before occlusion of the left anterior descending or left circumflex coronary artery. Measurements were then performed at 5 minute, 30 minute and hourly intervals after occlusion and, in some instances, after various periods of reperfusion. Simultaneous but separate blood samples were obtained for measurement of lactate and potassium. Lactate was deter-

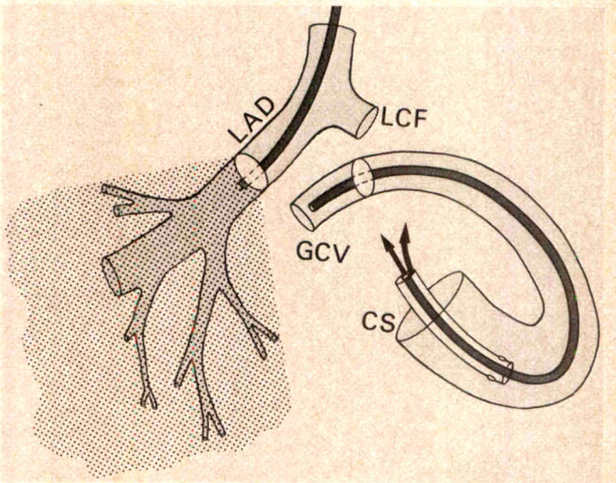

FIGURE 4. Schematic representation of the model of coronary arterial occlusion demonstrating how blood is simultaneously sampled from the great cardiac vein (GCV) draining the occluded and nonoccluded zones perfused by the left circumflex artery (LCF). During collection of blood samples, the balloon in the great cardiac vein catheter is temporarily inflated to separate blood draining the occluded zone from coronary sinus effluent. CS = coronary sinus; LAD = left anterior descending coronary artery.

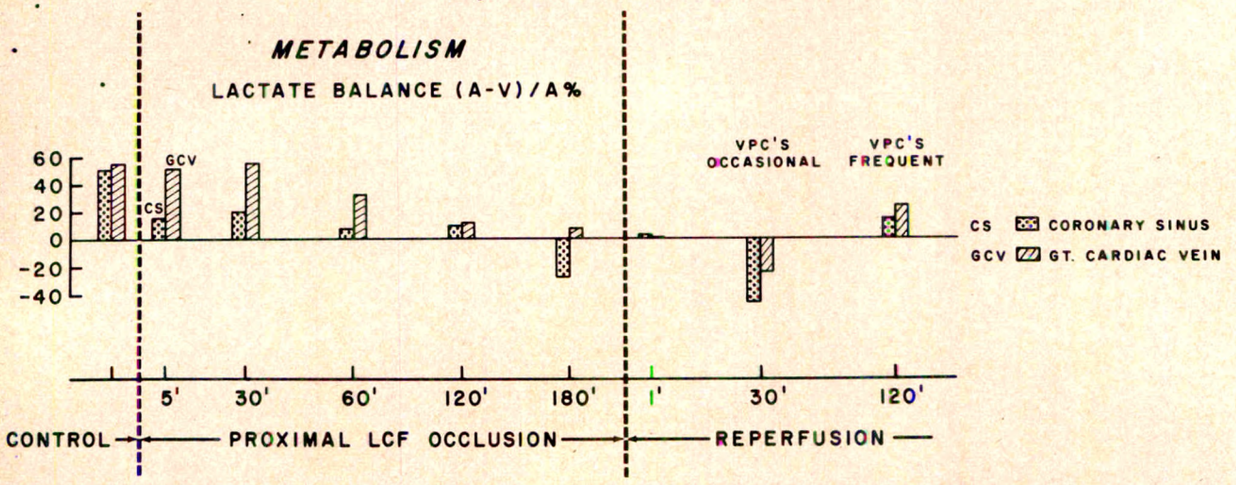

FIGURE 5. Bar graph demonstrating ability of the model to separate venous drainage from the occluded and nonoccluded zones. Lactate measurements were made before and during occlusion of the left circumflex artery and with reperfusion. The coronary sinus blood represents drainage from the occluded zone of the great cardiac vein blood drainage from the nonoccluded segment of the left anterior descending coronary artery. Immediately after occlusion, coronary sinus lactate balance is reduced to 15 percent, indicating abnormal lactate metabolism in the occluded myocardium. After 3 hours of occlusion, the occluded area also shows lactic acid production and the nonoccluded area shows abnormal lactate metabolism. Excellent separation of venous drainage from both segments is evident. Further lactate production occurred during reperfusion (A-V/A) = arteriovenous difference/arterial; VPC's = premature ventricular contractions.

mined by the Hans-Jurgens-Hohorst technique[7] and potassium by means of flame photometry. Both lactate balance and potassium balance were measured from the occluded and nonoccluded regional venous drainage. Blood gases (PO_2 and PCO_2) were monitored throughout the experiment. Hemoglobin and oxygen saturation were measured to provide data for computation of oxygen extraction and regional myocardial oxygen consumption from both occluded and nonoccluded regions. Myocardial arteriovenous creatine phosphokinase (CPK)[8] was measured in several experiments. After the period of occlusion or reperfusion, gross and microscopic examinations were made of the excised heart to assess myocardial damage. Hemodynamic data and intracoronary and standard electrocardiograms were recorded at paper speeds of 50 and 100 mm/sec. The statistical results are expressed as means ± standard error of the mean.

TABLE I

Metabolic Data in 31 Dogs

		Acute LAD Coronary Occlusion	
	Control	30 Minutes	3 Hours
Lactate (%)			
NO [(Ao — CS)/Ao] × 100	34.6 ± 2.2	25.6 ± 2.8	21.1 ± 3.2
O [(Ao — GCV)/Ao] × 100	34.8 ± 2.0	5.6* ± 6.7	10.5* ± 3.7
Potassium (mEq/liter)			
NO (Ao — CS)	−0.05 ± 0.02	−0.13 ± 0.03	−0.13 ± 0.03
O (Ao — GCV)	−0.06 ± 0.02	−0.26* ± 0.05	−0.21* ± 0.04

* $P < 0.05$ relative to nonoccluded segment of the left ventricle.
Ao = aorta; CS = coronary sinus; GCV = great cardiac vein; LAD = left anterior descending coronary artery; NO = nonoccluded segment; O = occluded segment.

Experimental Applications

Selective occlusion of coronary arteries: The desired occlusion of specific arteries or their branches was accomplished without difficulty in 102 animals. The duration of the occlusion extended from several minutes to 8 hours. Ventricular fibrillation occurred in 29 dogs after coronary occlusion, within 30 minutes in 20 dogs and within 3 hours in the other 9. In 14 experiments, at least three coronary arteries were occluded sequentially.

Reperfusion: Reperfusion was performed in 42 dogs through gradual or sudden deflation of the intracoronary balloon after a period of occlusion. Measurements of cardiac function were made for periods of 3 minutes to 5 hours. Regional myocardial metabolic, hemodynamic and coronary flow data are reported for a series of seven dogs during 3 hours of occlusion followed by 5 hours of reperfusion.[9] Stepwise reperfusion was carried out in three dogs by pumping graduated volumes of blood from the left subclavian artery into the central lumen of the intracoronary balloon catheter beyond the occlusion.

Regional measurement of metabolic function: Regional lactate and potassium balances were analyzed from the venous drainage of myocardial segments normally supplied by the occluded and nonoccluded arterial segments (Fig. 5 and 6). Table I indi-

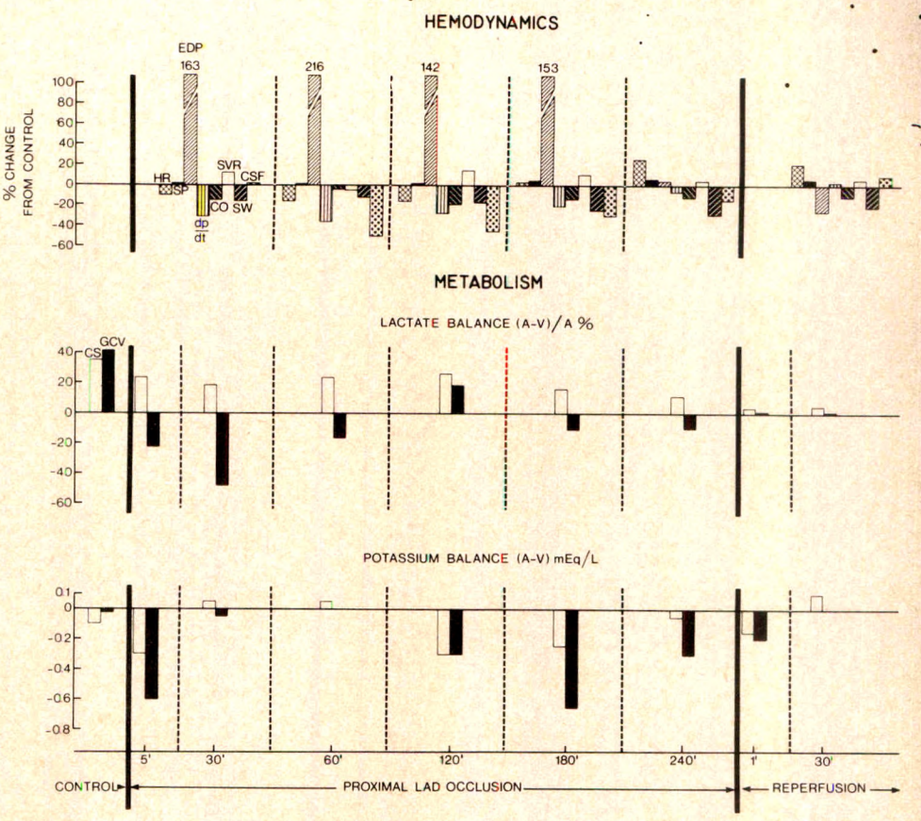

FIGURE 6. Bar graph demonstrating simultaneous hemodynamic measurements and potassium and lactate balance before, during occlusion of the left anterior descending coronary artery, and after reperfusion. Hemodynamic base line represents the control measurements of heart rate (HR) 103 beats/min; systemic pressure (SP) 118 mm Hg; left ventricular end-diastolic pressure (EDP) 10 mm Hg; left ventricular dP/dt 1,348 mm Hg/sec; cardiac output (CO) 2.8 liters/min; systemic vascular resistance (SVR) 3,196 dynes sec cm^{-5}; stroke work (SW) 37 g·m/stroke; and coronary sinus flow (CSF) 97 ml/min. The venous effluent in the great cardiac vein (GCV) represents venous drainage of the occluded zone and in the coronary sinus (CS) drainage of the nonoccluded segment. Note the severe lactate production and potassium loss in the occluded zone (GCV) and also lesser metabolic dysfunction of the nonoccluded (CS) segment. (A-V)/A = arteriovenous difference/arterial.

cates the significant difference between measurements in the two segments and demonstrates the successful separation of metabolic data in a series of 31 dogs. After coronary occlusion, a significant reduction in lactate extraction, often reaching production levels, was observed in the occluded zone. The nonoccluded zone often exhibited abnormal lactate metabolism after coronary occlusion.

Regional coronary flow measurements: The great cardiac vein almost exclusively drains the region of the myocardium perfused by the left anterior descending coronary artery. This great cardiac venous flow enters the coronary sinus and mixes with the venous blood drained from the myocardium perfused by the left circumflex coronary artery. Temporary balloon occlusion of the great cardiac vein provides separation of the venous compartments. Regional coronary blood flow measurements, coupled with arteriovenous oxygen content determinations in the occluded and nonoccluded segments, permit assessment of regional myocardial oxygen consumption.

Coronary venous flow measurements from both the occluded and nonoccluded zones of the myocardium were performed in 16 closed chest dogs during occlusion of the left anterior descending coronary artery. Blood flow measured in the coronary sinus during balloon inflation of the great cardiac vein represented the effluent mainly from the nonoccluded region. Venous drainage of the occluded zone was calculated by subtracting the flow in the nonoccluded region from the coronary sinus flow determined when there was no balloon inflation of the great cardiac vein.

Occlusion of the left circumflex artery was performed in two dogs (Fig. 7). In these animals, coronary sinus flow in the presence of balloon occlusion of the great cardiac vein represented the venous drainage of the occluded region. The flow from the nonoccluded zone was computed by subtracting the flow from the occluded region from the coronary sinus flow measurements made when the great cardiac vein balloon was deflated (Fig. 7, A and B).

Measurements distal to intracoronary occlusion: Coronary arterial pressure distal to intracoronary balloon occlusion was measured in 55 dogs (Fig. 2). Before occlusion, coronary arterial pressure approximated and paralleled that in the aortic root, but upon occlusion it was sharply reduced. Its characteristics then resembled the pressure in the left ventricle.

In one series of 24 dogs, the early coronary peak systolic pressure during occlusion averaged 43 mm Hg (a decrease of about 70 percent from the control level). The diastolic phase of coronary arterial pressure remained about the same during the 4 hours of occlusion.

In 9 of the 24 dogs ventricular fibrillation developed within the first hour after occlusion and defibrillation attempts were not successful. The mean postocclusion coronary arterial diastolic pressure in

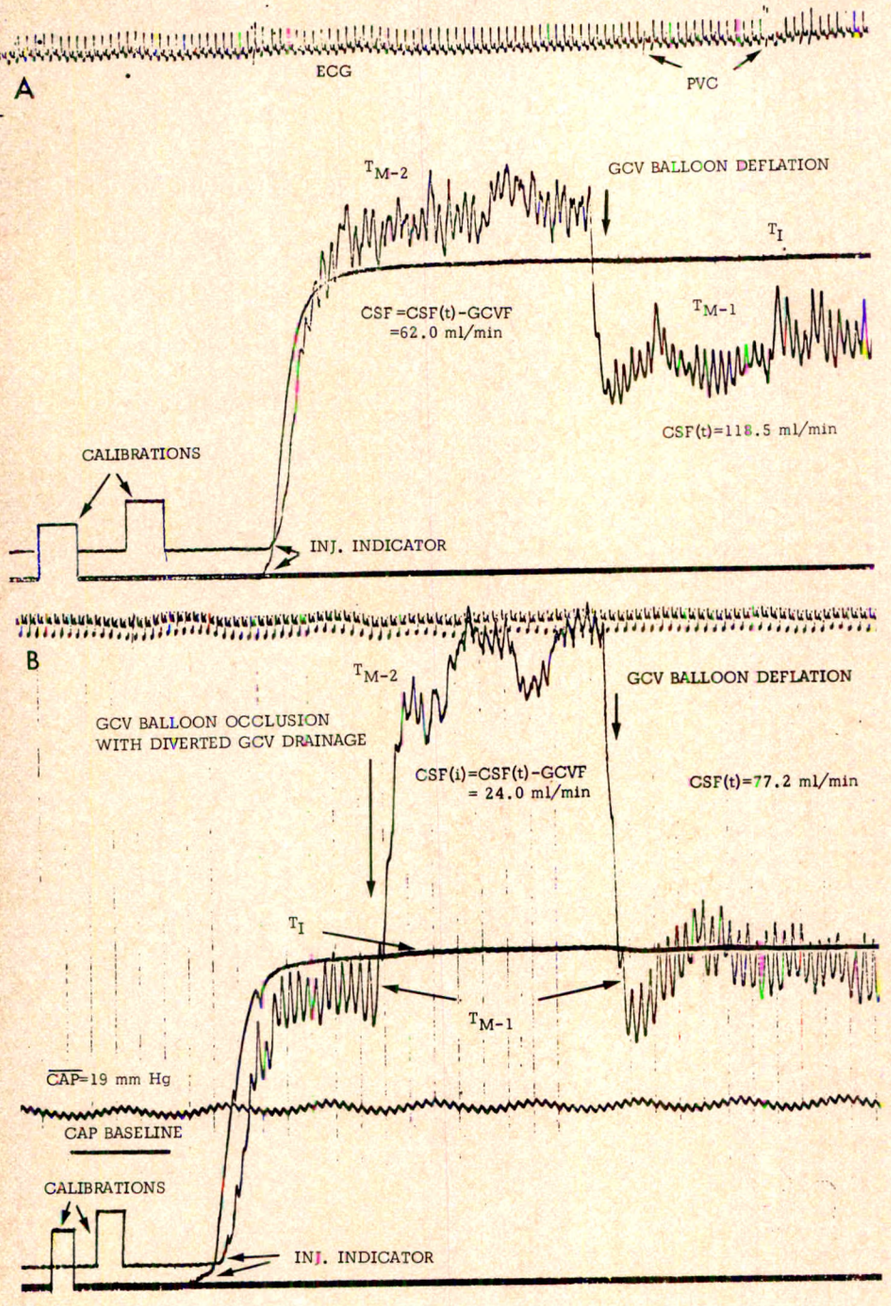

FIGURE 7. Regional coronary flow measurements by thermodilution technique. **A,** before occlusion of the left circumflex coronary artery. With the great cardiac vein (GCV) balloon inflated, the regional coronary sinus flow (total coronary sinus flow minus great cardiac vein flow) measures 62.0 ml/min. With the balloon deflated, total coronary sinus flow is 118.5 ml/min. **B,** during occlusion of the left circumflex artery, with the cardiac vein balloon inflated, the coronary sinus flow which represents the occluded area is decreased to 24 ml/min. When the balloon is deflated, the total coronary sinus flow is 77.2 ml/min. $\overline{CAP}$ = mean coronary arterial pressure.

these dogs was 12.0 ± 1.2 mm Hg. The remaining 15 dogs had no ventricular fibrillation after occlusion and had a higher level of mean diastolic coronary arterial pressure (19.1 ± 1.6 mm Hg). The statistical difference between these two groups was significant ($P > 0.02$).

Retrograde arterial blood flow through the central lumen of the intracoronary catheter beyond the point of occlusion demonstrated a high level of oxygen saturation, paralleling that of the aortic blood. Blood samples from this region were compared during breathing of room air and oxygen (Table II). The results indicate that administration of oxygen can increase PO_2 in the collateral circulation distal to the coronary occlusion.

Intracoronary epicardial electrocardiogram: In 11 closed chest dogs the intracoronary epicardial electrocardiogram was monitored during the coronary occlusion simultaneously with a precordial electrocardiogram. Figure 8 shows the comparison of an epicardial lead with a tracing of lead V_4 obtained during occlusion of the left anterior descending coronary artery in a dog that underwent shock 2 hours after occlusion. The epicardial electrocardiogram re-

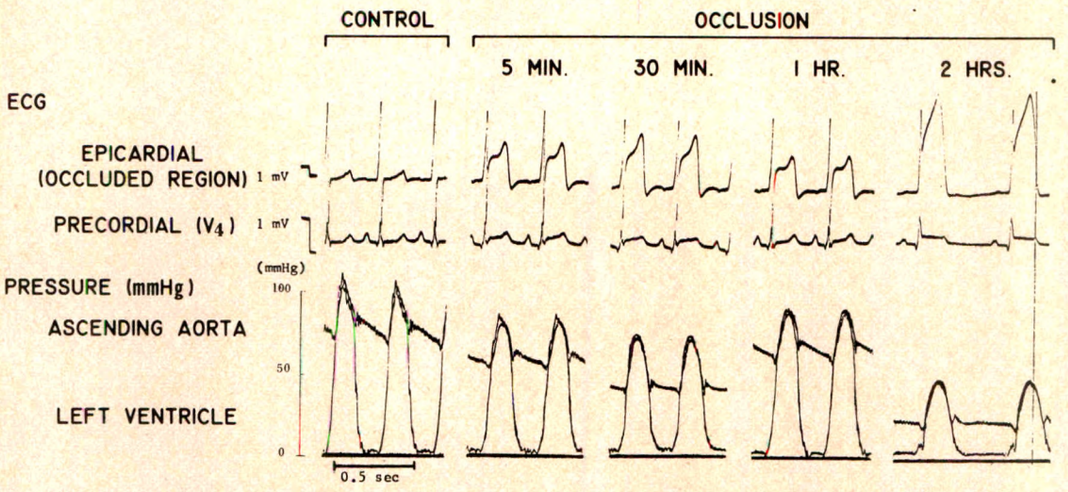

FIGURE 8. The epicardial intracoronary electrocardiogram in closed chest dog recorded in the occluded zone demonstrates marked S–T segment elevation after balloon occlusion which becomes more pronounced with progressive reductions in systemic pressure. A precordial V_4 tracing with much greater standardization is simultaneously recorded to demonstrate the greater voltages obtained by the intracoronary electrocardiogram.

vealed much greater voltages and a more pronounced current of injury than the conventional V_4 lead. When severe hypotension occurred, the S–T segment elevation of the intracoronary epicardial lead correlated inversely with left ventricular systolic pressure measurements.

Residual potassium measurements of ischemic and nonischemic myocardium: Myocardial tissue samples were obtained at the end of the experiment from the ischemic and nonischemic regions and the borderline intermediate zones of the left ventricle for measurement of their potassium content. These data may be important in checking the veracity of myocardial potassium balances in the beating heart and in assessing the extent of regional myocardial damage and the effectiveness of therapeutic agents.[9]

Arteriovenous differences in enzyme CPK: After occlusion of the left anterior descending coronary artery, arteriovenous differences in CPK were determined from the great cardiac vein and aorta. No significant increase in CPK from either area was noted in the first 3 hours, but after 4 hours, a distinct change in the arteriovenous differences was observed.

Selective infusions into the ischemic zone: Blood flow from the left subclavian artery was channeled by connecting a catheter externally into a distal segment of the occluded artery so that the ischemic area could be reperfused at various flow rates to determine effects of flow rate on myocardial func-

TABLE II

Effect of Oxygen Administration on Coronary Arterial PO_2 in 15 Dogs

		Left Anterior Descending Occlusion		
	Control	1st Hour Room Air	2nd Hour 100% O_2 Administration	3rd Hour Room Air
Aortic PO_2	100 ± 14.3	100.6 ± 15.5	396.0 ± 40.8	85.4 ± 6.0
Coronary arterial PO_2*	99 ± 13.8	90.5 ± 11.0	322.0 ± 30.3	80.2 ± 5.8
P value	NS	NS	NS	NS

* Distal to occlusion of the left anterior descending artery.
NS = nonsignificant.

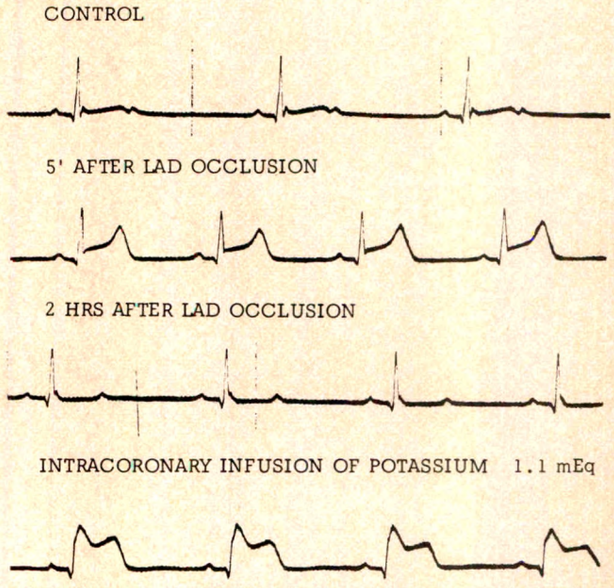

FIGURE 9. Effect on the electrocardiogram (lead V_4) of infusing 1.1 mEq potassium into the ischemic zone through the central lumen of the catheter in the left anterior descending coronary artery.

tion. Various pharmaceutical agents, such as potassium (Fig. 9) and alleged vasodilators, were also infused through the central lumen of the intracoronary catheter into the region beyond the balloon occlusion to determine their effect on the peripheral coronary bed and regional metabolism.

Measurement of cardiac function during arrhythmias: After an initial 5 minutes of occlusion of the left anterior descending coronary artery, 3 of 17 dogs had ventricular tachycardia; 14 continued to have normal sinus rhythm. Myocardial potassium balances from nonischemic and ischemic areas were compared during sinus rhythm and ventricular tachycardia (Fig. 10). During sinus rhythm, potassium concentration from the occluded zone of the great cardiac vein increased significantly to 8 percent above the control level before occlusion, but remained relatively constant in the nonoccluded segment. When ventricular tachycardia occurred, the net myocardial potassium loss increased in both the occluded and nonoccluded segments of the heart to 13 percent above the preocclusion level, thereby suggesting that the nonoccluded myocardium may also be seriously affected by arrhythmias.[10]

Discussion

A recently published report of a task force of the National Heart and Lung Institute[1] concluded: "There is no adequate animal model for simulating human coronary heart disease. Consequently, much of the indicated investigation must be carried out in man until such time as an adequate model becomes available. The importance of a good animal model for clinical coronary heart disease exhibiting myocardial infarction, arrhythmia, and sudden death were repeatedly emphasized. If such were available, studies of blood flow, collateral circulation development, drug action, and the effects of surgical revascularization could be subjected to critical evaluation prior to their application in man. The development of such an animal model can accelerate progress in many areas and must, therefore, be given high priority." The panel recommended the development of animal models that would permit (1) quantitation of myocardial ischemia for use in trials of medical and surgical therapy, (2) study of the metabolic, mechanical and electrophysiologic properties of the ischemic myocardium with special attention to the pathogenesis of arrhythmias and the protection of the ischemic myocardium, and (3) study of the relations of arrhythmias and sudden death due to coronary artery disease, to expedite and accelerate progress in the development and testing of preventive and therapeutic agents, devices and surgical procedures.

In spite of certain objections, the dog preparation has been widely used in gathering data essential to the study of mechanisms of myocardial disease.[11] Obviously, the physiologic differences between man and the dog may affect the interpretation and application of experimental data in the clinical setting. Nevertheless, since the dog is sufficiently similar to man physiologically and metabolically and since the limitations of extensive experimentation in man are so prohibitive, application of data obtained from the dog can be justified. Anesthesia, invasive measurements, catheterization and other interventions also may introduce significant artifacts. Sham experiments performed in the same fashion as the experimental series act as a control and rule out possible artifacts. Investigations of the effects of coronary occlusion should encompass simple models that can be used for study of acute occlusion of a single artery or chronic multiple occlusion configurations. The model described here provides a valid physiologic simulation for the study of regional as well as global cardiac function, to compare preocclusion control data with the alterations that occur after occlusion and subsequent reperfusion or other interventions.

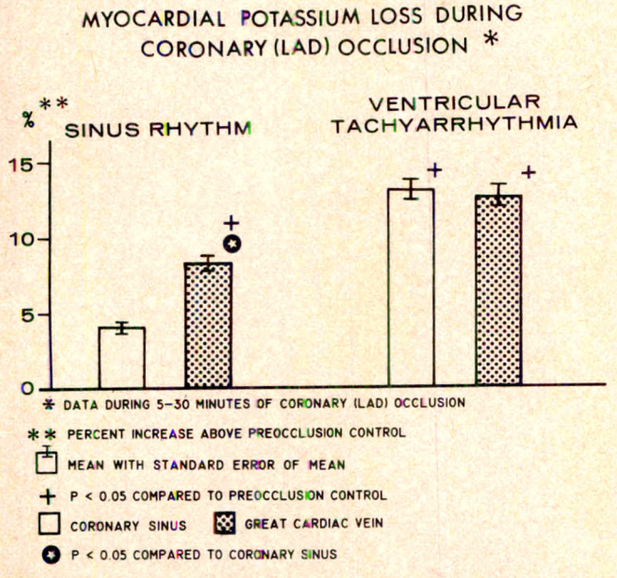

FIGURE 10. Statistical comparison of myocardial potassium loss after occlusion of the left anterior descending artery (LAD) during sinus rhythm and ventricular tachycardia. **White bars** represent percent change from control potassium levels in coronary sinus blood and **stippled bars,** that of the great cardiac vein. Occlusion of the left anterior descending artery caused a more significant rise in potassium in the great cardiac vein. During ventricular tachycardia, both coronary sinus and great cardiac vein effluent exhibit a significant increase in potassium concentration relative to preocclusion control levels.

Evaluation of Other Models for Studying Coronary Occlusion

Information derived from open chest animal experiments must be viewed with caution because changes in intrathoracic pressure and in the temperature of the myocardium can affect cardiac output and reduce it as much as 50 percent.[12] Hence, there has been increasing emphasis on closed chest models of occlusion. These include "shot-gun" microsphere embolization of the coronary arteries[13] or selective embolization of one or two of their major branches.[14,15] A modification consists of embolization by

means of mercury.[16] Embolized particles may be found in either pulmonary or systemic peripheral vessels, causing false alterations in peripheral vascular resistance and afterload. Mercury may have toxic effects on the myocardium and other organs. The presence of solid particles within the myocardial zone of coronary occlusion could modify regional compliance and contraction and seriously alter functional measurements. Diffuse obstruction of the coronary microvasculature by beads or mercury may lead to excessive depression of cardiac function, which does not simulate human coronary occlusion.

Local coronary arterial thrombosis has been produced by electrical cauterization or use of an intracoronary spiral wire,[17,18] but it is difficult to assess the actual time course and development of the intravascular thrombosis. Such electrical and mechanical stimulation and thermal effects may cause unusual myocardial damage, resulting in disruption of the depolarization-repolarization cycle, electrical instability and associated hemodynamic and metabolic derangements. Recently, investigators have also utilized insertion into a coronary artery of a solid or hollow cylinder,[19-21] spiral wire,[22,23] plastic cones,[24] steel balls[25] or lead foil.[26] Such methods permit study of acute and gradual occlusion; however, because the occluders migrate, they do not provide control of location of the occlusion. In addition, these techniques may be accompanied by significant artifacts, and do not insure completeness of occlusion.[19] These modes of coronary occlusion are not reversible, but the use of circulating magnetic products has recently been reported[27] to provide a controlled occlusion technique that is also irreversible.

Many investigators are using long-term implantation of hydraulic or pneumatic cuffs[28,29] or ameroid constrictors[30,31] around selected coronary arteries to provide coronary occlusion. These procedures require previous thoracotomy and pericardiotomy, which may result in adhesions, fibrosis, interruption of coronary innervation[32] and interference with coronary veins, all of which may alter cardiac function. Therefore, a well controlled, flexible and totally reversible mode of coronary balloon occlusion was devised to simulate the human occlusion and to offer a more complete technique for the study of cardiac metabolic, hemodynamic and mechanical function, both regional and global.

Capabilities of Occlusion-Reperfusion Model

To date, the new closed chest model has been successfully applied in 102 dogs to perform the following procedures:

1. Selective intracoronary balloon occlusion of specific coronary arteries and their branches. The occlusion can be complete or partial and sudden or gradual.
2. Sequential occlusion of the left anterior descending, left circumflex or right coronary artery, or any combination of the main arteries or branches.
3. Reperfusion (sudden or gradual) by deflation of the occluding intracoronary balloon.
4. Regional metabolic measurements of pH, myocardial oxygen consumption, lactates, electrolytes, enzymes and fatty acids from occluded and nonoccluded segments.
5. Determination of regional coronary flow from ischemic and nonischemic myocardium.
6. Stress-strain measurements of regional myocardium.
7. Intracoronary electrocardiogram of the ischemic and nonischemic zones.
8. Local infusion of pharmaceutical agents through the central lumen of the intracoronary balloon catheter.
9. Residual tissue measurements of myocardial enzymes and electrolytes.
10. Correlation of hemodynamic and metabolic data with pathologic findings.

The completeness of the balloon occlusion was demonstrated by coronary angiography[4] and also by pressure tracings, which revealed typical alterations in pressure distal to the occlusion (Fig. 2). It was essential to determine whether positioning of the uninflated balloon catheters within the coronary arteries might interfere with flow in the regional myocardium subserved by that coronary artery. Specifically designed experiments utilizing electromagnetic flowmeters revealed that deflated no. 4F catheters did not affect the rates of coronary blood flow.

Applications

The new closed chest occlusion-reperfusion model provides a means of studying simultaneous but separate measurements of regional metabolic function in the occluded and nonoccluded zones of the heart. The coronary sinus receives 70 to 95 percent of the total venous drainage from regions of the heart perfused by the left anterior descending and circumflex arteries.[33] The great cardiac vein drains the region perfused by the left anterior descending artery and empties into the coronary sinus. Thus, coronary sinus blood normally represents a mixture of both venous drainages. After temporary balloon occlusion of the great cardiac vein, blood in the coronary sinus represents venous drainage from the region perfused by the left circumflex artery. Anatomic studies have occasionally shown the existence of veno-venous shunts between the great cardiac vein and the coronary sinus.[34] Our angiographic studies confirm the presence of small shunts; their exact volume is now being determined by isotope studies.[34] Total separation of venous drainage may not be physiologically feasible, because an overlap of coronary arterioles from adjoining vessels or those branching off above the site of occlusion may dilute measurements of metabolic function from the ischemic zone. One of the main conclusions from numerous measurements performed to date is that the regional metabolic data from the occluded site differ significantly from those based on coronary sinus samples (mixed venous drainage from areas perfused by the left anterior descending and left circumflex arteries). Therefore, the metabolic consequences of an occlusion of the left

anterior descending coronary artery are best studied by direct measurements of venous drainage directly from the zone of ischemia rather than by inferring, as in the past, that coronary sinus blood samples demonstrate alterations in metabolic function of a localized zone of ischemia.

When the left circumflex artery is occluded, drainage from the great cardiac vein represents the venous return from the nonischemic zone perfused by the left anterior descending artery. Venous drainage from the ischemic myocardium is represented by the coronary sinus effluent when the great cardiac vein balloon is inflated. This coronary sinus effluent may be slightly contaminated by drainage from the right coronary artery.

Measurement of regional flows by our technique, which separates the venous blood draining occluded and nonoccluded segments, allows assessment of regional myocardial oxygen consumption and quantification of myocardial lactate and potassium balances. Correlation of these metabolic measurements with segmental coronary flow and regional myocardial hemodynamics in the closed chest provides information required for the better understanding of ischemic mechanisms.

Comparison of the intracoronary epicardial electrocardiogram with the precordial electrocardiogram demonstrated that the former provided greater amplitude and much more detail for the study of S–T segment elevation. The electrocardiographic alteration correlated closely with the physiologic state reflected by either systemic or coronary perfusion pressures. One important feature of the new model is its provision of a simple method of reversing coronary occlusion for study of reperfusion mechanisms and their effects on myocardial viability.[9] Additionally, the intracoronary balloon catheter has a central lumen that allows communication with the region distal to the balloon occlusion. This capability has been utilized for the following:

1. Indirect assessment of coronary collateral vessels by study of alterations in retrograde blood, coronary flow and pressure distal to the occlusion.
2. Blood sampling from the ischemic myocardium beyond the inflated balloon.
3. Provision at a regional intracoronary electrocardiogram by insertion of a platinum wire through the lumen into the occluded zone.
4. Drug infusions through the central lumen, thus permitting selective pharmacologic interventions whose effects in the ischemic region can be isolated from systemic effects. Among present studies to be reported are controlled rates of infusion of saline solution, arterial and venous blood into the occluded region to compare the effects of anoxia, hypoxia and ischemia, evaluation of alleged vasodilator drugs and other factors affecting coronary collateral circulation.
5. Assessment of regional myocardial mechanical function. We have devised miniaturized force and stress gauges that may be inserted in the closed chest preparation by means of the intracoronary catheter and wedged within a branch distal to the occlusion.[35] The localization and insertion of miniature gauges into the endocardium through a left ventricular catheter is also being investigated.[36] The ability to quantitate regional mechanical forces in this manner is being critically evaluated.

Clinical application of regional metabolic measurements is currently being studied at this center. Blood samples collected from a catheter in the coronary sinus and a second catheter advanced into the great cardiac vein allow regional sampling. Preliminary data confirm the value of performing regional and global metabolic determinations.

Hemodynamic and regional metabolic function was assessed simultaneously in 34 closed chest dogs during a preocclusion control period and 3 hours of intracoronary balloon occlusion of the proximal left anterior descending artery. The data indicate immediate alteration in hemodynamic measurements with many fluctuations in the 3 hour occlusion period. No specific hemodynamic pattern was evident. When the mean data were analyzed, occlusion was found to cause early increases in left ventricular end-diastolic pressure (43 percent) and systemic vascular resistance (21 percent), and decreases in peak systolic pressure (5 percent), maximal rate of rise of left ventricular pressure (dP/dt) (20 percent), cardiac output (19 percent), stroke work (26 percent) and coronary sinus blood flow (19 percent).

Regional metabolic measurements showed significantly different metabolic function in the occluded and nonoccluded zones of the left ventricle. Lactate balance decreased to near production levels, and a substantial potassium loss occurred in the occluded zone shortly after occlusion; lactate and potassium balances later fluctuated, but usually remained depressed. Abnormal lactate metabolism and potassium efflux were often observed in the nonoccluded zone. A 6 to 8 percent increase in oxygen extraction was noted in both segments.

Progressive alterations in hemodynamic and metabolic function of the heart after coronary occlusion are not uniform and exhibit dynamic fluctuations. Although a direct relation was noted between the degree of metabolic dysfunction and hemodynamic change, individual experiments often revealed a distinct metabolic-mechanical dissociation.

The progressive consequences of myocardial ischemia are difficult to study in man since preocclusion control data are rarely available, and complex invasive regional measurements cannot readily be performed. Hence, much of the needed basic information must be derived from animal experimentation. Many animal models of coronary occlusion have been used, but most of them are deficient because they (1) involve open chest preparations that greatly alter cardiac function, (2) do not properly simulate coronary occlusion in man, or (3) do not permit simultaneous and separate metabolic evaluation of the occluded and nonoccluded zones of the myocardium.[1]

In the preceding report[1] we described a new closed chest model for production of localized intracoronary occlusions of coronary arteries. This model features simultaneous determinations of hemodynamic status and regional metabolic function, myocardial flow and oxygen consumption. The purpose of this study is to provide information about the progressive response of the intact heart preparation to coronary occlusion and to supply data that might be used as a base line for subsequent evaluations of the effects of reperfusion, pharmaco-

logic treatment, circulatory assistance or other interventions.

Methods

The methods used for induction of anesthesia and maintenance of body fluids in closed chest dogs are reported in the preceding article.[1] The application of intracoronary balloon catheters for occluding specific coronary arteries and for simultaneous measurements of hemodynamics, myocardial blood flow and metabolic functions of occluded and nonoccluded myocardial segments are also previously described and for brevity referred to hereafter as the Corday-Lang model.[1]

The proximal left anterior descending coronary artery was selected for a 3 hour acute occlusion by means of an intracoronary balloon catheter. Venous drainages from the myocardium supplied by the occluded left anterior descending coronary artery and from the nonoccluded region were separated during sampling by the temporary inflation of a balloon at the tip of a catheter positioned within the great cardiac vein. This procedure permits determination of regional lactate and potassium arteriovenous balances, coronary flow rates and myocardial oxygen consumption. Pressure measurement and sampling beyond the point of occlusion were performed by way of the central lumen of the intracoronary balloon catheter.

Duplicate hemodynamic and metabolic measurements were carried out during a 30 minute stabilization, preocclusion control period. After inflation of the intracoronary balloon, measurements were performed 5 and 30 minutes and 1, 2 and 3 hours after occlusion.

To provide sham base-line data and to assess the effects of anesthesia as well as other procedures in the preparation used, five fully catheterized and fully instrumented dogs were studied without coronary arterial balloon inflation over a period of time equivalent to that of the occlusion study. Hemodynamic measurements were recorded and blood was collected for metabolic determination at exactly the same time intervals as those provided in the occlusion protocol. The excised hearts were examined to assess myocardial damage.

All data were subjected to statistical analysis by computing mean and standard error of mean values. Paired t tests for significance comparisons were carried out relative to preocclusion control data, and between measurements performed simultaneously in the occluded and nonoccluded arterial segments of the left ventricle. Data from individual experiments were studied in addition to the statistical mean trends.

Results

The proximal left anterior descending coronary artery was acutely occluded in closed chest dogs for 3 hours. Thirty-nine animals survived the 3 hour occlusion during which experimental observations were conducted. Five of the 39 dogs were excluded from

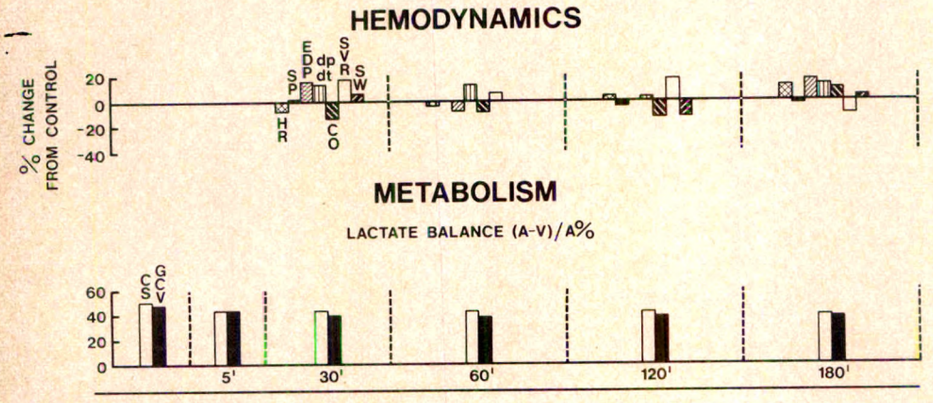

FIGURE 1. Hemodynamic and metabolic measurements recorded over a 3 hour period in the sham series of 5 dogs, prepared with instrumentation similar to that for the study series of 34 dogs. Coronary arteries were not occluded. Bar graph demonstrates hemodynamic changes from base-line control values, expressed as percent change from control. Control measurements were: Heart rate (HR) 79 beats/min; aortic systolic pressure (SP) 168 mm Hg; left ventricular end-diastolic pressure (EDP) 12 mm Hg; left ventricular dP/dt (dp/dt) 1,417 mm Hg/sec; cardiac output (CO) 2.2 liters/min; systemic vascular resistance (SVR) 5,284 dynes sec cm^{-5}; and stroke work (SW) 50 g·m/beat. The lower line demonstrates lactate balance. Although there is some mild fluctuation, there is no significant difference between the zones perfused by the left anterior descending (great cardiac vein [GCV] samples), and left circumflex (coronary sinus [CS] sampling with temporary GCV occlusion) arteries. (A-V)/A = arteriovenous difference/arterial.

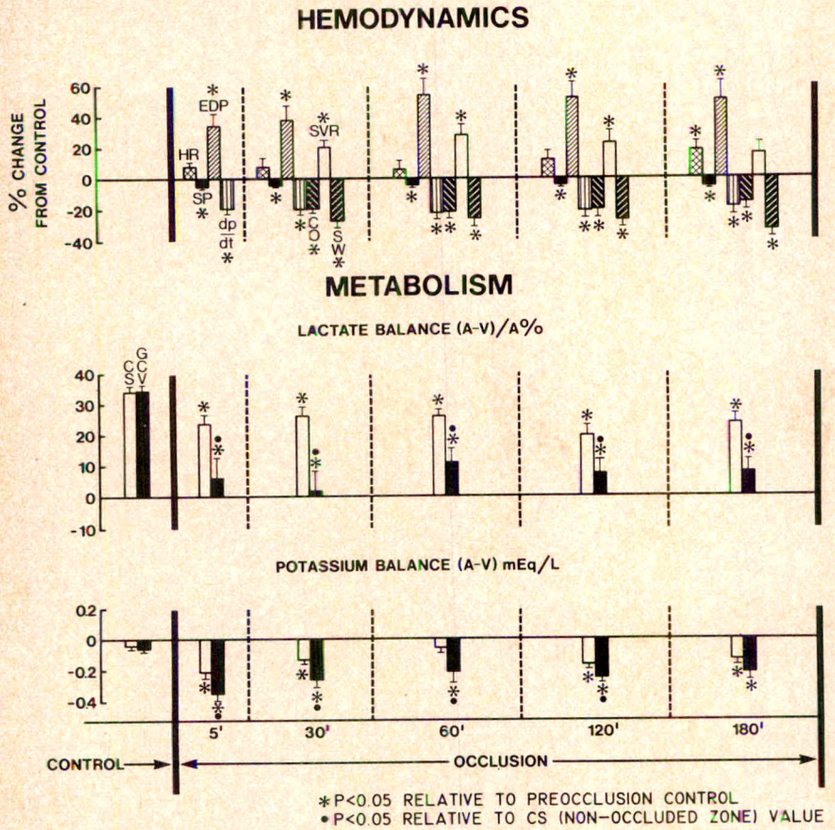

FIGURE 2. Mean measurements of hemodynamic and metabolic function made in 34 dogs during a control period and after 3 hours of coronary occlusion. The top bar graph demonstrates hemodynamic percent changes from base-line control levels. Control measurements were heart rate 109 beats/min; systolic pressure 141 mm Hg; left ventricular end-diastolic pressure 7 mm Hg; left ventricular dP/dt, 2,842 mm Hg/sec; cardiac output 2.8 liters/min; systemic vascular resistance 3,680 dynes sec cm^{-5}; and stroke work 43 g-m/beat. Thirty minutes after occlusion there was a significant decrease in maximal left ventricular dP/dt, cardiac output and stroke work and an increase in systemic vascular resistance which persisted over a 3 hour period. The occluded zone (great cardiac vein) demonstrated abnormal lactate metabolism throughout the entire 3 hour occlusion. Potassium balance showed an intermittent loss from the nonoccluded (coronary sinus) zone and persistent loss from the occluded zone for the 3 hour period. Abbreviations as in Figure 1.

this study because they underwent severe hypotension and fulfilled the criteria adopted for designating cardiogenic shock (30 percent or greater reduction in both cardiac output and systolic pressure). These animals are the subject of a subsequent report on factors that apparently precede the onset of the shock state.[2] This study of the remaining 34 dogs (Table I) is concerned with progressive events in animals that remained normotensive after acute occlusion of the proximal left anterior descending coronary artery.

Series A—Hemodynamic and Metabolic Measurements in Sham Preparation

Five dogs were prepared with instrumentation and placement of catheters identical to those of the 34

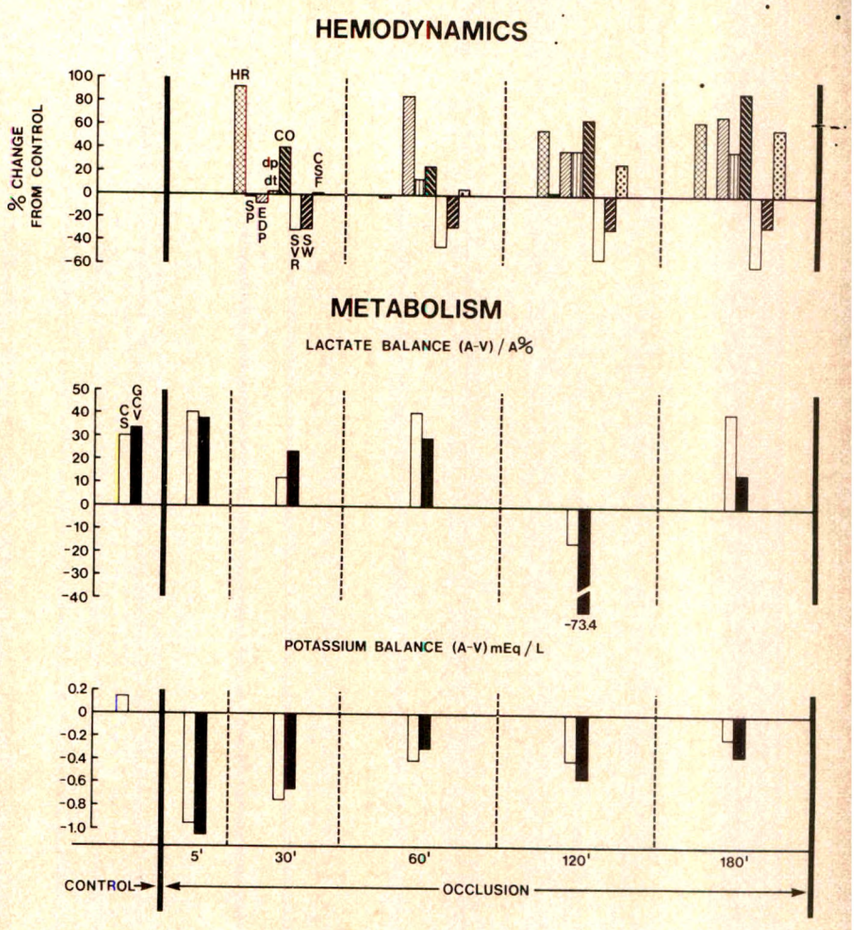

FIGURE 3. Hemodynamic and metabolic measurements made during a control period and 3 hours of coronary occlusion in a dog. Hemodynamic function is reported as percent change from base-line control levels. Control measurements were heart rate 84 beats/min; systolic pressure 162 mm Hg; left ventricular end-diastolic pressure 13 mm Hg; left ventricular dP/dt 2,455 mm Hg/sec; cardiac output 1.5 liters/min; systemic vascular resistance 6,611 dynes sec cm^{-5}; stroke work 30.5 g-m/beat; and coronary sinus flow 90 ml/min. Abnormal lactate metabolism occurred in the nonoccluded (coronary sinus) segment 30 minutes after balloon inflation; lactate production occurred 2 hours after occlusion in both zones. There was a consistent potassium loss in both the occluded and nonoccluded segments during the 3 hours of occlusion. Abbreviations as in Figure 1.

dogs in the occlusion series, but the coronary arteries were not occluded. Figure 1 illustrates hemodynamic and regional metabolic measurements in a typical sham dog. During 3 hours of observation, all five dogs demonstrated a rising heart rate (from 105 to 132 beats/min), fluctuations in cardiac output and systemic vascular resistance and a minor decrease in peak systolic pressure (from 150 to 146 mm Hg). These effects may be due to the influence of initial and supplemental anesthesia. Regional lactate extraction and myocardial potassium balances showed mild fluctuations, but there was no significant difference in metabolic measurements in zones perfused by the left anterior descending and left circumflex coronary arteries.

Series B—Hemodynamic and Regional Metabolic Measurements During 3 Hours of Coronary Occlusion

I. Hemodynamics

Heart rate: During the 3 hour occlusion period, the mean heart rate rose progressively from 109 to 128 beats/min (Table I, Fig. 2 to 4). This 18 percent increase is comparable to that noted in the five sham dogs in Series A that did not undergo occlusion. Nineteen of these 34 dogs had an increased heart rate during occlusion; the rate decreased in 8 dogs, and remained relatively unchanged in 7. Transient arrhythmias produced by ischemia during the first hour of occlusion were noted in 19 of the 34 dogs, but they did not persist for more than 20 minutes. The arrhythmias included sinus bradycardia and tachycardia, premature ventricular systoles, ventricular rhythm and rapid tachyarrhythmias. Fewer arrhythmias occurred in the next 2 hours.

Peak systolic pressure: Peak systolic pressure decreased 5 percent shortly after occlusion of the proximal left anterior descending coronary artery. At the end of 3 hours of occlusion, peak systolic pressure was reduced an average of 6 percent below the preocclusion control level. This reduction in blood pressure was about the same as that noted at the end of the 3 hours in the sham experiments. Study of individual animals revealed variations: 6 of the 34 dogs had a more significant reduction in pressure of 15 to 25 percent over the 3 hour period. The pressure increased gradually in six dogs (average 12 percent), and remained near control level in the remaining dogs. Peak systolic pressure was not reduced to less than 100 mm Hg in any animal during the 3 hour period of occlusion.

Left ventricular end-distolic pressure: Left ventricular end-diastolic pressure increased significantly (43 percent) immediately after occlusion. The mean

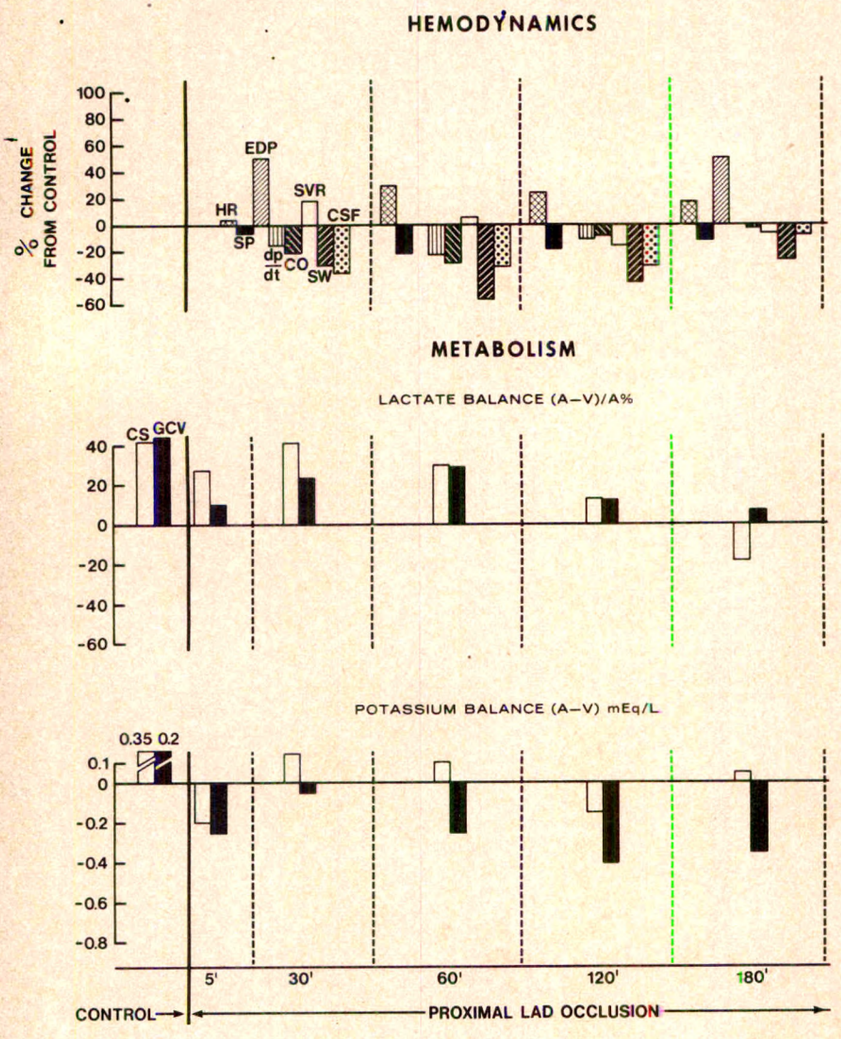

FIGURE 4. Hemodynamic and metabolic measurements during a control period and 3 hours of coronary occlusion in a dog. Hemodynamic function is reported as percent change from base-line control values. Control measurements were heart rate 124 beats/min; systolic pressure 139 mm Hg; left ventricular end-diastolic pressure 6 mm Hg; left ventricular dP/dt, 1,534 mm Hg/sec; cardiac output 2.1 liters/min; systemic vascular resistance 4,409 dynes sec cm^{-5}; stroke work 27 g-m/beat; and coronary sinus flow 75 ml/min. Immediately after occlusion there was a reduction in systolic pressure, left ventricular dP/dt, cardiac output, stroke work and coronary sinus flow. Coronary sinus flow values returned to normal during the occluded period in association with progressive improvement in all hemodynamic functions. However, there was progressive deterioration of lactic acid metabolism and potassium loss in the occluded and nonoccluded zones during the period of occlusion.

control value in this series was 7 mm Hg, and it reached 11 mm Hg at 3 hours of occlusion. By comparison, the sham series had smaller and nonsignificant changes in left ventricular end-diastolic pressure. Of the 34 dogs, 27 experienced an increase and 4 a decrease and 3 no change in left ventricular end-diastolic pressure during the course of occlusion. Only four dogs sustained a rise in left ventricular end-diastolic pressure above the level of 18 mm Hg after occlusion.

Maximal left ventricular dP/dt: Five minutes after occlusion, the maximal rate of rise of left ventricular pressure (dP/dt) had decreased significantly from a preocclusion mean control level of 2,840 to 2,270 mm Hg/sec (20 percent). Between 30 minutes and 3 hours of occlusion dP/dt fluctuated and averaged 2,310 mm Hg/sec at the end of the occlusion period. By comparison, the sham series had no significant change in dP/dt. Twenty of the study dogs had a decrease of more than 20 percent at the end of 3 hours of occlusion; the remaining 14 showed little change or a slight increase in dP/dt.

Cardiac output: Thirty minutes after occlusion, mean cardiac output had decreased 19 percent relative to the preocclusion control level. After this early reduction, cardiac output fluctuated somewhat, but at the end of the 3 hour occlusion period remained 15 percent below the control level. In the sham group, at equivalent measurement periods, cardiac output fluctuated near the control level. Fifteen of the 34 dogs sustained a reduction in cardiac output of more than 25 percent; in 8 dogs cardiac output occasionally exceeded the preocclusion control level.

Cardiac stroke work: Occlusion of the left anterior descending coronary artery caused an early reduction in mean stroke work (26 percent) which after 3 hours dropped further to 31 percent below control level. Increasing heart rate accounts for some of the reduction in stroke work. The sham group exhibited fluctuations, with a maximal reduction of 18 percent due to the increased heart rate. After occlusion, 11 of the 34 dogs had a sharp reduction in stroke work exceeding 45 percent, another 11 had a reduction exceeding 25 percent; only 1 dog showed an increase. Reduction in stroke work was not always related to increased heart rate; stroke work diminished 15 to 30

percent after occlusion in 15 animals that did not have an increased heart rate.

Systemic vascular resistance: Shortly after occlusion, mean systemic vascular resistance increased from 3,740 to 4,520 dynes sec cm^{-5} (21 percent). This early increase was followed by fluctuations, but at the end of the 3 hour occlusion period systemic vascular resistance was still 14 percent above control level. The sham group showed a transient mild increase at 30 minutes and 2 hours, but values returned to control levels at 3 hours. Immediately upon occlusion, 12 of the 34 dogs had a sharp increase of 59 percent in systemic vascular resistance. A more gradual increase occurred in 10 dogs. Systemic vascular resistance decreased in four dogs and remained unchanged in five.

Coronary sinus flow: During the control period, mean coronary sinus blood flow in 15 dogs was 125 ml/min, and after 3 hours was 108 ml/min. Six dogs sustained a marked and persistent decrease of 22 to 33 percent in coronary sinus flow immediately after occlusion. Five dogs showed no change, whereas four others had an initial decrease but a return to control levels at the end of 3 hours (Fig. 4). Four dogs had an increase in coronary sinus flow during the occlusion period (Fig. 3). In two of these, the increased flow was related to increased heart rate.

Coronary arterial pressure and sampling distal to the occlusion: Coronary arterial pressure dropped sharply as a result of acute occlusion of the left anterior descending coronary artery. Progressive changes in coronary arterial pressure were noted. It was necessary to analyze the individual diastolic and systolic phases in coronary arterial pressure. Although the average systolic coronary arterial pressure increased from 42 to 50 mm Hg, individual experiments revealed fluctuations ranging from 35 to 70 mm Hg. Diastolic coronary arterial pressure increased from 16 to 18 mm Hg during 3 hours of acute occlusion, indicating little increase in the preexisting collateral circulation.

Blood sampled from beyond the area of occlusion was found to be arterialized with a mean oxygen saturation of 90 to 96 percent.

II. Metabolism

Lactate balance: In the nonoccluded segment, mean lactate balance (arteriovenous [a-v] difference/arterial [A] × 100%) was 34.4 percent during the preocclusion control period and decreased significantly to 23.5 percent after 5 minutes of occlusion of the proximal left anterior descending coronary artery (Fig. 2). Subsequently, the lactate balance fluctuated but, after 3 hours of occlusion, mean lactate balance in this zone was 23.7 percent. This suggests that the metabolism of the nonoccluded segment is adversely affected. Study of individual lactate balances of the nonoccluded area revealed that, immediately after occlusion, abnormal lactate metabolism occurred in 22 animals and lactate production in 7; lactate balance remained normal in 5 dogs.

Lactate balance in the occluded zone decreased significantly from a mean preocclusion control level of 25 percent to 6.1 percent within 5 minutes, and to −1.0 percent after 30 minutes of occlusion (Fig. 2). The latter value indicates lactate production in the occluded zone. Lactate balance of this zone fluctuated thereafter, and after 3 hours of occlusion was +7.8 percent. In 17 dogs the occluded zone exhibited lactate production early in occlusion and in 17 others, abnormal lactate metabolism.

The metabolic derangements of the occluded zone were more pronounced than those of the nonoccluded segment. The difference between the lactate balance in the two segments was statistically significant throughout the period of occlusion.

Myocardial potassium balance: a-v difference fluctuated somewhat during the 3 hour occlusion period, but a loss of potassium was noted in both zones (Fig. 2 to 4). Within the first 5 minutes of occlusion, there was a large potassium loss (greater than 0.5 mEq/liter), from the occluded segment in 11 dogs and from the nonoccluded zone in 2. In the remaining 3 hours of occlusion, potassium loss from the occluded zone occurred in 17 dogs and from the nonoccluded segment in 12. The greatest potassium loss from any occluded segment was 1.35 mEq/liter. In this animal there was no significant potassium loss from the nonoccluded zone. The greatest potassium losses were noted from both occluded and nonoccluded zones when arrhythmias occurred.[1]

Oxygen extraction: Regional oxygen arteriovenous differences were measured in the zones of the left ventricle perfused by the left anterior descending and left circumflex coronary arteries. Control oxygen extraction values were 57 percent in both areas (Table I). During the initial period of occlusion, there was a 6 to 8 percent increase in oxygen extraction relative to control values in both regions and, for the remaining 3 hours of occlusion, oxygen extraction values in both zones remained at about this level.

III. Histopathology

After 3 hours of occlusion of the left anterior descending coronary artery, the hearts were excised and examined, and sections were subsequently stained with hematoxylin-eosin for light microscopy study. Sections of myocardium from the anterior left ventricles exhibited only mild peripheral vascular congestion and a faint suggestion of increased eosinophilic staining of myocardial fibers. Nuclei and individual fibers appeared intact. There was no inflammatory response. Sections of the myocardium from one dog showed mildly increased granularity of myocardial fibers, and, at the periphery, occasional margination of leucocytes was seen.

Discussion

The closed chest Corday-Lang model[1] used in this series provided simultaneous data on hemo-

dynamic status and regional metabolism during 3 hours of acute occlusion of the proximal left anterior descending coronary artery.

Regional Metabolic Effects

Metabolic data gathered simultaneously from the occluded as well as the nonoccluded segments of the left ventricle are essential to the study of regional effects of coronary occlusion. Many studies have used the coronary sinus effluent to represent events occurring in the ischemic zone after coronary occlusion.[3-5] However, data based on blood sampling in the coronary sinus alone represents mixed venous drainage from both the left anterior descending and left circumflex arteries and therefore cannot be used to study regional mechanisms.[6,7] Our new method of separately sampling the great cardiac vein draining the segment perfused by the left anterior descending coronary artery allowed assessment of the metabolic function of that zone, while simultaneous sampling from the coronary sinus represented function of the nonoccluded myocardium mainly perfused by the left circumflex artery.[1]

When myocardial lactate balance is less than 20 percent, most investigators consider that this is a sign that abnormal lactate metabolism has occurred.[4,5] There is general agreement that negative balance signifies lactate production. In the current study, data obtained from the occluded zone revealed a significant metabolic derangement within 5 minutes of occlusion, as evidenced by a reduction in mean lactate balance from 35.0 to 6.1 percent. The lactate balance in the occluded zone deteriorated further to production levels and remained abnormal throughout the occlusion period.

An unexpected and important finding was that the nonoccluded zone showed significant reduction of lactate extraction within a few minutes of occlusion in 65 percent of the dogs (Table I, Fig. 2). Lactate balance remained depressed thereafter, and in 20 percent of the animals reached production levels (Fig. 2 to 4). For example, in three animals, lactate balance decreased from a normal extraction value of 30 to 45 percent to production levels of −15 to −19 percent (Fig. 3, 4). Recently investigators[9] have reported other indications of metabolic dysfunction of the nonoccluded region when they observed a marked reduction in adenosine triphosphate (ATP) and creatine phosphate (CP) levels after occlusion.[9] A direct correlation was noted between the depressed ATP levels and reduced left ventricular stroke work and dP/dt. It was postulated that this metabolic derangement is caused by a depletion of tissue catecholamines.[10]

Detailed comparison of data from the occluded and nonoccluded zones revealed that, although abnormal lactate metabolism and potassium loss occurred in both areas, a far greater derangement occurred in the occluded region. Our experiments seldom confirmed the direct quantitative relation between potassium loss and lactate production reported by other investigators.[4,8] Our data also contrast with those of other workers who demonstrated similar potassium and lactate levels in the great cardiac vein and coronary sinus.[7] They found a significant increase only in a local vein draining a small area of infarction in the zone perfused by the left anterior descending coronary artery. We believe that the effluent from a small infarction is substantially diluted by other venous flow from nonoccluded myocardium before reaching the great cardiac vein, precluding true metabolic assessment of the ischemic zone by great cardiac vein or coronary sinus sampling. By contrast, our study reports data from a more extensive ischemic region secondary to occlusion of the proximal left anterior descending coronary artery. Also, the effluent from the ischemic zone (great cardiac vein) is temporarily separated during sampling from the nonischemic region (coronary sinus) by inflating a balloon within the great cardiac vein. Thus, measurements of metabolic function from the two zones are distinctly regional. Although some overlap or shunting might be expected between the occluded and nonoccluded segments and might possibly affect measurements during temporary occlusion of the great cardiac vein, we believe that such contamination was minimal because we noted distinct differences in both potassium and lactate balances between the two zones.

Hemodynamic Events

The mean hemodynamic response during the first 5 to 30 minutes of occlusion of the left anterior descending coronary artery was a significant change in cardiac function: left ventricular end-diastolic pressure increased 43 percent, maximal left ventricular dP/dt decreased 20 percent, cardiac output decreased 19 percent, stroke work was reduced 26 percent, and systemic vascular resistance increased 21 percent. These changes were significant relative to the sham animal results. Further alterations in mean hemodynamic measurements up to 3 hours of occlusion were relatively minor; however, heart rate increased (18 percent) and systemic vascular resistance showed a partial return in the direction of control values. Study of individual dogs revealed differing and often conflicting trends. Thus, systemic vascular resistance would occasionally markedly increase or decrease during the 3 hours of occlusion, and the related change in left ventricular afterload may be responsible for the fluctuations noted in cardiac output and other hemodynamic variables. Left ventricular end-diastolic pressure remained increased and maximal left ventricular dP/dt depressed in most cases, but there were instances of reduced left ventricular end-diastolic pressure and alterations in left ventricular dP/dt that could not be correlated with other indexes of cardiac function. We conclude that the dynamics of the occlusion process cannot be fully comprehended by studying only the statistical results, and that consideration of individual case data is equally important in studies of occlusion mechanisms.

Coronary Circulation

In contrast to previous reports that a compensatory increase in coronary arterial blood flow occurs in

the nonoccluded segment of the myocardium during occlusion of an adjoining artery,[11,12] our preliminary regional coronary flow measurements revealed that venous blood drainage from the nonoccluded myocardium was actually reduced 10 to 15 percent after occlusion of the left anterior descending artery.[13] This discrepancy may be due to differences in measurement techniques and preparations used. A reduction in coronary flow could be due to reflex angiospasm, associated hypotension or increased coronary resistance resulting from compensatory hypercontraction causing increased muscle tension in the nonoccluded segment. We postulate that the metabolic derangements in the nonoccluded myocardium can be attributed to a combination of reduced regional coronary blood flow, in association with increased oxygen demands due to regional compensatory hypercontraction or increased left ventricular afterload.

Study of the progressive alterations in coronary arterial pressure measured distal to the occlusion of the left anterior descending artery led to detailed analysis of the systolic and diastolic phases of coronary arterial pressure. Only the diastolic phase of coronary arterial pressure can be used as an approximate index of the coronary collateral circulation. In many instances, the level of coronary arterial pressure depends on the pressure differential between anastomosing occluded and nonoccluded coronary arteries. In contrast, the systolic pulse of coronary arterial pressure is greatly influenced by ventricular muscle tension and exhibits fluctuations that tend to correspond to those in left ventricular pressure during the occlusion period. It is well known that during arrhythmias coronary arterial pressure reflects systemic pressures.[14] When the level of systemic pressure drops critically during arrhythmias, this coronary arterial pressure, which reflects the coronary collateral circulation to the occluded zone, is also critically reduced.

In this study, the diastolic phase of coronary arterial pressure increased only slightly, suggesting that coronary collateral circulation distal to the occlusion did not improve significantly. Our metabolic studies indicate that the collateral circulation is unable to alleviate the metabolic dysfunction of the occluded region.

Clinical implication: Occlusion of the proximal left anterior descending coronary artery usually resulted in significant and immediate, although sometimes temporary, deterioration in global mechanical and hemodynamic function. At the same time, metabolic function was depressed in both nonoccluded and occluded myocardial regions and an anaerobic state often supervened in the latter zone. In the ensuing 3 hours of observation, mean measurements of metabolic and hemodynamic function generally did not show significant improvement. There were considerable fluctuations suggesting the influence of dynamic processes. Individual experiments occasionally showed progressive improvement in mechanical function even though regional metabolism remained depressed or an anaerobic state developed (Fig. 3, 4). Conversely, deterioration in hemodynamic function was noted in some experiments in which metabolism remained normal (Fig. 4). Thus, metabolic and mechanical functions after coronary occlusion may follow opposing trends. Examination of individual factors such as heart rate and systemic vascular resistance suggested that each of these can cause derangements of either mechanical or metabolic function in specific experiments. In some instances the heart appeared to contract well and maintain hemodynamic status during short periods of anaerobic metabolism. A phase lag between metabolic and mechanical myocardial events may be implicated. The period of these observations was admittedly limited and, therefore, the significance of such mechanical-metabolic dissociations is not clear.

It is possible that measurement of mechanical function of the left ventricle locally, rather than "globally," might clarify these idiosyncrasies and explain mechanisms. Unfortunately, our series did not provide sufficient data on regional mechanics. To adapt the Corday-Lang model to perform regional measurements of myocardial forces and strains, we are attempting to develop more suitable miniature gauge instrumentation.[1]

An increase in heart rate was generally observed, and short-lived arrhythmias were occasionally encountered in the early period of occlusion. These arrhythmias were often, but not always, associated with increased potassium efflux from both normal and occluded segments. The anaerobic state did not seem to be associated with onset of arrhythmias; however, spontaneous arrhythmias usually induced severe metabolic dysfunction of both the ischemic and nonischemic myocardium.

The most striking finding in this study was the significant metabolic dysfunction, manifested by disturbed regional lactate metabolism and potassium loss, that occurred in the nonoccluded segment after the occlusion period. This segment is usually assumed to remain normal after a remote coronary occlusion. In the study reported next,[15] involving the same model and 3 hours of occlusion of the proximal left anterior descending coronary artery, subsequent reperfusion caused an immediate and major "washout" of metabolites from the nonoccluded as well as the occluded zones. Further study is required to determine whether this "washout" related to the accumulation of metabolites in the cell and interstitial spaces during occlusion.

The depressed metabolic function of the nonoccluded segment may be attributed, in part, to the tentatively established decrease in regional coronary flow. However, it might be due to increased oxygen demands in this zone resulting from increased left ventricular afterload caused by greater aortic impedance or compensatory hypercontraction of the nonoccluded zone, or both. Thus, the coronary blood supply of the nonoccluded segment may be insufficient to maintain normal metabolic function. The latter observations are in accord with recent reports indicating metabolic derangements of adenosine triphosphate and creatine phosphate in the noninfarcted

zones,[9,10] as well as decreased coronary arterial flow in the remote nonoccluded segment.[16]

Simultaneous oxygen percent saturation measurements in the aorta and in the temporarily separated two venous drainages, from the occluded and nonoccluded segments of the left ventricle, indicated an approximate 6 to 8 percent increase in oxygen extraction during the occlusion in both myocardial segments. These measurements may be interpreted differently for the two regions: (1) In the occluded zone, the ischemic myocardium attempts to extract more oxygen to compensate for the significantly reduced coronary flow; and (2) in the nonoccluded zone, the higher level of extraction may be attributed to a compensatory hypercontraction of the nonoccluded segment,[17,18] increased left ventricular afterload associated with increased systemic vascular resistance, and relative ischemia and metabolic derangements caused by a decreased regional coronary flow.

These metabolic alterations in myocardial function in the nonoccluded area during coronary occlusion should be considered important because, after 3 hours of occlusion, damage in the central occluded zone may be irreversible, whereas myocardium may be salvageable in the border zone and also in the all-important nonoccluded segment, now known to be jeopardized. The genesis of cardiogenic shock is still unknown. It is possible that the compromised metabolic function of the still viable myocardium described here may play a principal role in establishing a series of vicious cycles. When a shock state occurs, pharmacologic and circulatory assist interventions may restore function to this nonoccluded segment, whereas function of the occluded zone cannot be restored. This new concept of the involvement of the nonoccluded segment may provide a better understanding of the genesis and treatment of cardiogenic shock.

Consequences of Reperfusion After Coronary Occlusion

Effects on Hemodynamic and Regional Myocardial Metabolic Function

Hemodynamic and regional metabolic measurements were obtained in seven closed chest dogs during a control period, 3 hours of coronary occlusion and 5 hours of reperfusion. Reperfusion resulted in intermittent ectopic arrhythmias in five dogs and severe shock in two. It usually caused increases in heart rate, coronary sinus flow and maximal isovolumetric rate of rise in left ventricular pressure (dP/dt), which were associated with a decrease in systemic pressure, left ventricular end-diastolic pressure, systemic vascular resistance and stroke work. A transitory increase in cardiac output occurred. Global myocardial oxygen consumption, which was reduced during occlusion, increased with reperfusion. Reperfusion induced abnormal lactate metabolism and myocardial potassium loss in the previously occluded area and often in the nonoccluded segment as well. Histopathologic changes of accelerated necrosis, reactive hyperemia and hemorrhage were often noted after reperfusion.

These studies indicate that reperfusion after 3 hours of occlusion caused serious abnormalities in hemodynamic states, metabolic function and morphologic features of the heart.

Although the progressive alterations in cardiac function after coronary occlusion have been studied[1], only limited data are available on the effects of reperfusion on metabolic and mechanical function.[2-4] A common goal of investigators is to determine whether injury to myocardial tissue can be reversed by reperfusion after various periods of coronary occlusion. Debate persists about the criteria of myocardial viability after coronary occlusion, particularly with regard to temporal relations.[5-12] At low temperatures and drastically reduced metabolic demands, myocardial tissue may survive for as long as 24 hours without its coronary supply, whereas at normal body temperatures, the damage caused by occlusion for 20 to 180 minutes might not be reversed by reperfusion.[5,9] Clearly, viability depends upon many factors whose elucidation requires sophisticated measurements and improved models. Insight into mechanisms of viability should be derived by studying the metabolic and hemodynamic indexes of myocardial function. It is of great importance to determine whether cardiac dysfunction can be reversed by reperfusion. The scope and time course of regional and global myocardial alterations during coronary occlusion and subsequent reperfusion are of interest to the cardiac surgeon and clinician who need to establish the time during which revascularization might still restore cardiac function and viability.

Viability of cardiac muscle has largely been studied by histopathologic and histochemical methods.[7-9] However, because study of tissue morphology alone does not adequately resolve the issue of myocardial viability, further extensive studies are deemed necessary to fill in the gaps in our knowledge and to correlate the pathologic, mechanical, hemodynamic, electrophysiologic and metabolic effects of

reperfusion after coronary occlusion. Recent studies of reperfusion used epicardial S–T segment mapping in the open chest and measurement of alteration in myocardial enzymes to demonstrate the extent of myocardial injury.[3,13,14]

In this study we attempted to establish the effects of reperfusion on hemodynamic and regional metabolic functioning of the left ventricle. We believe that applicable information can be derived from controlled animal experiments when adequate physiologic simulation is feasible. The main questions we hope to answer are how reperfusion affects the occluded and nonoccluded segments of the myocardium, and whether adverse functional and morphologic derangements occur that might complicate the course of myocardial recovery.

Methods and Procedures

The study was carried out in seven anesthetized, closed chest dogs weighing 30 to 35 kg. The application of intracoronary balloon catheters for occlusion of a specific coronary artery and for simultaneous measurement of hemodynamic status, myocardial blood flow and regional myocardial metabolism has been described.[1,15] Blood volume depleted through blood sampling and fluid losses was replaced by infusion of physiologic saline solution at a rate of 75 to 100 cc/hour.

Acute occlusion of the proximal left anterior descending coronary artery was performed through inflation of an intracoronary balloon at the tip of a special no. 4F catheter.[15] The methodology of this intracoronary occlusion procedure and the collection of blood samples from the great cardiac vein and coronary sinus, and simultaneous measurement of hemodynamics, were fully described as the Corday-Lang model.[15] Deflation of the balloon and removal of the intracoronary catheter provided total reperfusion of the coronary artery. Regional myocardial, metabolic and coronary flow measurements were achieved by the previously described technique of temporary separation of venous compartments through inflation of a balloon placed in the great cardiac vein.[1,15]

Cardiac function was measured in a preocclusion control period, after a 30 minute stabilization period, at intervals of 5, 30, 60, 120 and 180 minutes during occlusion of the left anterior descending coronary artery, and 1, 30, 60, 120, 180, 240, and 300 minutes after reperfusion. After completion of 3 hours of occlusion and 5 hours of reperfusion, each heart was excised. After gross examination to insure the absence of arterial or venous thrombosis, the area of gross infarction was delineated and tissue sections of the occluded and nonoccluded zones were prepared for light microscopy using standard and specialized stains.

Results

Hemodynamic data of seven closed chest dogs obtained during a preocclusion control period, 3 hours of proximal occlusion of the left anterior descending coronary artery and 5 hours of reperfusion are presented in Table I. Percent changes from the preocclusion control values are shown in Figures 1 through 4; both mean statistical results and individual data

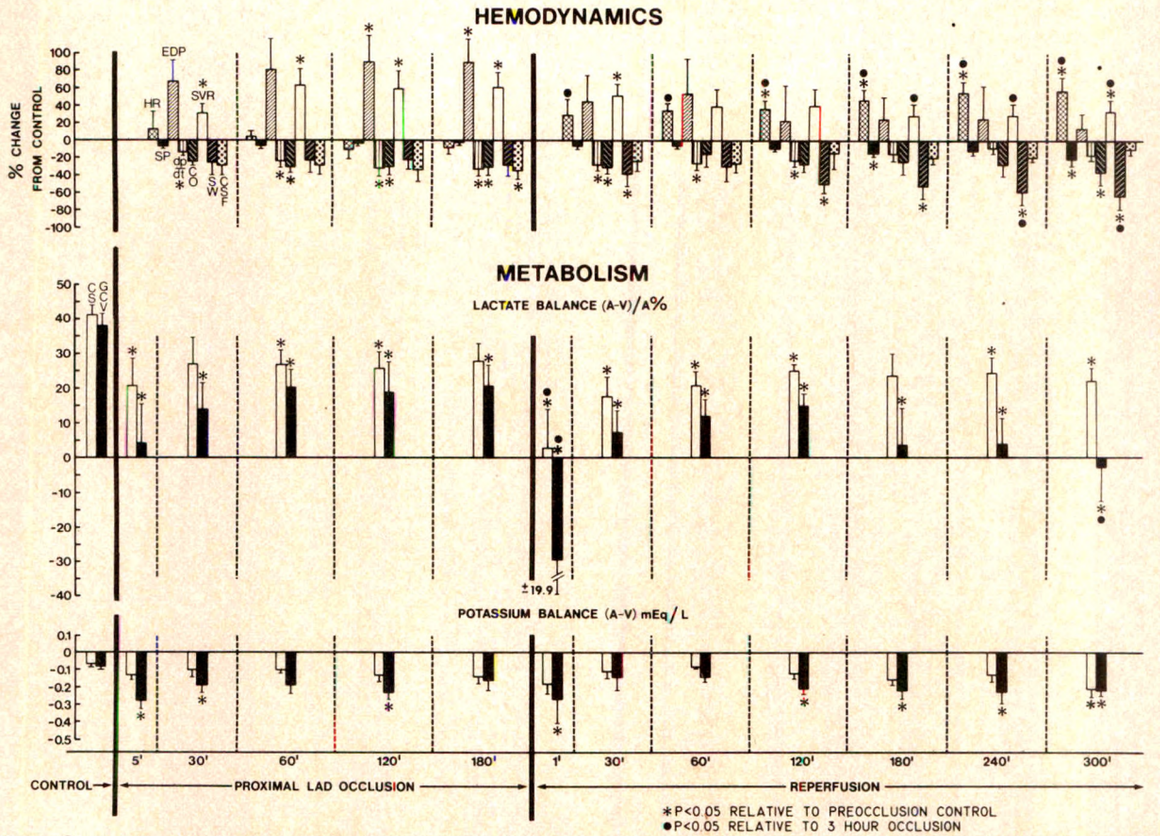

FIGURE 1. Composite statistical summary (seven dogs) of hemodynamic and metabolic measurements (lactate and potassium balances) during a control period, 3 hours of occlusion and 5 hours of reperfusion. The **top bar graph** demonstrates the percent change from the base-line control values. Control measurements were heart rate (HR) 109 beats/min; systolic pressure (SP) 136 mm Hg; left ventricular end-diastolic pressure (EDP) 6 mm Hg; left ventricular dP/dt (dp/dt) 2,740 mm Hg/sec; cardiac output (CO) 3.3 liters/min; systemic vascular resistance (SVR) 2,720 dynes sec cm^{-5}; stroke work (SW) 47 g-m/beat; coronary sinus flow (CSF) 179 ml/min. Significant changes during the occlusion period were an increase in left ventricular end-diastolic pressure and systemic vascular resistance and progressive decreases in cardiac output, left ventricular dP/dt, stroke work and coronary sinus flow. With reperfusion there was a further decrease in stroke work because of increased heart rate, and systolic pressure, cardiac output, systemic vascular resistance and left ventricular end-diastolic pressure also decreased. Left ventricular dP/dt increased despite the reduced cardiac output. Five minutes after coronary occlusion there was a change from normal lactate extraction to abnormal lactate metabolism in the occluded and nonoccluded segments. During the reperfusion period there was an initial lactate washout from both segments. Three to 5 hours after reperfusion there was further deterioration as evidenced by lactic acid production in the occluded zone although the coronary flow had returned toward normal. There was a large potassium loss from the occluded area and a smaller loss from the nonoccluded zone almost immediately after occlusion. The potassium loss continued 2 to 5 hours after reperfusion. (A-V)/A = arteriovenous difference/arterial; CS = coronary sinus; GCV = great cardiac vein; LAD = left anterior descending coronary artery.

are presented. Hemodynamic fluctuations necessitated averaging of measurements during periods of arrhythmias.

The measurements include heart rate, peak systolic aortic pressure, left ventricular end-diastolic pressure, maximal isovolumetric rate of rise in left ventricular pressure (dP/dt), cardiac output, systemic vascular resistance, cardiac stroke work and total coronary sinus flow. Regional metabolic data during control, coronary arterial occlusion and reperfusion periods are reported for myocardial segments perfused by the left anterior descending and left circumflex coronary arteries, respectively. These regional measurements, presented in Table II, include percent lactate balance, ([arteriovenous (a-v)/arterial] × 100), a-v difference in potassium balance, percent oxygen extraction (arteriovenous oxygen saturation) and total myocardial oxygen consumption. The progressive alterations in lactate and potassium balances are shown in Figures 1 through 6. Coronary sinus flow measurements and left ventricular myocardial oxygen consumption measurements were performed in five of the seven dogs. Individual experiments are also presented (Fig. 2 to 4). Residual myocardial potassium and histopathologic findings and their significance are reviewed in the Discussion.

Hemodynamics

Heart rate: During the 3 hours of occlusion of the left anterior descending coronary artery, heart rate fluctuated and reached a value 8 percent below the preocclusion control value (Fig. 1, Table I). Immedi-

ately after reperfusion, heart rate rose to 29 percent, and after 5 hours was 57 percent above the control value. This corresponds to a 41 percent and 71 percent rise, respectively, above the 3 hour occlusion level.

Individual results were variable. Heart rate increased markedly during the occlusion period in one dog, decreased in three and remained near control level in three. After 5 hours of reperfusion, heart rate was substantially increased in six of the seven dogs (Fig. 3, 4). In six dogs, reperfusion caused arrhythmias consisting principally of sinus tachycardia, multifocal premature systoles, slow ventricular rhythm and intermittent and sustained ventricular tachyarrhythmias.

Peak systolic pressure: Mean peak systolic pressure decreased 6 percent below control level 5 minutes after occlusion of the left anterior descending coronary artery and then remained near control level throughout the 3 hour period of occlusion. Reperfusion caused a gradual further decrease in this mean pressure until it was 21 percent below control level at the end of 5 hours of reperfusion, or 20 percent below the value obtained at 3 hours of occlusion.

During occlusion, the systolic pressure decreased in two dogs, increased in one and remained essentially unchanged in the other four. After 5 hours of reperfusion, a substantial reduction in peak systolic pressure occurred in three of the seven dogs, and in two reached shock levels, defined as a reduction in both systolic pressure and cardiac output to 30 percent below control levels (Fig. 4).

Left ventricular end-diastolic pressure: Mean left ventricular end-diastolic pressure was 6 mm Hg in the control period and increased 89 percent after 3 hours of occlusion. Reperfusion resulted in a decrease to near control level at the end of the 5 hour period (Fig. 1, Table I). This represents a 45 percent decrease from the 3 hour occlusion level.

In four of the seven dogs, left ventricular end-diastolic pressure remained increased after occlusion, and in one dog it increased to a high value of 31 mm Hg (Fig. 4). The increased values usually returned to normal after reperfusion. In three dogs they remained substantially below control levels during the reperfusion period even though fluid replacement of 75 to 100 cc/hour was maintained throughout the 8 hour period.

Maximal left ventricular dP/dt: Maximal left ventricular dP/dt dropped gradually to 33 percent below control level at the end of 3 hours of occlusion of the left anterior descending coronary artery. After 5 hours of reperfusion, there was a rise to 23 percent above the 3 hour occlusion value, corresponding to 17 percent below control level (Fig. 1, Table I).

During occlusion, maximal left ventricular dP/dt was substantially depressed in five of the seven animals. After 5 hours of reperfusion, it returned to nor-

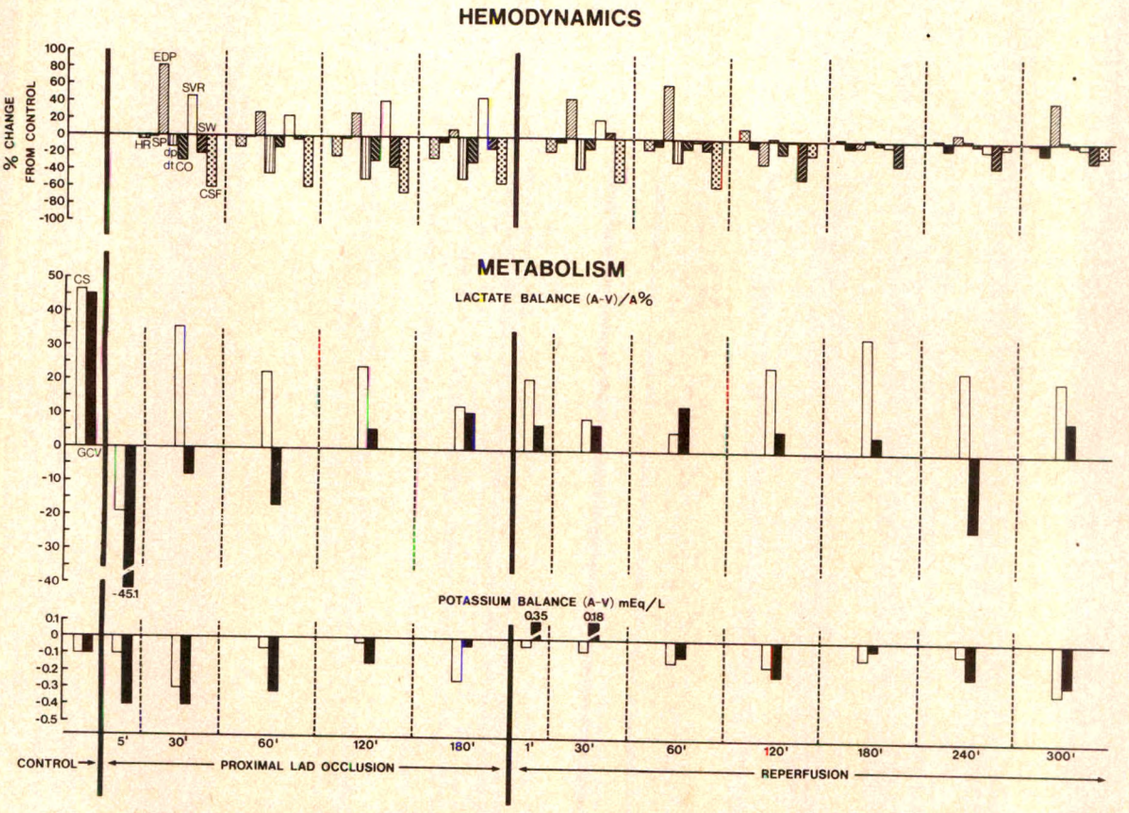

FIGURE 2. Hemodynamic and metabolic data obtained in a dog during 30 minute control period, after 3 hours of occlusion of the left anterior descending coronary artery and 5 hours of reperfusion. The control hemodynamic measurements were heart rate 118 beats/min; systolic pressure 131 mm Hg; left ventricular end-diastolic pressure 6 mm Hg; left ventricular dP/dt 3,400 mm Hg/sec; cardiac output 2.83 liters/min; systemic vascular resistance 2,835 dynes sec cm^{-5}; stroke work 35 g-m/beat; coronary sinus flow 203 ml/min. Immediately upon occlusion lactic acid production occurred in both the occluded and nonoccluded segments and there was a significant potassium loss in the occluded zone. There was some improvement in the lactic acid and potassium balances over the next 3 hour period. However, heart rate, left ventricular dP/dt, cardiac output, stroke work and coronary sinus flow were reduced as systemic vascular resistance increased. With reperfusion there was no lactate or potassium washout. During the next 5 hours of reperfusion hemodynamic function improved; however, lactic acid production and potassium loss returned in the occluded zone. Abbreviations as in Figure 1.

mal in three dogs (Fig. 2) and deteriorated further in four others (Fig. 4). A disparity was occasionally noted between maximal left ventricular dP/dt, cardiac output and left ventricular end-diastolic pressure, particularly during experiments in which shock occurred.

Cardiac output: The mean cardiac output was reduced 30 percent after 3 hours of occlusion. Immediately after reperfusion it averaged 11 percent below control level, and after 5 hours of reperfusion it was reduced to 36 percent below control level, that is, an 8 percent decrease relative to the value at the end of the occlusion period (Fig. 1, Table I).

Two animals sustained a 55 to 65 percent reduction in cardiac output, became markedly hypotensive and experienced shock after reperfusion (Fig. 4). Two other dogs that did not become hypotensive had a reduction in cardiac output of 41 and 51 percent, respectively.

Systemic vascular resistance: Mean systemic vascular resistance increased 16 percent immediately after occlusion and increased to 63 percent above control level after 3 hours of occlusion. During 5 hours of reperfusion, systemic vascular resistance fluctuated downward to about 33 percent above control level, or 17 percent below the final occlusion value.

In four normotensive dogs, systemic vascular resistance increased 32 to 80 percent above control level at 5 hours of reperfusion. In two dogs, it dropped below control level. In one dog, the decrease in systemic vascular resistance was associated with a reduction in cardiac output (Fig. 2); in the other, cardiac output showed an increase (Fig. 3). Of the two dogs with shock, one had a reduction and the other an increase in systemic vascular resistance (Fig. 4).

Stroke work: Stroke work was reduced after 3 hours of occlusion of the left anterior descending coronary artery and decreased further to 64 percent below control level at the end of the 5 hour reperfusion period, a 50 percent reduction below the 3 hour occlusion level. This reduction was usually associated with an increase in heart rate (Fig. 1, Table I).

Two animals that experienced shock sustained a marked decrease in stroke work, to 84 and 88 percent, respectively, below control values (Fig. 4).

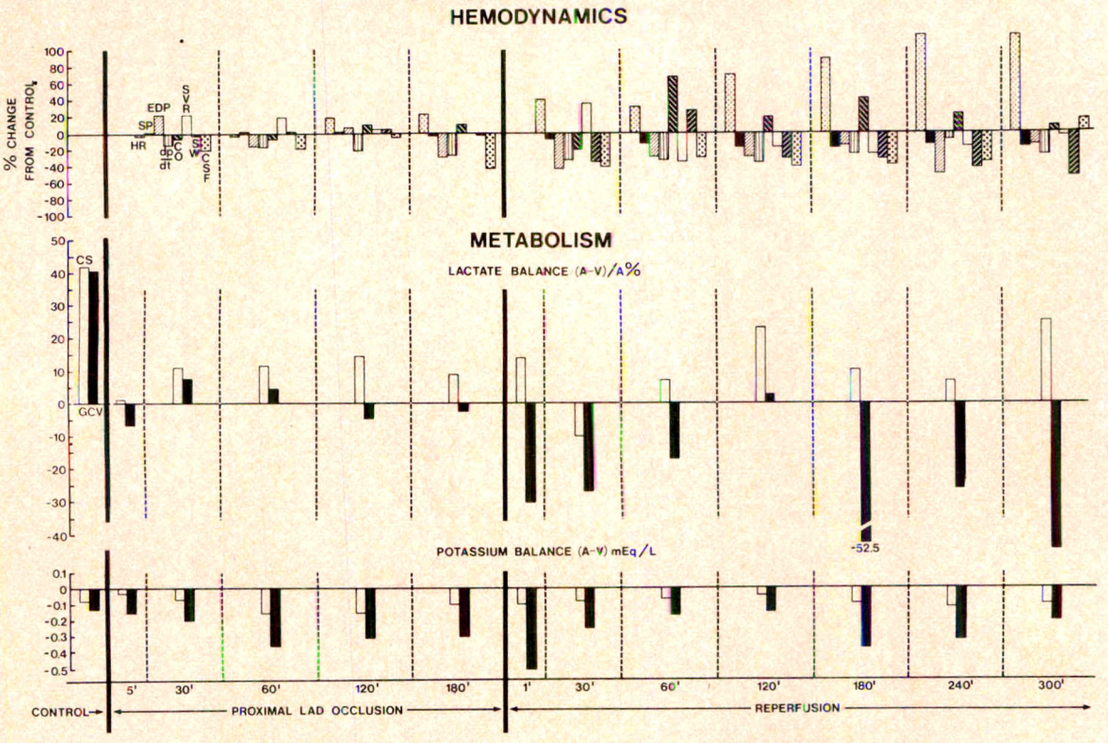

FIGURE 3. Hemodynamic, lactate and potassium measurements in a dog during a 30 minute control period, 3 hours of occlusion of the left anterior descending coronary artery, and 5 hours of reperfusion. Base-line hemodynamic data during preocclusion control were: heart rate 83 beats/min, systolic pressure 167 mm Hg, left ventricular end-diastolic pressure 5 mm Hg, left ventricular dP/dt 3,736 mm Hg/sec, cardiac output 3.4 liters/min, systemic vascular resistance 2,820 dynes sec cm^{-5}, stroke work 74 g·m/beat, and coronary sinus flow 182 ml/min. Immediately upon occlusion, abnormal lactate metabolic and potassium loss occurred in the occluded and nonoccluded regions. At the end of 3 hours of occlusion, coronary sinus flow was reduced 40 percent. Left ventricular dP/dt was reduced, whereas cardiac output was maintained slightly above control levels. After reperfusion, a drastic increase in lactate production and potassium loss occurred in the occluded zone, which persisted throughout the 5 hours of reperfusion. Potassium loss and abnormal lactate metabolism occurred to a lesser degree in the nonoccluded zone after reperfusion. At the end of 5 hours of reperfusion, cardiac output was maintained near control levels, but stroke work was sharply reduced because of a rapid heart rate. Coronary sinus flow returned to slightly above control values.

Coronary sinus flow: Total coronary sinus flow was measured in five dogs. It was reduced 21 percent below control level in the early occlusion period and at the end of 3 hours was reduced to 36 percent below control level. After 30 minutes of reperfusion the mean coronary sinus flow was 24 percent below control level. Total coronary sinus flow 5 hours after reperfusion was still 11 percent below the preocclusion control value, which is a 37 percent improvement compared to the value at the end of occlusion (Fig. 1, Table I). In two dogs the coronary sinus flow was increased 10 and 27 percent, respectively, above control levels, immediately after reperfusion, thus suggesting that reactive hyperemia had occurred.

Metabolism

Lactate balance ([a-v difference/arterial] × 100 (%)): Five minutes after occlusion of the left anterior descending coronary artery there was a significant decrease in lactate balance in the occluded region from a preocclusion mean control level of 39 to 4 percent, indicating severely deranged lactate metabolism (Fig. 1, 5, Table II). The nonoccluded segment also exhibited a significant initial decrease in lactate extraction, from 41 to 21 percent. The subsequent 3 hours of occlusion were characterized by some fluctuations in both zones. Three hours after occlusion, lactate balance in the occluded zone increased to 21 percent and in the nonoccluded zone to 28 percent. Immediately upon reperfusion, there was a marked reduction to −30 percent in the occluded zone and to +3 percent in the nonoccluded region. These sudden changes are thought to represent washout of accumulated metabolites. After 5 hours of reperfusion the previously occluded zone exhibited lactate production with a balance of −3 percent; the nonoccluded zone at this time showed a balance of +22 percent (Fig. 1, 5, Table II).

In three dogs, 3 hours of occlusion of the left anterior descending coronary artery resulted in a substantial reduction of lactate balance in the nonoccluded zone (2 to 20 percent) (Fig. 3, 4). All seven dogs exhibited instances of abnormal lactate metabolism, and three showed lactate production in the occluded zone (Fig. 2 to 4). After 5 hours of reperfusion, three of the seven dogs had substantial lactate production in the previously occluded area (Fig. 3); one dog had improved lactate balance. Five of the seven showed improved lactate extraction in the nonoccluded region (Fig. 2 to 4).

Potassium balance (a-v difference): Five minutes of occlusion of the left anterior descending coro-

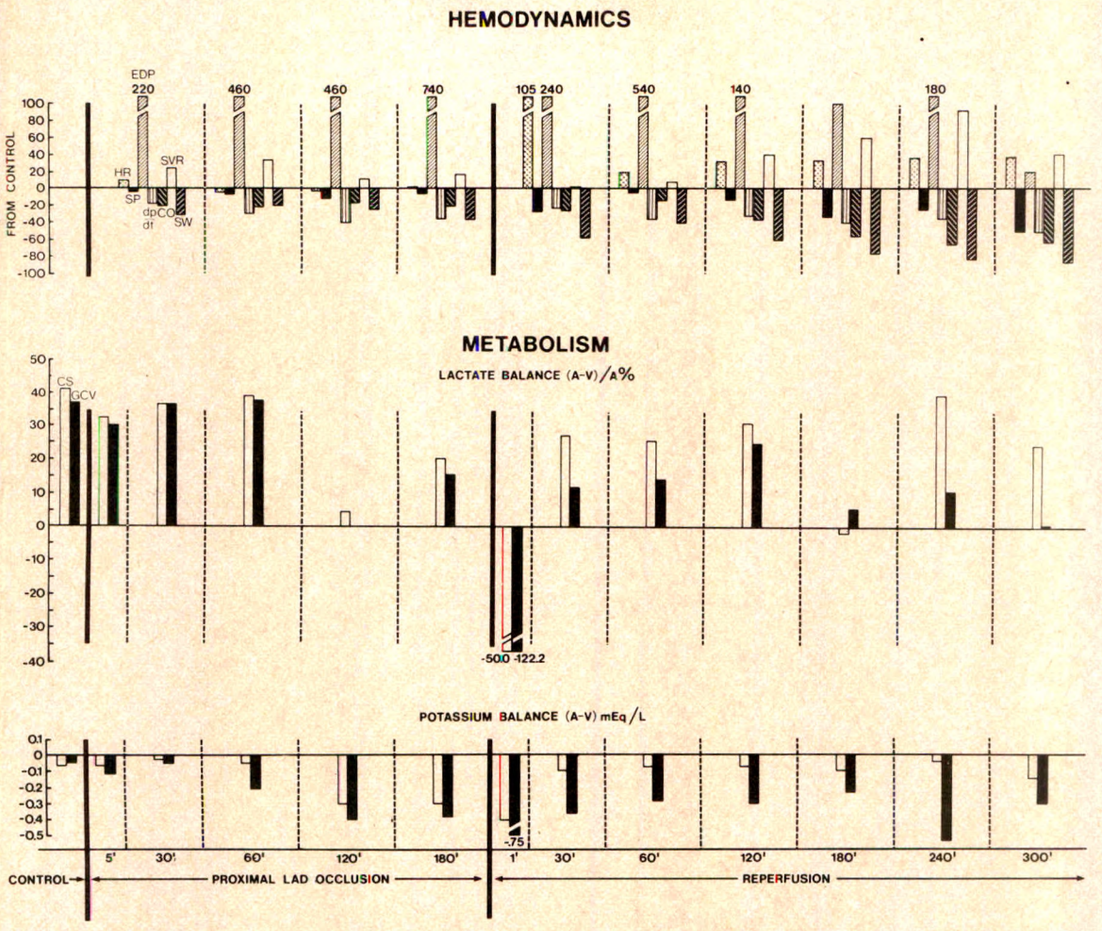

FIGURE 4. Hemodynamic, lactate and potassium data obtained in a dog during a control period, 3 hours of occlusion of the left anterior descending coronary artery and 5 hours of reperfusion. The bars represent percent changes from the control values which were: heart rate 130 beats/min; systolic pressure 151 mm Hg; left ventricular end-diastolic pressure 3 mm Hg; left ventricular dP/dt 2,565 mm Hg/sec; cardiac output 4.7 liters/min; systemic vascular resistance 2,096 dynes sec cm^{-5}; stroke work 67 g-m/beat; coronary sinus flow 229 ml/min. In the late occlusive period there was a large potassium loss from both occluded and nonoccluded zones. With reperfusion, a large lactate and potassium washout occurred. The potassium loss from the occluded segment continued over 5 hours of reperfusion. Shock occurred 3 hours after onset of reperfusion as exhibited by decreases of 40 percent in systolic pressure and 50 percent in cardiac output. Abbreviations as in Figure 1.

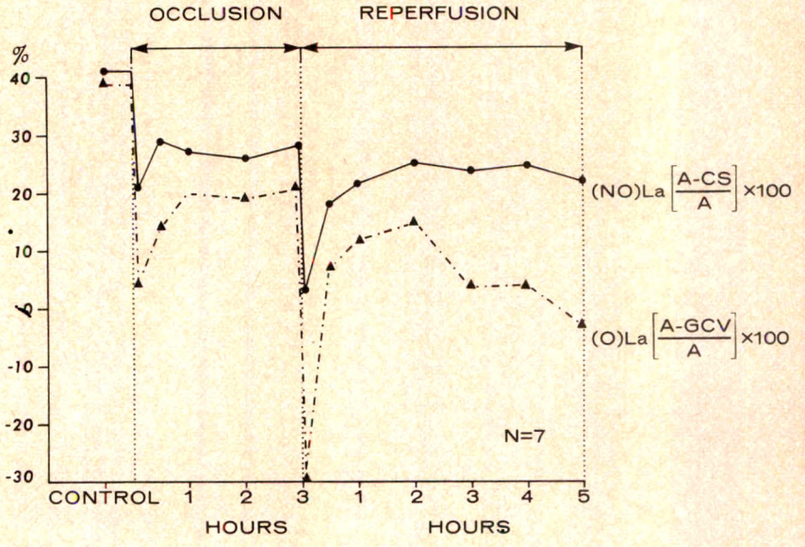

FIGURE 5. Average lactate balances in seven dogs, measured in nonoccluded (NO) (**solid line**) and occluded (O) (**broken line**) areas during a control period, 3 hours of occlusion and 5 hours of reperfusion. Abnormal lactate metabolism occurred immediately after occlusion in both zones. Immediately after reperfusion the lactate acid level was reduced to −30 in the occluded zone and to +3 in the nonoccluded area. This probably represents a washout. During the last 2 hours of reperfusion, lactate metabolism deteriorated in the occluded zone. A = arterial; CS = coronary sinus; GCV = great cardiac vein; La = lactate.

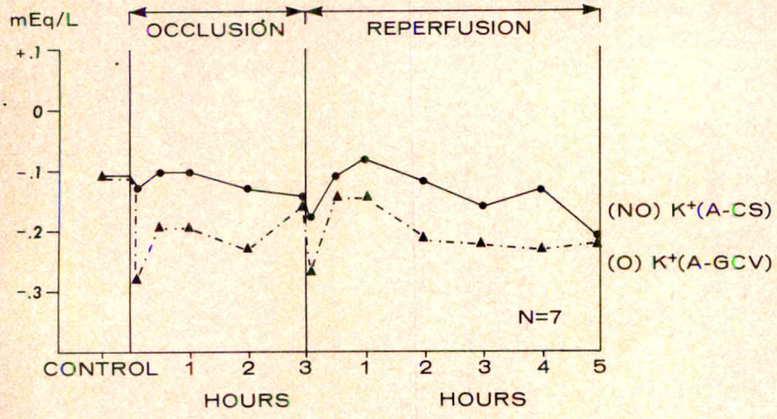

FIGURE 6. Average potassium balance in seven dogs, measured in nonoccluded (NO) (**solid line**) and occluded (O) (**broken line**) zone during a 30 minute control period, 3 hours of occlusion and 5 hours of reperfusion. A large immediate potassium loss from the occluded area after occlusion continued during the 3 hour period. After reperfusion there appeared to be an immediate washout of potassium and later a secondary potassium loss from both zones. Abbreviations as in Figure 5.

nary artery resulted in a significant reduction in potassium balance in the occluded zone from a mean control level of −0.08 to −0.28 mEq/liter, indicating a significant potassium loss (Fig. 1, 6, Table II). Meanwhile, there was only a slight change in the nonoccluded myocardium. During the remaining period of occlusion, a lesser rate of potassium loss occurred in the occluded zone, ranging from −0.16 to −0.23 mEq/liter. Immediately after reperfusion there was a significant loss of potassium from both zones, probably indicating a washout phenomenon. Thereafter, both regions exhibited a small loss of potassium.

A review of individual experiments showed that five of the seven dogs had a major potassium loss from the occluded zone during the first 5 minute period of occlusion, as great as 0.47 mEq/liter. At 3 hours of occlusion, four of the seven dogs had potassium loss from the occluded region, and two also had potassium loss from the nonoccluded zone. After reperfusion, the potassium loss in the previously occluded zone continued (Fig. 3, 4), but at lesser levels in three animals. Two animals began to lose potassium from both occluded and nonoccluded zones 5 hours after reperfusion (Fig. 2).

Regional oxygen extraction (a-v difference): During the 3 hour occlusion of the left anterior descending coronary artery, there was evidence of a slight (5 percent) increase in oxygen extraction in both the occluded and nonoccluded regions of the left ventricle (Table II). Except for a decreased extraction rate seen immediately upon reperfusion, the slightly increased extraction value in both zones was maintained with some fluctuations throughout the 5 hours of reperfusion.

Total myocardial oxygen consumption: Total myocardial oxygen consumption decreased progressively over the 3 hour period of occlusion from a mean of 10.1 to 6.7 ml/min per 100 g. During reperfusion, total oxygen consumption gradually increased to 9.8 ml/min per 100 g and then reached a level of 9.2 ml/min per 100 g at 5 hours of reperfusion (Table II). In two animals, oxygen consumption was reduced to 50 percent below control levels after 3 hours of occlusion, and then increased to 90 percent of control levels during reperfusion.

Pathologic Studies

Of the seven animals, six demonstrated myocardial infarction, five of which were transmural. These infarcts were located in the anterior left ventricular wall and the anterior apex. In two of the three dogs that had hypotension, infarcts were also seen in the posterior left ventricle. One dog that experienced shock associated with rapid tachycardia had no infarction. Four dogs, including the two hypotensive animals, demonstrated distinct microthrombi in the areas of infarction. Infarction was accompanied by various degrees of cellular necrosis and fragmentation of myofibrils, most pronounced in the dogs with shock. Intramyocardial vascular congestion (hyperemia) and hemorrhage accompanied the infarctions.

Discussion

Relation of Reperfusion and Viability

A review of experimental viability studies must consider the differences between the various preparations used.[2,6–10,12,16,17] The site and size of the coronary artery chosen for occlusion are of primary importance. The often quoted relation of the period of ischemia to the amount of necrosis found in the myocardial tissue was derived by Jennings et al.[7,17] from histopathologic studies of the posterior papillary muscles after temporary occlusion of the proximal circumflex branch of the left coronary artery. They reported an average zero percent of necrosis up to 20 minutes of occlusion, the percent of necrosis increasing rapidly to 42 percent at 30 minutes and then to 72.5 at 1 hour of occlusion. They did not attempt reperfusion after occlusion periods of more than 1 hour because the papillary muscles then exhibited hemorrhages, indicating that the vascular system was no longer intact and available for appropriate reperfusion. In evaluating such viability studies, consideration must be given to the fact that the coronary collateral circulation of the papillary muscles is minimal; thus, the results obtained in such prepara-

tions cannot be compared to results in segments of the heart with a more comprehensive collateral blood supply.

Extensive investigations in cats by Krug,[18,19] Enderle et al.[20] and Korb and Schlosser,[21] largely based on histopathologic and histochemical as well as enzymatic studies, indicate that irreversible myocardial cell damage occurred only after 75 to 90 minutes of temporary coronary arterial occlusion. Reperfusion, after a 90 to 120 minute occlusion period, caused only part of the previously occluded zone to be reperfused. In the early postocclusion reperfusion period there was little evidence of vessel damage, but subsequent reperfusion was associated with involvement of the microcirculation. Our studies noted thrombi in the microcirculation in four of the seven dogs. Irreversible myocardial tissue damage, characterized by increased tissue hydrogen ion content, reduced glycogen and intracellular and interstitial edema was reported.[11,18,22] A 3 hour temporary coronary occlusion with subsequent reperfusion generally led to transmural infarction. These investigators proposed that the primary factors causing irreversible damage were the duration of the temporary occlusion, disturbances engendered through reperfusion of previously ischemic regions, and the extent of the area perfused.

Reports by Hamer,[23] Maroko,[2] and Ginks[3] and their co-workers emphasized that coronary occlusion extending beyond 3 hours may be at least partially reversible through extended reperfusion. In particular, Hamer et al.[23] reported recovery of heart muscle after longer durations of occlusion followed by extended periods of reperfusion. A limited zone of damage may develop in the center of the ischemic region, chiefly at the subendocardial level, but since this damage need not bring about permanent global cardiac dysfunction, reperfusion could be beneficial.

Comment on the Present Technique

The current study involved only seven dogs, and a larger series is needed to arrive at a full description of the benefits as well as limitations of reperfusion. The regional metabolic measurements indicate a distinct separation of the ischemic and nonischemic compartments.[1,15] Separation is not total, in that our occlusion of the proximal left anterior descending coronary artery may leave a few arterial branches above the balloon intact, and there is a certain overlap of arterial supply and venous drainage from the major adjoining coronary systems. This could dilute the blood samples and lower the concentration of metabolites. Nevertheless, regional occlusion and reperfusion measurements usually provided a significant differentiation between data from the occluded and nonoccluded zones.[1,15]

The differing conclusions reported by various investigators may be attributed to inadequacies of most of the experimental preparations used to date. Thus, open chest preparations cannot be relied on because of the significant physiologic artifacts, such as depression in cardiac function relative to the closed chest model. Many experimental models of occlusion do not provide adequate control of the location and completeness of the occlusion. When the coronary occlusions are performed in the closed chest they are seldom reversible for the study of reperfusion. It has been suggested that extracoronary occluders or ligations may result in damage to pericoronary nerves, leading to unphysiologic artifacts.[24] Systematic regional flow and metabolic measurements, in addition to determinations of global cardiac function, during closed chest occlusions and reperfusions, have not been reported. Almost all data on the effects of reperfusion following coronary occlusion have been gathered in open chest dogs and are based on epicardial electrocardiographic mapping and serum creatine phosphokinase measurements in the ischemic and nonischemic zones.[2,3,25]

Questions are frequently raised about differences between the coronary circulation and cardiac function in dogs and man. One important factor, the coronary collateral circulation, was studied and discussed by us in a previous publication.[26] Our data indicated that, like the normal human heart, the normal beating dog's heart apparently has minimal functional collateral circulation. The preceding article[1] used the diastolic phase of pressure distal to the occlusion as an approximate index, and showed that acute coronary occlusion of 3 hours' duration failed to change significantly the extent of collateralization. Hence, for acute occlusions, we assume that the functional trends noted in the dog experiments should be applicable in man.

Myocardial Response to Occlusion and Reperfusion

A detailed study of the progressive alterations of cardiac function during 3 hours of intracoronary occlusion of the left anterior descending artery in 34 closed chest dogs has been reported in the preceding article.[1] The present series of seven dogs provides data on the progressive changes in hemodynamic status and regional metabolism during 5 hours of reperfusion after 3 hours of acute occlusion of the left anterior descending artery.

Effects of 3 hours of occlusion: In this series, 3 hours of occlusion of the left anterior descending coronary artery resulted in significant reduction in cardiac output, maximal left ventricular dP/dt, stroke work and coronary sinus flow, whereas left ventricular end-diastolic pressure and systemic vascular resistance increased significantly (Fig. 1, Table I). The hemodynamic results correspond to those outlined in the preceding article,[1] except that in this series a small decrease was noted in the heart rate at the end of the 3 hour period of occlusion. Before reperfusion, mean lactate balance of the occluded zone had reached 21 percent (control value 39 percent), whereas lactate balance in the nonoccluded zone was 28 percent (control value 41 percent). Potassium loss from the occluded zone as well as a lesser loss from the nonoccluded zone occurred during the occlusion

period. These metabolic derangements are in general accord with the previous more extensive occlusion study.[1] Data from this study confirm the striking metabolic derangement in the nonoccluded zone during the occlusion.[1,27,28]

During occlusion, total coronary sinus flow was decreased 36 percent below control level. Regional measurements indicate that coronary flow in the nonoccluded zone was decreased 10 to 15 percent below its preocclusion level.[1,15,29] This reduction in coronary flow differs from the results of others[30,31] and is ascribed by us to reflex coronary angiospasm, associated hypotension or increased resistance in the coronary circulation due to compensatory hypercontraction and increased muscle tension in the nonoccluded segment.[1] Recent reports[32] indicate similar reduction in remote coronary flow in the nonoccluded segment.

Myocardial oxygen extraction increased slightly during occlusion in both occluded and nonoccluded zones. Left ventricular oxygen consumption was reduced to 65 percent of the control level (Table II).

Effects of 5 hours of reperfusion—hemodynamics: The mean initial hemodynamic response to reperfusion compared with measurements after 3 hours of occlusion consisted of a significant 41 percent increase in heart rate, a small (5 percent) reduction in systolic pressure, a 27 percent reduction in left ventricular end-diastolic pressure, a 7 percent increase in maximal left ventricular dP/dt, a 5 percent decrease in systemic vascular resistance, a 15 percent decrease in stroke work and a 16 percent increase in coronary sinus flow. After 5 hours of reperfusion, heart rate increased 71 percent, peak systolic pressure decreased 20 percent, left ventricular end-diastolic pressure was reduced by 45 percent, maximal left ventricular dP/dt increased 23 percent, cardiac output decreased by 8 percent, systemic vascular resistance decreased 17 percent, and stroke work was sharply reduced by 50 percent. Coronary sinus flow increased 37 percent to near preocclusion control levels.

An important trend noted in this series was the sharp rise in heart rate that occurred immediately after reperfusion and persisted for 5 hours in five dogs. In addition, intermittent arrhythmias occurred immediately after reperfusion in six of the seven dogs and frequently reappeared during the reperfusion period. The elevated heart rate and particularly the arrhythmias may have contributed to the abnormal hemodynamic and metabolic function during reperfusion in three dogs. One animal had sinus tachycardia, with an increase in heart rate from 115 to 224 beats/min, followed by cardiogenic shock. Autopsy did not reveal necrosis of the myocardium. Another animal (Fig. 2) had a normal heart rate and improved hemodynamic status after reperfusion, but after 1 hour of reperfusion abnormal lactate metabolism occurred intermittently in both nonoccluded and occluded segments. Pathologic study of this animal indicated multiple foci of necrosis in the center of the occluded zone. These data suggest a dissociation between hemodynamic and metabolic function and lack of correlation with morphology.

The predominant finding in three of the seven animals was declining mechanical function during 5 hours of reperfusion, that is, decreased blood pressure, reduced cardiac output and sharply diminished stroke work.

Mean coronary sinus flow increased immediately upon reperfusion, and after 5 hours rose to a value 11 percent below the preocclusion control level, that is, a 37 percent rise relative to the end of the 3 hour occlusion period. The slightly lower value for coronary flow may be due to a reduced coronary perfusion pressure. There was essentially no change in oxygen extraction during the five hours of reperfusion. Myocardial oxygen consumption was restored to 91 percent of the control level during reperfusion, that is, a 33 percent rise relative to the final occlusion value (Table II).

Metabolism: The immediate effect of reperfusion was a marked "washout" of lactic acid and potassium from the previously occluded zone and often also from the nonoccluded region (Fig. 1, 3 to 6). Washout may be taken as additional evidence of an abnormal regional metabolism in both zones during the preceding period of occlusion. Our findings suggest that metabolites accumulated in the interstitial spaces and were washed away by sudden reperfusion. It cannot be ascertained whether the initial effects of reperfusion include improvement or deterioration in metabolism, because the sudden washout may mask or distort the measurement of regional metabolic function.

Measurements of regional myocardial metabolism after 5 hours of reperfusion revealed a remarkable but often intermittent deterioration of the previously occluded zone in six of seven dogs. Thus, the occluded zone that exhibited a 21 percent lactate extraction at 3 hours of occlusion, demonstrated lactate production (−3 percent) during reperfusion (Fig. 1, 5). A further small intermittent reduction in lactate balance was often noted in the nonoccluded zone. During reperfusion, potassium loss occurred intermittently in both occluded and nonoccluded regions (Fig. 1, 6).

A survey of the individual experiments indicates variations in data and trends during the reperfusion period. Various lactate and potassium measurements did not always show a correspondence, and there were instances (Fig. 2 to 4) in which lactate extraction decreased, but potassium loss increased and vice versa. The dynamics of the reperfusion process are illustrated in Figures 2 and 4, which show considerable fluctuations in both metabolic and hemodynamic function. A dissociation of metabolic and mechanical trends was observed in many instances, showing either improved hemodynamics in the presence of depressed metabolism (Fig. 2) or mechanical dysfunction in the presence of stable or improved myocardial metabolism. A phase lag between meta-

bolic and mechanical events may play a role in this dissociation, but other mechanisms could be involved.

Residual Tissue Analysis and Histopathology

Tissue analysis for residual myocardial potassium concentration taken at autopsy corroborated the finding that the previously occluded segment has less residual potassium than the nonoccluded myocardium. The borderline zone between segments has an intermediate potassium level (Fig. 7).

Microscopic sections of the heart were stained with hematoxylin basic fuchsin picric acid in addition to standard hematoxylin-eosin. Necrosis and fragmentation of the myofibrils, microthrombi and hemorrhages that were not evident in dogs after 3 hours of occlusion[1] were observed after reperfusion. This finding suggests that reperfusion accelerated changes of necrosis. It is postulated that the hemorrhages are related to reperfusion in areas that have sustained damage to the microvasculature or in which hyperemia has occurred. The degree to which microthrombi interfere with the effectiveness of reperfusion is not clear, but these lesions are probably of fundamental importance.

The hematoxylin basic fuchsin picric acid stain was reported to have affinity for myocardial cells altered by ischemia.[33] We found that reperfusion, which was evidenced by the microscopic finding of reactive hyperemia, caused a loss of stainability of this agent, although hematoxylin-eosin stain revealed ischemic necrosis and microthrombi. Patchy stainability with hematoxylin basic fuchsin picric acid was usually retained only in areas that demonstrated microthrombi. We postulate that this stain is bound by the accumulated ischemic metabolites that are washed away during reperfusion. It thus appears that after reperfusion this stain is not helpful in delineating the extent of damage in the previously occluded zone.

Clinical Implications

Our study leads to the conclusion that reperfusion may not be capable of reversing hemodynamic and metabolic disorders induced by 3 hours of acute coronary occlusion. In fact, it may cause serious deterioration of metabolic and hemodynamic function. Only two animals showed persistent improvement of hemodynamic indexes. Two animals experienced cardiogenic shock. Four animals showed the largest loss of potassium starting 4 to 5 hours after onset of reperfusion. At that time the previously occluded area revealed a severe reduction in lactate balance while the nonoccluded zone showed less metabolic dysfunction. Whether a shorter or longer period of reperfusion, either gradual or sudden, would alter these cardiac functions remains to be clarified. Correlative autopsy studies revealed that reperfusion accelerated morphologic alterations and caused reactive hyperemia, microthrombi and hemorrhages that were not evident at the end of 3 hours of occlusion.

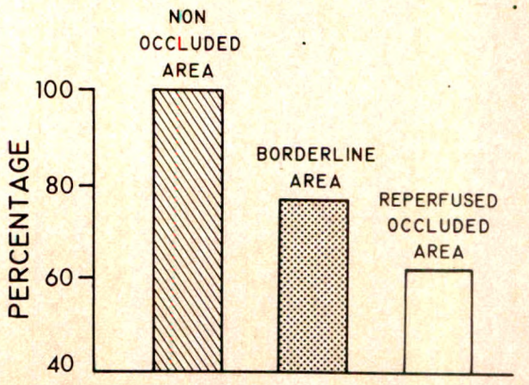

FIGURE 7. Comparison of myocardial residual potassium measurements in percent of potassium from the nonoccluded zone. Heart muscle from the occluded segment had a substantially lower potassium concentration (62 percent) than the nonoccluded segment. The borderline area potassium content was also distinctly less (77 percent) than the concentration in the nonoccluded zone.

This investigation clearly indicates that reperfusion after 3 hours of acute coronary occlusion may have a detrimental effect on both the viability and mechanical and metabolic function of the myocardium. It is possible that reperfusion after shorter intervals—for example, 1 or 2 hours—of occlusion may not cause accelerated necrosis and deterioration of cardiac function. Investigations of shorter periods of occlusion followed by reperfusion are currently underway.

The next logical question concerns the beneficial or detrimental effects of various periods of reperfusion on an admittedly precariously balanced myocardium following 3 hours of occlusion of the proximal left anterior descending coronary artery. One of our most interesting observations, made possible through the regional measurements of the new model, concerns the "washout" that immediately follows the reperfusion. Individual experiments show considerable variability and differences in the magnitude of this lactate and potassium "washout" in both occluded and nonoccluded segments. We believe that the "washout" of accumulated metabolites can serve as an indication of the degree of metabolic dysfunction and possible ischemic damage caused by a 3 hour period of coronary occlusion, and we are now correlating histopathologic data with lactate washout measurements. It might thus be reasoned that the myocardium could have been in a precarious state even though systemic compensatory factors such as increased systemic vascular resistance may have prevented or postponed total circulatory collapse. In the presence of damage to the ischemic region and its microcirculation, a sudden burst of reperfusion and associated reactive hyperemia might be the cause of the patchy hemorrhages. The ischemic damage and reactive hyperemia, in turn, could cause additional metabolic derangements that would be reflected in increased or prolonged "washout." To minimize myocardial damage during reperfusion, we

are studying modifications to make reperfusion more gradual or staged, as well as systems that combine reperfusion with administration of pharmacologic agents such as mannitol, allopurinol or cortisone. The large washout of potassium during sudden reperfusion could well be the reason for tachyarrhythmias[34] which may cause serious derangements in cardiac function and contribute to the genesis of vicious cycles leading to ventricular fibrillation.[33-37]

We do not yet know whether a more prolonged reperfusion period could have averted the dire metabolic and morphologic consequences we observed. Cases have been cited in which an akinetic segment remained inert for several hours after 3 hours of occlusion but became almost fully contractile after days or weeks.[23] On the other hand, we frequently noted a severe potassium loss or development of shock 4 to 5 hours after reperfusion, suggesting that extension of the reperfusion period might generate further deterioration and shock.

A recent report[38a] contends that when coronary bypass was performed in patients immediately after acute coronary occlusion, the mortality rate was three times higher than if acute infarction was not present. Another human study[38b] indicated that the mortality rate was 80 percent when coronary bypass was performed on the first day after occlusion, 38 percent 2 to 8 days after occlusion, 13 percent 8 to 30 days after occlusion and only 6 percent 31 to 60 days after occlusion. It is not known how many patients in the latter study had cardiogenic shock and this factor could have weighted the results. Such studies suggest that revascularization might have a detrimental effect in the first week after acute coronary occlusion. Successful attempts to correct cardiogenic shock by revascularization of the heart by coronary bypass immediately after occlusion have been reported.[39] Of course, total circulatory assistance, which was used during such operations with frequent intermittent periods of coronary reperfusion while the heart was at rest, may provide essential nutrition to the myocardium and restore function of the vital nonoccluded segment and thus overcome the shock state.

Sudden death due to ventricular fibrillation frequently occurs in patients whose coronary arteries are not occluded. We have found a high frequency of ventricular fibrillation in animals after reperfusion of the coronary arteries. This observation was first reported by Tennant and Wiggers in 1935.[40] The question arises whether the sudden release of coronary angiospasm or lysis of a thrombus in a coronary artery may set up reperfusion disorders described in this study such as sudden electrolyte washout, anaerobic metabolism and loss of mechanical function, which could precipitate resistant ventricular fibrillation. This study contributes new knowledge about the precursors and mechanisms of sudden death which might lead to more adequate therapy of the nation's number one health problem.

Deleterious Effects Due to Hemorrhage After Myocardial Reperfusion

The effect of coronary reperfusion on evolving myocardial infarction was examined in 16 conscious dogs. Coronary arterial occlusion was produced by inflating an exteriorized balloon cuff, and reperfusion was initiated 5 hours later by deflating the cuff. Infarct size calculated from 24 hour serial serum creatine phosphokinase (CPK) values was compared to infarct size predicted from log normal curves best fit to initial 5 hour serial CPK changes. With sustained occlusion, predicted and observed infarct size correlated closely (r = 0.94, no. = 11). Reperfusion produced two disparate effects. In nine dogs, observed infarct size was less than predicted, reflecting 42 ± 6 percent (standard error) salvage of myocardium. In seven dogs, observed infarct size exceeded predicted size by more than 100 percent. Thus, reperfusion resulted in extension of myocardial infarction in 44 percent of the animals. Extension of infarction was associated with myocardial hemorrhage. Hemoglobin content in biopsy specimens from the center of the infarct was 10 times greater in the animals with extension of infarction than in those with myocardial salvage. Thus, reperfusion is not without hazard during evolving infarction in the conscious dog; although it frequently diminishes ischemic injury, it may precipitate myocardial hemorrhage and extension of infarction.

The availability of saphenous vein bypass grafting for patients with acute myocardial infarction has accentuated the need to examine the effects of myocardial reperfusion on infarct size. We have recently shown that reperfusion early after coronary arterial occlusion reduces the extent of myocardial necrosis in anesthetized dogs[1,2]; however, its effectiveness may depend on how soon it is performed after occlusion.

This experimental study was designed to determine whether infarct size is influenced by reperfusion initiated 5 hours after coronary occlusion, an interval analogous to one that might be used in clinical settings. The experiments were performed in conscious animals to obviate effects of anesthesia. We[3,4] have previously shown that analysis of serial serum creatine phosphokinase (CPK) changes provides an accurate estimation of infarct size in conscious dogs and that there is a close correlation and linear relation between infarct size* determined in this manner and infarct size determined by analysis of myocardial CPK depletion (r = 0.96). Recently, we[5] used curve fitting techniques to predict infarct size 5 hours after coronary occlusion in the conscious dog and found that this value correlated closely with ultimate infarct size resulting from a sustained coronary occlusion (r = 0.96, no. = 11). In the present investigation we used the same technique to predict infarct size 5 hours after occlusion, immediately before reperfusion. Predicted infarct size was compared to infarct size calculated from all serum CPK values measured during the 24 hour interval after coronary occlusion.

* For convenience this term will be used to refer to the extent of myocardial injury reflected by myocardial CPK depletion, since we have previously demonstrated that myocardial CPK depletion and independent indexes of necrosis correlate closely.[3]

To assess the effects of reperfusion on the extent of myocardial injury, we used an experimental preparation that eliminated the need for concurrent surgery. Coronary occlusion was produced in 16 conscious dogs by inflating a balloon cuff that had been placed around the left coronary artery 7 to 10 days previously. Reperfusion was initiated 5 hours later by deflating the balloon. Infarct size was predicted 5 hours after occlusion, immediately before reperfusion, on the basis of early serum CPK changes; this value was then compared to observed infarct size calculated from serum CPK changes measured during the ensuing interval. Thus, each animal served as its own control. Myocardial tissue was considered salvaged when observed infarct size was smaller than predicted. Infarction was considered extended when observed infarct size exceeded that predicted. Contrary to our initial expectation, only nine animals (56 percent) showed salvage of myocardial tissue after reperfusion; the remaining seven had apparent extension of infarction. Extension of infarction was consistently associated with myocardial hemorrhage. The methods used provide information about the total mass of myocardium undergoing ischemic injury and do not distinguish between extension of infarction beyond the original "border" of the ischemic area and extension of infarction due to more intensive damage within the original "border."

Methods

Animal Preparations

Sixteen animals were anesthetized with sodium thiamylal (10 mg/kg body weight), and anesthesia was maintained with 0.5 percent Fluothane®. A silastic balloon cuff was placed loosely around the left anterior descending coronary artery through a left thoracotomy.[6] A polyvinyl catheter continuous with the balloon cuff was exteriorized and secured to the skin. A jugular venous catheter was inserted for obtaining blood samples, and the animals were permitted to recover from operation. Seven to 10 days after operation all animals were premedicated with lidocaine, 1 mg/kg intravenously. Coronary arterial occlusion was produced by inflating the balloon. No sedation was required. Blood samples were obtained immediately before coronary occlusion for determination of base-line serum CPK activity. Additional samples were obtained hourly for 24 hours. Five hours after coronary occlusion the balloon was deflated to initiate reperfusion. Lidocaine, 1 mg/kg intravenously, was again administered, immediately before reperfusion. Twenty-four hours after coronary occlusion each animal was anesthetized with sodium pentobarbital. Through a left thoracotomy, the coronary artery was incised distal to the cuff to determine whether the vessel was patent and whether free reflow had been established. The heart was excised and left ventricular biopsy specimens were taken from the nonischemic posterior myocardium and from the center of the infarct (estimated grossly). The remaining myocardial tissue was used for preparation of whole ventricular homogenates.[4]

Calculation of Infarct Size

Determination of infarct size from analysis of serial serum CPK changes: Infarct size was determined, as previously described,[4] by analysis of serial serum CPK changes based on the equation $dE/dt = f(t) + kdE$, where E = enzyme activity, kd = the fractional disappearance rate and t = time in minutes after the initial increase in serum CPK. Rearrangement of terms, integration, multiplication by the distribution volume of CPK and division by the proportion of myocardial CPK depleted appearing in serum provides an expression used to calculate the amount of CPK depleted from myocardium based on measurement of serial serum CPK changes. Since myocardial CPK depletion is directly proportional to infarct size,[3,4] infarct size can also be calculated.[4]* We refer to infarct size calculated by this method as observed infarct size. Its value is calculated from changes in serum CPK activity during the entire 24 hour interval after coronary occlusion. This interval is selected because after 24 hours myocardial CPK depletion is minimal.[4]

Prediction of infarct size from projected serum CPK curves: We have previously shown that infarct size can be predicted 5 hours after coronary occlusion in the conscious dog on the basis of serum CPK values obtained from the projected portion of the best fit curve derived from early data relating serum CPK changes to time. Serum CPK changes after sustained coronary occlusion conform to a log normal function. Accordingly, the best fit curve conforming to this general function can be obtained from data obtained during the first 5 hours after the initial enzyme increase by conventional curve fitting techniques.[5] Predicted infarct size is calculated from CPK values on the projected portion of the best fit curve. After sustained coronary occlusion, observed and predicted infarct size differ by less than 5 percent, and the correlation coefficient between the two is 0.96.[5] Predicted infarct size derived from projected CPK values can be used to assess the efficacy of an intervention initiated after the prediction has been made because the projected best fit curve is independent of events occurring after the first 5 hours. Since the fraction of CPK released into serum of CPK depleted from myocardium is a critical parameter in the calculation of infarct size, we assessed the relation between CPK depleted from myocardium and the amount of CPK released into blood. The amount of CPK released was calculated from serial serum CPK changes. The value for myocardial CPK depletion, calculated from CPK activity in normal myocardium, total left ventricular CPK content and left ventricular weight, was used to calculate infarct size as previously described.[4]

Tissue Preparations

The animals were anesthetized, the beating heart was rapidly excised, and blood was quickly drained from the ventricular cavities. The left ventricle including its septal wall was isolated, washed three times for 1 minute each in cold saline solution (4° C), blotted dry with a paper towel and weighed. Full wall thickness biopsy specimens were taken from nonischemic regions of the posterior left ventricular free wall and from ischemic regions of the center of the infarct. Supernatant fractions at 16,000 g were prepared from individual biopsy specimens and from the remainder of the left ventricle by mincing the tissue, homogenizing it in 0.25 M sucrose containing 0.001 M neutralized sodium ethylenediaminetetinetic acid with 0.001

* Infarct size = $K \sum_{0}^{T} (\Delta E/\Delta T + kd\ \bar{E})\Delta t$ where kd = CPK disappearance rate; E = serum CPK, $\bar{E}$ = mean CPK during Δt, K = [(BW)(DV)]/[(D) (CPK_N-CPK_I)], BW = body weight, DV = distribution volume, and D = depleted/released CPK, CPK_N and CPK_I = CPK in normal and ischemic myocardium.

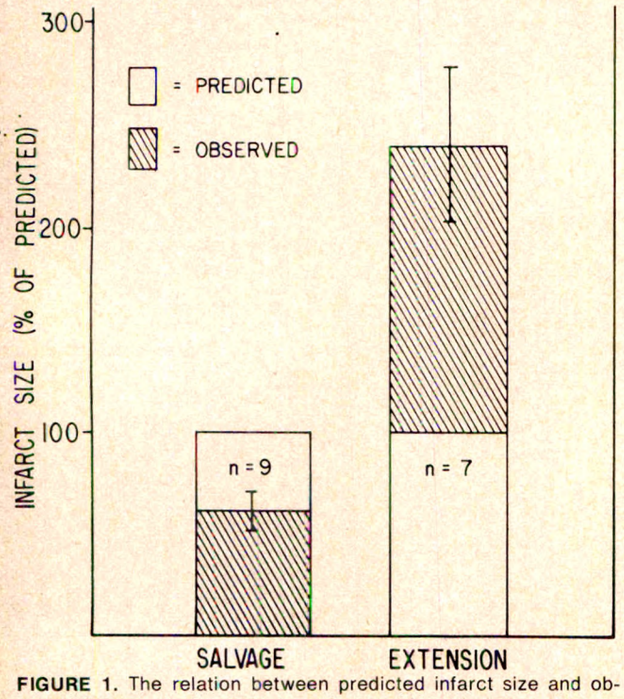

FIGURE 1. The relation between predicted infarct size and observed infarct size in conscious dogs subjected to coronary occlusion and reperfusion 5 hours later. Predicted infarct size in nine animals exhibiting salvage of myocardium averaged 27 ± 6 (standard error) CPK-g-eq compared to 14 ± 4 in seven animals exhibiting extension of infarction.

M mercaptoethanol, and centrifuging as previously described.[4]

Lysates were prepared from red blood cells. Cells were separated by centrifugation at 3,000 g for 10 minutes, washed three times in cold saline solution (4° C) and hemolyzed in distilled water.

Biochemical Procedures

Protein was measured by the biuret procedure.[7] Creatine phosphokinase (CPK) activity in serum, myocardial supernatant fractions and red cell lysates were assayed spectrophotometrically[3,8] with 50 μliter aliquots in a final assay volume of 1.050 ml. Samples with activity exceeding 0.1 international units (IU)/ml were diluted with 0.01 M trishydroxymethylaminomethane (Tris), pH 7.4, containing bovine serum albumin 0.2 percent (Tris-BSA). CPK activity was expressed in international units per milliliter or per milligram of protein.

Hemoglobin was assayed spectrophotometrically[9] in supernatant fractions of myocardium from the center of the infarcts and from nonischemic regions. To determine whether adenylate kinase, adenosine triphosphate (ATP), or glucose-6-P were influencing apparent CPK activity, experiments were performed in which creatine phosphate was omitted from the CPK reaction medium. CPK isozymes were assayed by electrophoresis on cellulose acetate for 65 minutes at 250 volts with 5 μliter serum samples from animals with and without apparent salvage of myocardium after reperfusion. Isozymes were quantified by fluorescent scanning techniques.[10]

Results

Effect of reperfusion on infarct size: Reperfusion 5 hours after coronary occlusion in conscious dogs modified infarct size (Fig. 1). In nine dogs, observed infarct size was appreciably less than that predicted. Hence, reperfusion modified infarct size favorably and led to salvage of 42 ± 6 percent (mean ± standard error) of myocardial tissue expected to undergo infarction in the absence of a favorable intervention. The absolute values for salvaged myocardial tissue ranged from 0.6 to 29.0 CPK-g-eq (mean 11 ± 3). Predicted infarct size in this group averaged 27 ± 6 CPK-g-eq. Thus, in this group of nine animals representing 56 percent of those subjected to reperfusion, the intervention led to substantial salvage of myocardial tissue. In the remaining seven dogs subjected to reperfusion, observed infarct size was 100 percent greater than that predicted. Thus, reperfusion resulted in apparent extension of infarction. The absolute values for myocardial damage exceeding that predicted ranged from 0.6 to 56 CPK-g-eq (mean 24 ± 9). Predicted infarct size in this group averaged 14 ± 4 CPK-g-eq, although this value was not significantly less ($P = 0.13$) than that in the animals with salvaged myocardial tissue.

The ratio of CPK depleted from myocardium to CPK released into the circulation varied by less than 10 percent (no. = 9). Results with the methods used would not be influenced by the rate of release of CPK from myocardial tissue but would be influenced by a change in the proportion of released CPK appearing in blood. Since animals with apparent salvage of myocardium and those with extension of infarction exhibited comparable proportions of CPK released to CPK depleted, variations in this ratio did not appear to influence our results.

Association between extension of infarction and myocardial hemorrhage: Although extension of infarction was not anticipated initially, it became apparent that it was associated with gross myocardial hemorrhage. Results of determinations of hemoglobin in myocardium from animals with myocardial salvage and animals with extension of infarction are shown in Figure 2. Hemoglobin in myocardial tissue from the center of the infarcts and in homogenates prepared from the entire left ventricle was 1,000 and 350 percent greater, respectively, in animals with extension of infarction than in those with myocardial salvage. Thus, extension of infarction after reperfusion was associated with myocardial hemorrhage, which was particularly marked in the central regions of the infarct.

Potential extraneous sources of apparent CPK activity: To exclude spurious contributions to apparent CPK activity from constituents of blood or hemorrhagic myocardium, such as adenylate kinase, ATP and glucose-6-P, we performed assays without creatine phosphate as substrate and measured CPK activity in lysates of red blood cells. Serum CPK isozyme profiles exhibited a "myocardial band"[11] and were comparable in samples from dogs with extension of infarction and those with myocardial salvage, thereby suggesting that the increased CPK in serum was indeed coming from myocardial tissue. Serum samples from both groups of dogs exhibited virtually no CPK activity when substrate was omit-

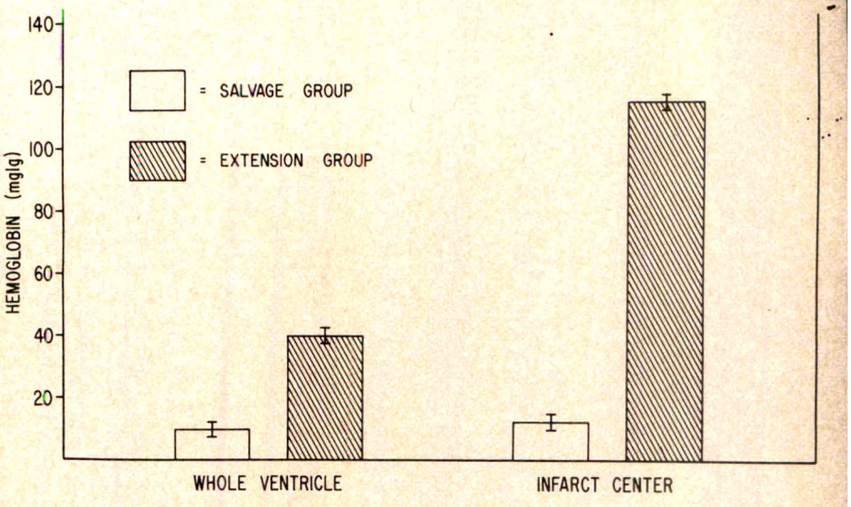

FIGURE 2. Hemoglobin content of homogenates prepared from the whole ventricle **(left)** and from samples obtained from the center of the infarct **(right)** in animals with salvage of myocardium and extension of infarction after reperfusion. Extension of infarction was associated with myocardial hemorrhage manifested by considerable increases in hemoglobin.

ted, excluding appreciable contributions from adenylate kinase, ATP or glucose-6-P. Apparent CPK activity in lysates of red cells was less than 0.2 mIU/mg protein; thus, its contribution to apparent circulating myocardial CPK activity was negligible compared to that of myocardial CPK content (approximately 6 IU/mg protein.[4] Thus, serum CPK activity in samples from animals with myocardial salvage and in animals with extension of infarction did not appear to be influenced spuriously by other constituents from blood or hemorrhagic myocardium potentially capable of influencing the CPK assay.

Discussion

In this study reperfusion of myocardium in conscious dogs 5 hours after coronary occlusion was associated with salvage of myocardial tissue in nine dogs (56 percent) but extension of myocardial injury in the remaining seven dogs (44 percent). The effect of reperfusion on infarct size was assessed by comparing infarct size predicted 5 hours after occlusion, immediately before reperfusion, to infarct size observed during the 24 hour interval after occlusion. The fraction of depleted myocardial CPK released into the circulation was found to be virtually constant (no. = 9).

Factors potentially capable of influencing apparent serum CPK activity such as ATP, adenylate kinase, or glucose-6-P were excluded by assaying samples without substrate in the CPK reaction medium. Red blood cells were excluded as a source of apparent activity by measurement of CPK activity in lysates. In animals with extension of infarction gross hemorrhage was present in the myocardium and documented by measurement of hemoglobin in the tissue. These animals had a 1,000 percent greater increase in hemoglobin in the center of the infarct compared to animals in which reperfusion led to salvage of myocardium. Hemorrhage has been observed after reperfusion of previously occluded cerebral arterial vessels[12] and presumably reflects loss of structural integrity of vessels. Disruption of capillaries and extravasation of blood are detectable by electron microscopy in this setting.

Mechanisms of extension of infarction associated with myocardial hemorrhage: It is not yet clear why only some animals exhibit extension of infarction associated with myocardial hemorrhage whereas others subjected to coronary occlusion for comparable intervals do not. The difference may be related to initial predicted infarct size and to the likelihood that, in general, marginally perfused tissue on the periphery of the infarct is unfavorably influenced by reperfusion whereas jeopardized tissue within more central regions is influenced favorably. Thus, salvage would be more likely to occur in animals with large predicted infarctions since they might have proportionately less tissue in marginally perfused areas than in central zones.

At the conclusion of each experiment the patency of the vessel, the absence of clot and the presence of reflow were confirmed by incising the previously occluded vessel distal to the cuff while the heart continued to beat in situ. However, the possibility that less reflow occurred in the group with myocardial salvage because of spasm or unidentified factors cannot be excluded entirely. Diminished reflow, sufficient to prevent some ischemic tissue from dying but not vigorous enough to lead to extravasation of blood, might have been associated with salvage. In other animals, more complete restoration of reflow, with a resulting intracoronary pressure too great to be tolerated by the anoxic capillary bed, might have led to extension of infarction. An alternate mechanism might involve fewer collateral channels in hearts exhibiting apparent extension of infarction. Regardless of the mechanism, the close association between appreciable myocardial hemorrhage and extension of infarction suggests that hemorrhage in itself is deleterious. It may lead to increased interstitial pressure resulting from accumulation of fluid and potentiated by compression of veins and lymphatic vessels. Retardation of removal of metabolites may contribute to damage. Increased interstitial pressure may inhibit the development of collateral vessels or compress those already present.[14]

Results of this study in concert with those reported previously[1,2] suggest that the time of initia-

tion of reperfusion after coronary arterial occlusion is critical. Salvage of myocardium occurred when reperfusion was initiated 3 hours after occlusion,[1,2] although studies underway in additional animals indicate that some exhibit hemorrhagic infarction. However, the experiments reported here indicate that reperfusion performed 5 hours after occlusion is associated with deleterious effects in a substantial proportion of animals.

Clinical implications: We have previously shown[15] that the extent of depression of ejection fraction in patients with acute myocardial infarction is related to the extent of infarction estimated by analysis of serial serum CPK changes. Results obtained by others[16] indicate that reperfusion 1 to 3 hours after coronary arterial occlusion in cats[16] produces marked improvement in contractility but that little or no functional improvement occurs when reperfusion is delayed for 4 hours. Since improved function may be associated with salvage of myocardium, the results with cats suggest that myocardial salvage can be attained by reperfusion only during a critical interval of 3 to 4 hours.

In view of the availability of saphenous vein bypass graft procedures for patients with acute myocardial infarction, it is essential to determine whether reperfusion is likely to be beneficial under specific circumstances during evolution of infarction. Caution must be exercised in extrapolating our results to patients. The anatomy of the coronary arteries and the nature of collateral vessels differ considerably from species to species. Experimental coronary occlusion is not necessarily comparable to spontaneous clinical myocardial infarction,[17] in which diminished flow without complete occlusion frequently occurs. Yet, early experience with valvular surgery suggests that our findings may be relevant to patients. Hemorrhagic necrosis has been observed after valvular replacement particularly in patients who died in the early postoperative period.[18,19] Its incidence appears to be related to the duration of cardiac arrest and of myocardial hypoxia. In patients with coronary artery disease who underwent valve replacement hemorrhage occurred only when intermittent reflow was permitted during induced cardiac arrest. Furthermore, hemorrhage was associated with capillary damage detectable by electron microscopy.[20] Hypertrophied myocardium may be particularly sensitive to ischemia and prone to hemorrhagic 'necrosis.[18] Thus, severity of hemorrhagic necrosis may depend not only on the duration of myocardial hypoxia but also on the extent of hypertrophy antedating interruption of coronary flow. The results of our experimental investigation indicate that the effects of reperfusion during evolving myocardial infarction are sometimes deleterious. Further elucidation is needed of the effects of revascularization on functional and structural integrity of the myocardium in patients with coronary artery disease, particularly during impending or evolving myocardial infarction.

Physiologic Basis for Assessing Critical Coronary Stenosis

Instantaneous Flow Response and Regional Distribution During Coronary Hyperemia as Measures of Coronary Flow Reserve

K. LANCE GOULD, MD
KIRK LIPSCOMB, MD
GLEN W. HAMILTON, MD

Seattle, Washington

Quantitative hemodynamic assessment of coronary stenosis has not been previously reported. Resting coronary blood flow and its regional distribution are insensitive indexes for determining critical stenosis, but flow response to a hyperemic stimulus quantifies restrictions on maximal flow due to coronary arterial lesions. Coronary flow responses to temporary occlusion and to selective main coronary arterial injection of sodium diatrizoate (Hypaque-M 75 percent) were studied in 12 consecutive dogs with a surgically implanted electromagnetic flowmeter and separate micrometer constrictor on the left circumflex coronary artery. Selective Hypaque injection adequate for coronary cineangiography increased coronary flow to four times the resting base-line value, peaking at 6 seconds and lasting 3 minutes, a response equivalent to hyperemia after 10 seconds of circumflex arterial occlusion. With progressive micrometer constriction, resting flow measurements did not decrease until there was 85 percent stenosis. Hyperemia after intracoronary injection of Hypaque decreased when there was 30 to 45 percent stenosis and disappeared when there was 88 to 93 percent stenosis. Myocardial images obtained by gamma camera after left atrial injection of ^{131}iodine-macroaggregated albumin demonstrated uniform regional distribution of resting flow in spite of severe constriction. However, 6 seconds after selective Hypaque injection, left atrial injection of ^{99m}technetium macroaggregates demonstrated distinct perfusion abnormalities in the region of circumflex stenosis. Thus, flow distribution with a severe lesion was normal at rest but showed marked differences due to restricted circumflex versus normal anterior descending hyperemic response after injection of Hypaque. Flow response and regional distribution during coronary hyperemia caused by Hypaque are quantitative measures for physiologically assessing critical coronary stenosis and flow reserve with potential applicability to patients.

Previous efforts at quantitative evaluation of coronary arterial lesions in terms of altered coronary blood flow have been largely unrewarding, in part because of limitations in present techniques for measuring coronary flow in man.[1,2] However, an equally likely explanation may be that resting coronary blood flow and its distribution are unaffected by relatively severe constrictive lesions. Studies on peripheral arteries have demonstrated that a stenosis that markedly impairs flow at high levels of flow velocity has little effect at resting or low flow velocity levels.[3,4] It is therefore essential to evaluate coronary arterial lesions in terms of altered maximal, rather than resting, coronary blood flow. Despite this need, quantitative data on the effects of progressive coronary arterial constriction on maximal flow have not been previously reported. This study describes the physiologic basis of an approach for assessing the hemodynamic effects of coronary lesions on maximal blood flow or coronary flow re-

serve independent of arteriographic interpretation. Our approach was used initially to determine critical coronary stenosis in dogs and to establish experimentally the relation between severity of constriction, resting and maximal coronary blood flow and regional flow distribution. Critical coronary stenosis is defined here as a constriction sufficient to prevent an increase in flow over resting values in response to increased myocardial oxygen demands; as subsequently shown, this constriction also corresponds to the point at which resting coronary flow values start to decrease. With appropriate instrumentation our approach appears to be applicable to patients during cardiac catheterization.

Methods

Twelve consecutive 17 to 40 kg black Labrador or German shepherd dogs were prepared as follows: Anesthesia was induced with sodium pentobarbital (Diabutal®) 1 hour after subcutaneous administration of 45 mg of morphine sulfate. Respirations were controlled with a Harvard ventilatory pump through a cuffed endotracheal tube. Respiratory volumes were monitered continuously with a Draeger volumeter and blood gases were maintained normal by volume adjustment or by the addition of oxygen if necessary. The left circumflex coronary artery was isolated through a left thoracotomy, the arterial diameter was measured with calipers, and an appropriately sized, perivascular electromagnetic flowmeter transducer (Zepeda) was implanted. An occluder of the snare type attached to a machinist's micrometer was placed distal to the transducer before arterial branching. The snare could be closed by small, precise amounts according to the 0.01 mm micrometer scale. A 36 cm no. 9F catheter was inserted into the right carotid artery and advanced into the ascending aorta for recording pressure and a no. 4F catheter was inserted into the left atrium for subsequent injection of radionuclides.

A standard no. 7.5F, Positrol, Sones coronary arteriographic catheter was inserted through the left carotid artery and positioned under fluoroscopy at the orifice of the main left coronary artery so that both the circumflex and anterior descending branches could be simultaneously visualized by injection of sodium diatrizoate (Hypaque®-M 75 percent, Winthrop Laboratories). This catheter was easily positioned in the dog, usually in only a few minutes, and remained stable in position for several hours. The catheter did not interfere with coronary flow, even at high flow rates, as indicated by sudden withdrawal of it during peak hyperemia (see later).

Coronary flow was recorded with a Zepeda square wave, electromagnetic flowmeter operating at 400 Hz and perivascular flow transducers calibrated in vivo by beaker and stopwatch. Central aortic pressure was measured with a Kulite solid state PSL 126-6 or Statham P23 Db pressure transducer. Data were recorded on a 12 channel, Electronics for Medicine physiologic recorder. Coronary cineangiograms were made on 16 mm Kodak Shellburst film with a 9 inch Kelekat fluoroscopy-cine unit using a grid with 80 lines/inch.

Experimental procedure: All dogs were heparinized. Occlusive zero base line for the electromagnetic flowmeter was established at the beginning of each experiment and corresponded to occlusive zero after each experiment. Coronary hyperemic response after 10 seconds of complete occlusion of the left circumflex artery produced by gently clamping the artery was recorded twice consecutively. The Sones catheter was positioned at the coronary orifice and the hyperemia after 10 seconds of occlusion was again recorded twice consecutively to demonstrate that the catheter did not interfere with flow during hyperemia. A base-line coronary cineangiogram was obtained using 2 to 4 cc of Hypaque-M 75 percent to determine the amount required for adequate visualization of the left anterior descending and circumflex arteries. The same dose of Hypaque was subsequently used throughout an experiment.

As detailed under Results, intracoronary administration of Hypaque caused marked coronary hyperemia of three to seven times resting base-line flow values, a response equivalent to the hyperemia occurring after 10 seconds of complete occlusion. Because of these effects, contrast medium was utilized as a convenient means of recurrently stimulating coronary vasodilatation and increased flow. The hyperemic response to the selected Hypaque dose was recorded twice consecutively after the initial cineangiogram. The micrometer constrictor was then tightened around the artery until it fit snugly without causing a constriction noted on visual inspection or by coronary angiography. The micrometer reading at this point was recorded as a "no lesion" base line. From this base line the micrometer constrictor was tightened in steps progressing from no lesion to complete occlusion in 11 to 19 increments. At each step, the base-line resting coronary flow and the hyperemic response to Hypaque were recorded and a cineangiogram was obtained. Total excursion of the micrometer was determined from the base-line micrometer reading at no lesion and the reading at 100 percent occlusion. Percent lesion by diameter was then calculated for each intervening micrometer setting by the following equation:

$$\%\ \text{lesion} = 100\,[(\text{micrometer reading at no lesion} - \text{reading at each step})/\text{total micrometer excursion}]$$

Thus, values for resting and maximal coronary blood flow were obtained for a series of progressively severe coronary lesions up to complete occlusion.

Regional flow distribution was evaluated during rest and hyperemia by double radionuclide studies at a point during progressive constriction when the hyperemic response was blunted but the resting flow rate was still normal. The purpose was to determine whether moderately severe constriction that did not alter normal resting flow caused abnormalities in regional flow distribution at rest or at increased flow rates. At this point during constriction, 2 mCi of ^{131}iodine-macroaggregated albumin was injected through the left atrial catheter. Without further constriction, intracoronary Hypaque was injected through the Sones catheter and 6 seconds later 7 mCi of ^{99m}technetium-macroaggregated albumin was injected into the left atrium. Myocardial tissue supplied by the left anterior descending coronary artery could respond normally with a marked increase in perfusion during Hypaque-induced hyperemia. However, myocardial tissue supplied by the constricted left circumflex artery could not increase perfusion normally in response to the hyperemic stimulus. Thus, regional distribution of coronary flow could be ascertained during the resting base-line period, when all areas of myocardium were likely to be equally perfused, in spite of 80 to 85 percent stenosis of the left circumflex artery and during maximal hyperemia when differences between normally and abnormally perfused areas were maximal.

TABLE I

Effect of Intracoronary Hypaque Injection and 10 Seconds of Occlusion on Mean and Peak Phasic Left Circumflex Arterial Flow

Experiment No.	Body Weight (kg)	LC OD (mm)	Hypaque (cc/kg)	Control Mean LC Flow (cc/min)	Increase After Hypaque (× control)	Increase After Occlusion (× control)	Control Peak Phasic LC Flow (cc/min)	Increase After Hypaque (× control)

LC = left circumflex; OD = outside diameter; SD = 1 standard deviation.

At the end of each experiment the micrometer constrictor was released and the responsiveness of the coronary bed was tested twice consecutively by recording hyperemia after 10 seconds of occlusion. The animal was sacrificed, the heart removed and the left ventricle dissected from the rest of the heart. The ventricle was opened by cutting from base to apex along the left anterior descending coronary artery. The resulting specimen was placed flat with the left ventricular endocardium down for heart imaging (see upper right photograph, Fig. 4). Myocardial tissue supplied by the circumflex coronary artery was in the center of the specimen surrounded by myocardial tissue in the area perfused by the left anterior descending artery.

In this initial study, heart scans were made in postmortem specimens to document regional flow distribution as accurately as possible without the compromising problems of counting geometry in the intact animal. Images of the left ventricle were obtained on a Nuclear-Chicago HP gamma camera, using a pin-hole collimator; 100,000–400,000 count pictures were obtained of both ^{131}iodine and ^{99m}technetium distribution using a pulse-height analyzer with a 20 percent window. Small region-of-interest scans of equal size were then placed over specific areas of ventricular myocardium supplied by the left anterior descending or left circumflex coronary arteries. Counts from each region-of-interest scan were collected for 2 minutes and expressed as percent of total counts of the entire ventricle. ^{99m}technetium counts were corrected for ^{131}iodine cross-talk by counting a ^{131}iodine standard of the same geometric shape as the left ventricular sample.

Data analysis: For each dog, all flow measurements were divided by control or base-line resting coronary flow values recorded before each 10 second occlusion at the beginning of the experiment. The resulting ratios permitted comparisons between dogs of the changes in resting flow and hyperemic responses at each progressive step in coronary arterial constriction. For example, a flow ratio of 3.5 indicates that hyperemic flow was 3.5 times resting base-line flow values. A ratio of 1.0 indicates that there was no change from resting base-line values and a ratio of less than 1 indicates that flow values decreased below resting control values recorded at the beginning of each experiment. With a PDP 8 computer, flow ratios for each dog were plotted against percent constriction by multivariate regression analysis using the least squares fit to a power series to obtain the best fit curve and polynomial equations relating flow to percent lesion.[5] Composite curves and equations for all data combined from the 12 dogs were also obtained by multivariate regression analysis.

Results

Coronary flow responses: Table I shows body weight, diameter of the left circumflex artery, the standard visualizing dose of Hypaque-M 75 percent per kilogram body weight, resting control circumflex flow values and flow responses to Hypaque and to 10 second occlusion. Values for the hyperemic responses are expressed as ratios to base-line flow as described under Methods. For example, in the absence of constriction, mean circumflex arterial flow was 48 ± 18 (mean ± 1 standard deviation) cc/min and increased 3.9 ± 0.9 times after Hypaque injection. Control peak phasic (diastolic) circumflex flow was 76 ± 24 cc/min and increased 3.5 ± 0.9 times after injection of Hypaque. The response peaked 6 ± 1 seconds after injection, after all contrast had been washed from the coronary bed, and lasted 1 to 4 minutes. These responses to Hypaque are equivalent to the reactive hyperemia occurring after 10 seconds of complete occlusion of the left circumflex artery (Table I). In some dogs flow increase after Hypaque was greater than after 10 seconds of occlusion, probably because of biologic variation in the relative effectiveness of the arbitrary dose of Hypaque and arbitrary duration of temporary occlusion as stimuli for vasodilation. Mean base-line heart rate and systolic and diastolic aortic pressures were 143 ± 21 beats/min, 151 ± 22 mm Hg and 121 ± 18 mm Hg, respectively,

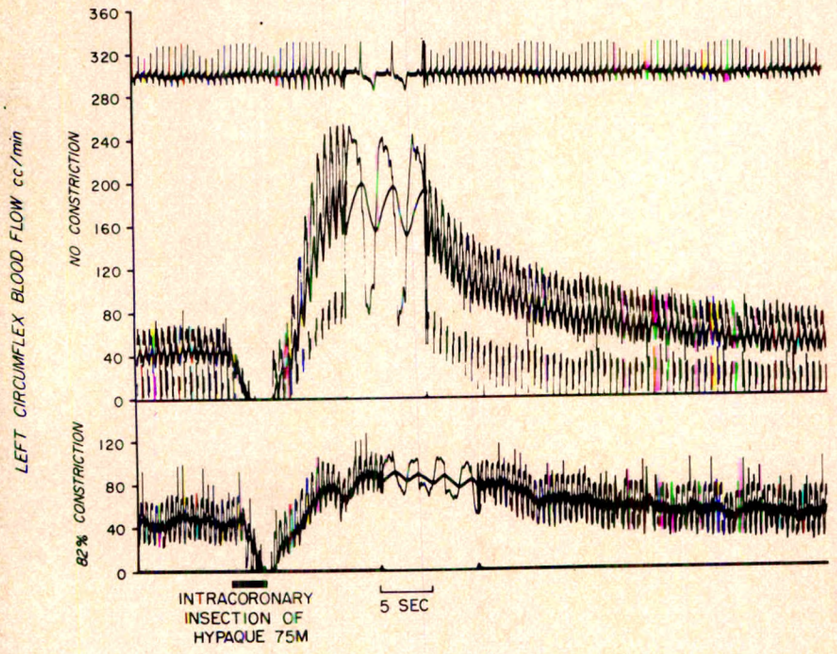

FIGURE 1. Hyperemic flow response in the left circumflex artery after intracoronary injection of Hypaque with no constriction **(upper tracing)** and with 82 percent constriction by diameter **(lower tracing).** The impairment of hyperemia **(lower tracing)** affects mean and peak phasic (diastolic) flow. **Heavy lines** indicate mean flow. Paper speeds are 5 and 25 mm/sec.

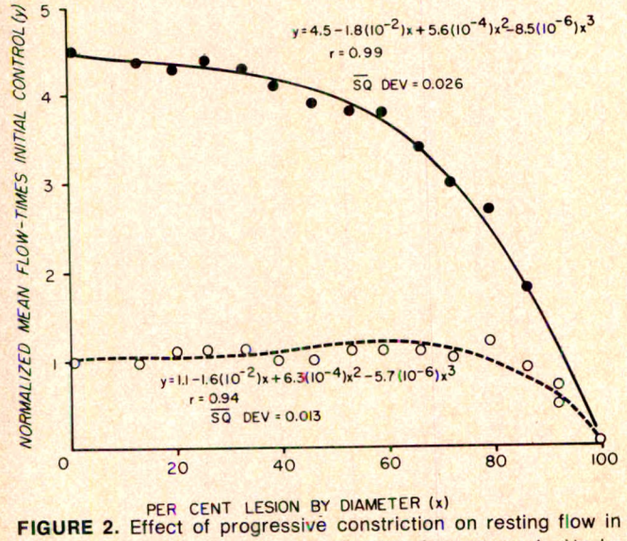

FIGURE 2. Effect of progressive constriction on resting flow in the left circumflex artery (––) and hyperemic response (—) to intracoronary injection of Hypaque in a single dog. Percent constriction by diameter is shown on the **horizontal** axis. Resting and mean hyperemic flow after Hypaque injection, expressed as the ratio of measured to control base-line flow values, is shown on the **vertical** axis. SQ DEV = mean square of deviations.

with no significant mean changes after intracoronary injection of contrast medium.

Hyperemia after injection of Hypaque is illustrated in Figure 1 by a recording of flow in the left circumflex artery. The upper tracing shows no constriction and a four-fold increase in flow in response to the injection. The lower tracing, obtained during 82 percent constriction of the left circumflex artery, shows a blunted hyperemic response; both mean and peak phasic (diastolic) flow responses are markedly reduced. Injection of saline solution did not affect coronary flow.

Figure 2 demonstrates the results of a typical single experiment. With progressive constriction of the left circumflex artery, the normal hyperemic response to Hypaque became blunted when there was 35 percent narrowing and diminished markedly before resting flow was affected. Every dog demonstrated results similar to those of Figure 2 with little scatter of data from the best fit curve, as indicated by correlation coefficients ranging from 0.98 to 0.99 and mean square deviations from 0.115 to 0.003. Figure 3 shows the relation between percent constriction, resting mean flow ratio and mean flow ratio after injection of Hypaque for all dogs. Resting mean flow was not affected until 85 percent constriction occurred, whereas hyperemic response was blunted when there was 45 percent narrowing, decreased precipitously before resting flow was affected, and was gone when narrowing was 93 percent.

Peak phasic or diastolic flow ratios correlated with percent constriction for all dogs together (r = 0.91; mean square deviation = 0.214); the plot and equation are similar to those shown in Figure 3. However, peak phasic flow ratios were affected to a greater extent than mean flow ratios for a given degree of narrowing. Although resting peak phasic flow ratio was unaffected until there was 85 percent stenosis, hyperemic peak phasic response to Hypaque began to fall with 30 percent stenosis and was gone with 88 percent stenosis.

Myocardial flow distribution: An example of myocardial flow distribution before and after injection of contrast medium is presented in Figure 4. Be-

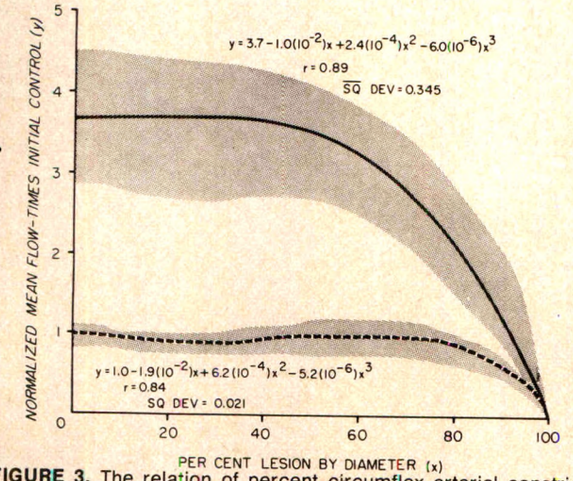

FIGURE 3. The relation of percent circumflex arterial constriction by diameter to resting mean flow(--)and hyperemic response(—)after intracoronary injection of Hypaque in 12 consecutive dogs. Flows are expressed as ratios to control resting mean values at the beginning of each experiment. The **shaded area** indicates the limits of the relation plotted for individual dogs. r = correlation coefficient. $\overline{SQ}$ DEV = mean square of deviations.

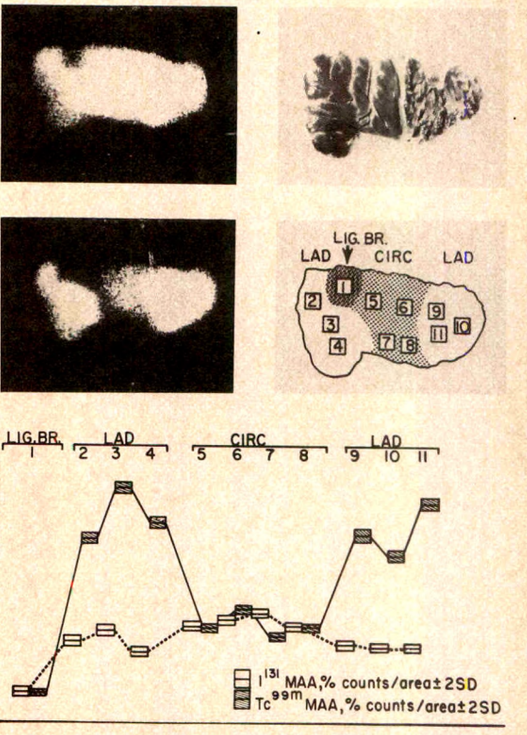

FIGURE 4. Left ventricular regional flow distribution in a dog before and after hyperemic stimulus during 80 percent constriction of the left circumflex artery (CIRC). The dissected, opened left ventricle is positioned endocardium down for postmortem heart scanning **(upper right).** The areas perfused by the circumflex artery are in the center of the specimen surrounded by myocardium supplied by the left anterior descending artery (LAD). The ^{131}iodine image **(upper left)** shows normal resting flow distribution in spite of 80 percent constriction of the left circumflex artery. After intracoronary injection of Hypaque, a ^{99m}technetium image **(lower left)** shows abnormal regional perfusion due to a normal hyperemic response in the anterior descending artery but lack of response in the constricted circumflex vessel. The location of small, equal-sized, region-of-interest scans are indicated by the drawing on the lower right corresponding to the photographed specimen above. Counts for each region-of-interest scan, expressed as percent of total ventricular counts (percent of total ventricular flow), are plotted on the **vertical axis** of the graph with its corresponding location on the ventricle indicated by number on the **horizontal axis.** The graph is a quantitative, rather than visual, demonstration of regional coronary flow distribution. Lig.Br. = a very small coronary branch ligated during transducer implantation.

fore injection, the distribution of myocardial flow was uniform in spite of 80 percent constriction of the left circumflex artery. After injection, there was a marked increase in perfusion of myocardium supplied by the normal left anterior descending coronary artery. However, myocardium within areas perfused by the left circumflex artery failed to demonstrate comparable hyperemia due to the constriction. Thus, flow distribution with an 80 percent lesion was normal at rest but showed marked abnormalities after injection of Hypaque because of the inability of flow to increase in the circumflex artery in response to hyperemic stimulus. The heart image was quantitatively analyzed by making several small, equal-sized region-of-interest scans distributed over myocardium supplied by the left anterior descending and circumflex arteries. The location and approximate size of the areas of interest for this example are demonstrated in the drawing of Figure 4. The number of counts recorded from each area of myocardium was divided by the total number of counts from the entire left ventricle and represents the percent of total left ventricular flow to that area. The graph in Figure 4 shows the percentage of left ventricular flow for the various areas of the myocardium at rest and after hyperemic stimulus. This example quantitatively demonstrates that with 80 percent stenosis of the left circumflex artery, resting flow to areas perfused by the circumflex and anterior descending arteries was relatively equal. After injection of Hypaque, the percent flow to each area perfused by the left anterior descending artery increased markedly but changed relatively little in areas perfused by the left circumflex artery. This relative maldistribution of flow during hyperemia caused an abnormal scan pattern after injection of Hypaque.

The visual and quantitative differences illustrated in Figure 4 may also be expressed as the ratio of counts over myocardium supplied by the anterior descending artery to counts over the myocardium supplied by the circumflex artery before and after the hyperemic stimulus. These ratios were averaged for all dogs (Fig 5). The mean data in Figure 5 were obtained with a mean left circumflex constriction of 85 percent by diameter. During resting flow measurements, before injection of Hypaque, the maximal ratio between peak counts for the left anterior descending artery and mean counts for the circumflex artery was 1.0 ± 0.2, indicating uniform flow distribution. However, after injection of Hypaque, this

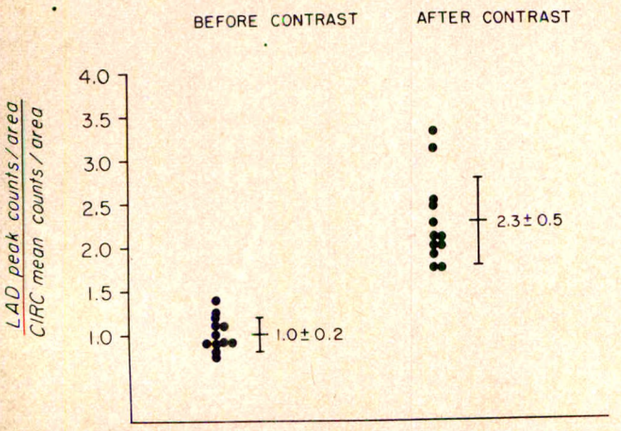

FIGURE 5. Left ventricular regional flow distribution in 12 consecutive dogs before and after hyperemic stimulus in the presence of an average 85 percent constriction of the left circumflex artery. The vertical axis shows the ratio of counts from myocardium supplied by the anterior descending artery (LAD counts) to counts from myocardium supplied by the constricted circumflex artery (CIRC counts). The ratios are significantly different ($P < 0.001$), thus demonstrating normal flow distribution at rest but markedly abnormal distribution during hyperemia.

ratio increased to 2.3 ± 0.5 ($P < 0.001$), indicating markedly abnormal flow distribution. Since the borders of myocardium supplied by the left anterior descending artery are not sharply delineated from those supplied by the circumflex artery, similar ratios were also calculated using mean counts from all small areas of interest taken over the areas perfused by the left anterior descending artery in each dog. Average ratios between mean counts for the left anterior descending and circumflex arteries were 0.9 ± 0.2 before injection of Hypaque and 1.8 ± 0.3 after injection ($P < 0.001$), again demonstrating the differences in regional perfusion during hyperemia but not with resting coronary flow levels.

Discussion

Critical coronary stenosis and the quantitative effects of progressive coronary arterial constriction on maximal coronary flow or coronary flow reserve have not been previously described. Resting coronary flow and its regional distribution are little affected by relatively severe stenosis and are therefore insensitive measures for evaluating coronary disease. Our data demonstrate that resting coronary flow is not altered until a constriction of at least 85 percent by diameter is present, whereas maximal coronary flow is affected by constriction as small as 30 percent. The capacity to increase coronary flow significantly in response to additional oxygen demands is abolished when there is 88 to 93 percent constriction, just after resting flow begins to diminish and this period is defined here as critical coronary stenosis. Thus, although the coronary arteriogram does provide anatomic definition of coronary lesions, it offers little insight into their hemodynamic consequences short of total or near total occlusion. This limitation is a particular problem in the presence of multiple lesions with cumulative effects on maximal coronary flow. With the advent of saphenous vein bypass surgery, hemodynamic assessment of coronary arterial lesions is of considerable practical importance.

Flow response to hyperemic stimulus as measure of effects of coronary constriction: An effective approach to physiologic evaluation of coronary lesions in man depends on solution of three related problems: (1) a method for following rapid changes in coronary flow and flow distribution; (2) a safe and convenient stimulus for increasing coronary blood flow, and (3) a background of basic experimental data relating severity of a lesion to resting and maximal blood flow or coronary flow reserve. This report describes an approach to these problems. The data presented indicate that the flow response to a hyperemic stimulus is in itself an excellent measure of the effects of coronary constriction. Flow responses have been presented in comparison to the more conventional means of describing lesions by percent of diameter constriction in order to demonstrate this approach. However, it should be emphasized that flow response to hyperemic stimulus provides independent, complementary information on the hemodynamic significance of angiographically demonstrated lesions.

Temporary occlusion of major coronary arteries is a potent stimulus for hyperemia, probably because of accumulation of vasodilator substances during the period of occlusion.[6] In chronically prepared intact dogs, occlusions of 5 to 7 seconds' duration are sufficient to elicit maximal increases in coronary stroke flow of three to seven times resting base-line value, and the absolute value is constant in an animal for a given period of occlusion.[6] It has also been noted incidentally during studies of collateral vessel development that reactive hyperemia diminishes during gradual occlusion by ameroid constriction, before resting flow rates are affected.[7] However, in these experiments the degree of constriction was not measured. Although described more completely in dogs, hyperemia also occurs after occlusion in man, as documented during saphenous vein bypass surgery.[8,9]

Temporary coronary occlusion as a stimulus to increased blood flow is unacceptable for diagnostic purposes in man. A number of other stimuli have been used experimentally. Physical exercise in trained dogs increases coronary flow two to five times above resting values.[10-12] Increasing heart rate from 60 to 260 beats/min by electrical pacing increases coronary flow only two times over control levels in unanesthetized intact dogs.[13] Intravenous administration of Persantin® may increase blood flow in dogs four-fold.[11] Administration of pharmacologic agents, such as norepinephrine,[14] nitroglycerin,[15] adenosine triphosphate and adenosine diphosphate,[16] also increases coronary flow but to a lesser extent than temporary occlusion. None of these techniques appear to provide a convenient, safe or effective method of stimulating brief hyperemia in man.

Intracoronary contrast agents are known to cause coronary vasodilatation and increased blood flow in both animals[17,18] and man[19] although the mechanisms are unknown. However, the timing, degree and duration of this response have not been adequately described or utilized previously. Our results indicate that Hypaque-M 75 percent in doses adequate for cineangiography causes brief, marked hyperemic responses that are three to seven times base-line values and equivalent to the reactive hyperemia observed after 10 seconds of complete occlusion. In man, coronary flow has been reported to increase only 15 to 35 percent after injection of contrast medium.[19] However, in that study flow was measured by the ^{133}xenon technique, which is quantitatively inaccurate in the presence of the heterogenous flow distribution found in coronary disease, particularly at increased flow rates.[22-24] In addition, use of this method assumes that coronary flow is constant during the 1 to 3 minute period of xenon washout.[25] There is no evidence to support this assumption and our flowmeter data indicate the contrary, that is, that coronary flow is not constant during the minutes after injection of Hypaque. Differences in species may also explain some of these quantitative differences in responses to Hypaque. Since Hypaque is used clinically in man for coronary angiography, it is a satisfactory stimulus for hyperemia in assessing the effects of lesions at increased flow rates.

Quantification of coronary flow reserve: The concept of coronary flow reserve is essential to the evaluation of coronary disease, but heretofore no approach has been reported for quantifying it. Coronary reserve relates to the ability of coronary vessels to increase blood flow in response to oxygen demands or as compensation for decreased oxygen carrying capacity of blood, or both. It is equivalent to the maximal coronary blood flow after oxygen deficit, that is, complete occlusion. For a given stimulus, this maximal or ceiling flow rate is constant for a given animal and ranges from three to seven times resting base-line flow values. Increases in base-line flow that "use up" some of this reserve result in less potential increase available to meet additional acute oxygen demands. For example, in this study an abnormally low level of arterial PO_2 usually caused an increase in base-line coronary flow but did not affect the absolute value of peak hyperemia. As a result, any relative increase compared to base-line flow values was reduced and remaining coronary reserve thereby diminished. For this reason, arterial PO_2 was carefully maintained within normal limits. Clinical situations corresponding to this experimental observation are found in disease states in which base-line coronary flow levels are elevated, such as anemia, thyrotoxicosis, pressure-volume overload or altitude hypoxia. The observed decrease in exercise tolerance due to cigarette smoking has been ascribed to increased time-tension index for a given level of exercise,[20] that is, increased oxygen demands, and to abnormally high arterial carbon monoxide levels, that is, decreased oxygen-carrying capacity. Thus, the deleterious effects of smoking on exercise tolerance may be viewed in terms of decreased or "used up" coronary flow reserve.

Coronary flow reserve distribution: An equally important concept not previously described is that of distribution of coronary flow reserve. Even if total coronary flow reserve were relatively intact in the face of localized disease, the distribution of blood to small regions of myocardium may become markedly abnormal during hyperemia. Our data indicate that resting flow distribution may be normal in the face of severe constriction of a coronary branch but that regional distribution becomes grossly abnormal after a hyperemic stimulus. Irregular or patchy myocardial regional perfusion which occurs in coronary disease is thus greatly exaggerated with stimuli for increased coronary flow.

Clinical applications: A physiologic approach and a hyperemic stimulus appropriate for evaluating coronary constriction have been described in this report. The application of this approach to man requires a method for following rapid changes in coronary flow and of assessing its regional distribution. Although coronary flow was measured with a surgically implanted electromagnetic flowmeter, we have also monitored changes in coronary flow velocity during canine coronary angiography using a Sones catheter with an ultrasonic, velocity sensing tip. Coronary flow velocity has been recorded in man with a similar instrument.[21] Values for flow velocity can be converted to absolute coronary flow values only if the diameter of the vessel and the angle between the flow stream and beam of ultrasound are known, two factors that have been drawbacks to its clinical use. However, since the ratio of hyperemic to resting flow velocity is equal to the ratio of hyperemic to resting absolute flow, it is not necessary to know vessel size or catheter angle to measure coronary flow reserve. Thus, our approach appears to be technically feasible. However, presently available ultrasonic coronary catheters for use in man do not have a lumen and therefore do not permit injection of contrast medium. A catheter that can be used to obtain cineangiograms and simultaneous velocity recordings requires development for use in patients. Videodensitometry also provides a particularly promising approach for measuring relative and absolute flow changes in each coronary artery. Flow distribution may be evaluated in man with the gamma camera. Although problems of counting geometry and spatial resolution have to be solved, our approach maximizes differences in regional perfusion and therefore should provide diagnostic information for physiologic assessment of the effects of coronary lesions independent of arteriographic interpretation.

Clinical implications: The usefulness of this approach in the clinical setting is speculative at present. Since the relation of flow and stenosis reflects fundamental physical principles, it is reasonable to extrapolate some of the results to man. Thus, a short

lesion of 45 to 50 percent by diameter probably does not impair coronary flow reserve in man but more severe lesions cause a progressive decrease. Unfortunately, prediction of flow reserve from angiographic appearance of a coronary lesion is difficult. Marked impairment of coronary flow reserve occurs with progressive stenosis of 65 to 95 percent by caliper determination, but with lesions of this degree angiography is not sufficiently accurate for measuring small luminal changes having major hemodynamic consequences; this limitation is compounded by multiple or long areas of stenosis. A more physiologic approach might be utilized if responses to Hypaque were established for normal and diseased human coronary arteries by clinical studies using a velocity sensing catheter, videodensitometry or gamma camera. Possibly a hyperemic/base-line flow ratio of less than 1.5 would be an indication for surgery. However, further investigation is essential before these concepts are of practical value in managing patients.

Cardiac Specialized Tissue in Hearts with an Apparently Single Ventricular Chamber (Double Inlet Left Ventricle)

ROBERT H. ANDERSON, MD
ROBERT ARNOLD, MB, ChB, MRCP
MOHINDER K. THAPAR, MD, DCH
RICHARD S. JONES, MD, FRCP, DCH
DAVID I. HAMILTON, MBBS, FRCS

Manchester and Liverpool, England

The morphologic and histologic findings in 14 univentricular hearts are described. All hearts had a single ventricle with a main chamber receiving both atrioventricular orifices and giving rise to the posterior great vessel. The anterior great vessel arose from a smaller outlet chamber.

The main finding was a grossly abnormal situation of the cardiac specialized tissue. Thus, in all 14 hearts the atrioventricular node was a small hypoplastic structure in the interatrial septum. Connection between the atria and ventricles was made by way of an anterior node situated at the junction of the right atrial appendage with the anterior interatrial septum. From this node an atrioventricular bundle descended in the outflow tract of the posterior vessel and lay on the right margin of the foramen between the main and outlet chambers. The bundle was found in this position in both dextro- and levo-bulboventricular loops. The bundle bifurcated astride the septum between the chambers, and a typical left bundle branch passed into the main chamber. Right bundle branch tissue was always present in the outlet chamber. In two hearts with complete heart block neither node made contact with ventricular myocardium, but specialized tissue was present in the ventricular subendocardium.

Because these findings have significance for surgical treatment, it is important to distinguish such hearts from "common" ventricles in which the specialized tissue is reported to lie in the posterior position. The mode of development of the abnormal tissue is discussed, with particular reference to the presence of anterior nodal tissue in normal human development. Finally, it is concluded that either of two concepts could account for the morphogenesis of the anomaly and that further studies are necessary to determine the correct hypothesis.

Hearts with a single or apparently single ventricular chamber have been extensively investigated for more than a century, as documented in a review by Van Praagh et al.[1] in 1964. Two later studies have shown that disagreement exists on several important features of such hearts.[2,3] First, there are fundamental differences of opinion on nomenclature. Thus, Lev et al.[2] use the adjectives "single" and "common" to describe two subgroups of the malformation. Van Praagh et al.,[1] disagreeing with this usage on semantic grounds, use the adjectives interchangeably. The term "double inlet left ventricle" [3] is criticized by Lev's group, who believe the main chamber of such hearts is composed of the sinuses of both ventricular chambers. An extension of this latter point produces the second source of controversy. Thus, the tissue between the chambers in the "single" ventricle (terminology of Lev et al.) is considered to be either bulbar in origin[2] or to represent the true interventricular septum.[1]

These points may seem to be of mainly academic interest, but recent experience in our center shows that they have far-reaching clinical significance. One of us (D.I.H.) recently attempted surgical correction of two univentricular hearts. The first heart was of the "common" ventricular type, in which the conducting tissue is reputed to lie on a posterior muscular ridge.[4] The anomaly was successfully corrected by avoiding this structure. The second heart was of the "single" ventricular type, in which specialized tissue is reported to be similarly situated. However, in this case a similar operative procedure produced traumatic heart block after inevitable suturing in the region of the foramen between the main and outlet chambers. This result indicated that further study of the specialized tissue is necessary in the "single" ventricular heart (type A of Van Praagh et al[1]). Such an investigation is further to be recommended since earlier workers had suggested that elucidation of the disposition of this tissue would clarify the nature of the chambers in such hearts. We have therefore taken appropriate hearts from the pathologic collection of the Royal Liverpool Children's Hospital and studied them histologically to define the course of the cardiac specialized tissue.

Materials and Methods

In view of the controversy concerning the nomenclature of univentricular hearts it is important to establish the morphologic features of the hearts studied in this investigation. We selected hearts corresponding to type A of Van Praagh et al.[1] or the "single ventricle with outlet chamber" of Lev et al.[2] Following the protocol of both these teams, we excluded hearts with atresia of an atrioventricular orifice but included hearts with an atrioventricular canal. Thus the specimens all had a main ventricular chamber that received both (or the common) atrioventricular orifices and gave origin to the posterior great artery (Fig. 1). We term this chamber the "main chamber." The anterior great vessel arose from a smaller chamber composed of ventricular myocardium, which we term the "outlet chamber." The tissue between the chambers is called the septum (Fig. 1).

Each heart was first studied to establish the morphologic characteristics of each chamber and the cardiac anatomy as a whole. To this end, each heart was photographed in anterior, posterior and internal views. All anomalies present were catalogued (Table I). Blocks of tissue were then removed for histologic investigation. When the size of the specimen permitted, the atrioventricular rings were removed in a single block of tissue, along with the septum between the chambers. In larger hearts two blocks were removed, comprising, first, the interatrial septum and adjacent ventricular myocardium and, second, the septum and bulboventricular foramen region. In some of the hearts incisions made at the original necropsies passed through these blocks; in others, all the structures were not present.

After removal, the blocks were prepared for sectioning by embedment in either paraffin wax or low viscosity nitrocellulose. Sectioning of the blocks was performed mostly in the frontal plane relative to the interatrial septum, but some specimens were cut in the transverse plane. Paraffin sections were cut in thicknesses of 10 μ, and low viscosity nitrocellulose sections in thicknesses of 20 μ. Originally 1 section in each 50 cut was mounted and stained by Masson's trichrome technique (1 in 5 for specimens embedded in nitrocellulose). After examination of these sections, additional sections were mounted and stained as required.

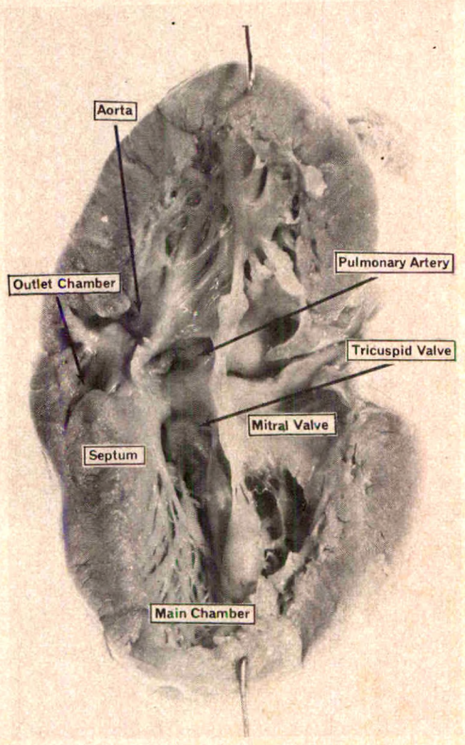

FIGURE 2. Morphologic features of typical hearts. Case 3 (D-loop, D-transposition). The heart has been opened by a cut through its sagittal plane, and is viewed from the left side. The small outlet chamber is anterior to the main chamber, and gives rise to the transposed aorta. Both atrioventricular valves and the pulmonary artery drain to or from the main chamber.

Results

Morphologic Findings

All the hearts studied manifested situs solitus and, as expected, the atrial chambers were in the solitus position. In every heart transposition of the great vessels was present, and the aorta lay to the front of the pulmonary artery. It was not always easy to decide if the aorta lay to the left or right, but we concluded in conjunction with study of the ventricular chambers that seven hearts were dextro-(D-) transposed and seven were levo-(L-) transposed. The main ventricular chamber formed the greater part of the ventricular mass (Fig. 2). The trabecular pattern was rather coarse, and typical fine trabeculae of the normal left ventricular sinus were rarely present. Two masses of papillary muscles were usually attached to each atrioventricular valve, and in several hearts the posterior muscles were fused together to form a prominent ridge of myocardium. It was often difficult to distinguish with certainty a tricuspid or bicuspid valve pattern in any given valve. In three hearts with D-transposition, chordae tendineae arose from the apex of the outlet chamber. These structures were usually paired and were muscular within the outlet chamber. Having traversed the foramen between the chambers, they inserted into the nearest cusp of the right atrioventricular orifice (Fig. 3). In one heart with L-transposition a small papillary muscle was present on the crest of the septum between the chambers, and chordae tendineae similarly arose from this structure to insert into the right atrioventricular valve; in another heart with L-transposition the papillary muscle arose within the outlet chamber. In a third heart with L-transposition one entire cusp of the left-sided valve arose from the outlet chamber and straddled the septum to reach the atrioventricular ring (Fig. 3D).

In all the hearts the foramen between the chambers was situated on the anterior wall of the main chamber, and the septal aspect of the main chamber was always nontrabeculated (Fig. 2). The foramen varied considerably in size but generally was larger in the hearts with L-transposition. One heart with D-transposition had no foramen, and left atrium and aorta were connected only by way of the pulmonary artery and a patent ductus arteriosus.

The outlet chamber was situated on the anterior aspect of the main chamber and in cases of D-transposition was located on the right shoulder of the heart; in cases of L-transposition it was situated on the left shoulder (Fig. 1). In all the hearts studied trabeculations were present in the outlet chamber, and in most hearts these extended for some distance below the level of the septum. Indeed, by using blunt dissection it was possible to define a potential chamber considerably below this level. The upper margin of the foramen between the chambers was composed of the conal septum, and the two limbs of this structure formed the lateral margins of the foramen. They merged with the septum between the chambers at their proximal ends. These muscular ridges were present in the outlet chamber of most of the hearts studied, but in some instances one of the ridges passed into the parietal wall of the main chamber.

Histologic Findings

The general disposition of the cardiac specialized tissue was identical in all the hearts studied (Fig. 4). The tissue was well differentiated in some hearts, less well differentiated in others, and in some hearts it was not possible to define all the structures to be described. We therefore discuss the general plan of the tissue, then its situation in several atypical hearts that warrant separate description. Other departures from the general plan in individual hearts are indicated in Table I.

Position of specialized tissue: *1. In the posterior interatrial septum (Fig. 5b, 6b).* This is the position in which one would expect to find the atrioventricular node. Examination of the region anterior to the coronary sinus revealed some specialized elements. These took the form of attenuated atrial cells that descended toward the fibrous ring. In this position they coalesced to form a small mass of bundles of cells compressed in a half oval against the fibrous ring by the attenuated atrial cells. This is the typical

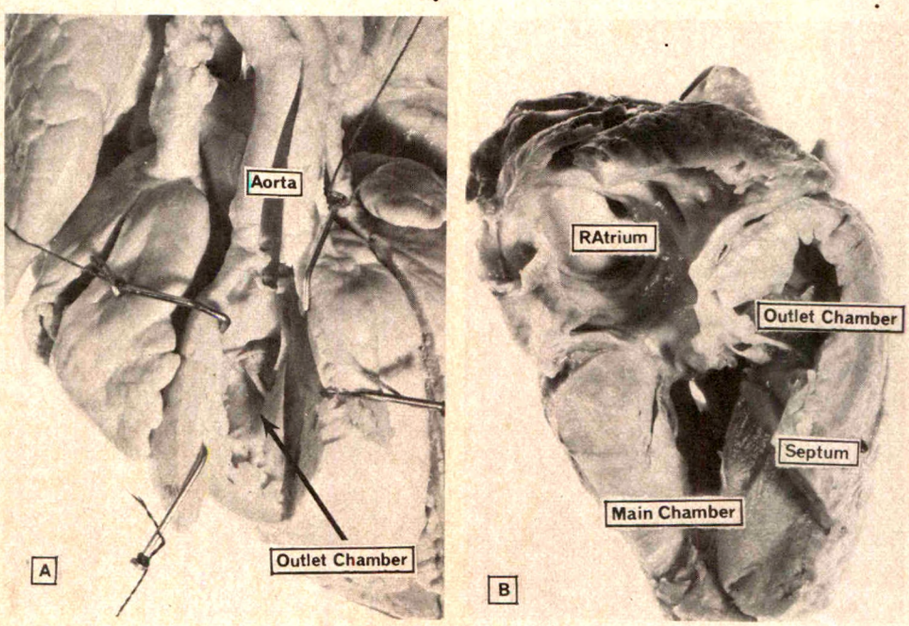

FIGURE 3. Two hearts exhibiting valvular tissue arising from the outlet chamber. **A,** Case 5. The small outlet chamber is opened from the front, and the chordae tendineae are seen passing through the foramen to the tricuspid valve in the main chamber. **B,** Case 7. The parietal wall of the right side of the heart has been removed. The outlet chamber is seen to be anterior to the main chamber, and chordae tendineae are clearly visible arising within the outlet chamber.

arrangement of the node, but in these hearts the mass of cells was much smaller than would normally be expected. When the cells were traced through serial sections, the specialized tissue gradually faded out, and the node made no contact with ventricular myocardium. Similarly, examination of the ventricular myocardium and subendocardium in this posterior region revealed no evidence of conducting tissues.

2. In the anterior interatrial septum (Fig. 5c, 6c, 7). Examination of this area revealed a second collection of atrial specialized cells. This area was situated at the anterior junction of the septum with the right atrial appendage, and medially it was related to the pulmonary arterial wall (in transposed position). As with the posterior node, the atrial cells became attenuated in this region both in the atrial septum and the wall of the appendage. These cells again joined together to form thick interwoven bundles of specialized tissue, again adjacent to the fibrous ring. In contrast to findings in the posterior node, when traced in serial sections this structure became continuous with the atrioventricular bundle, and this

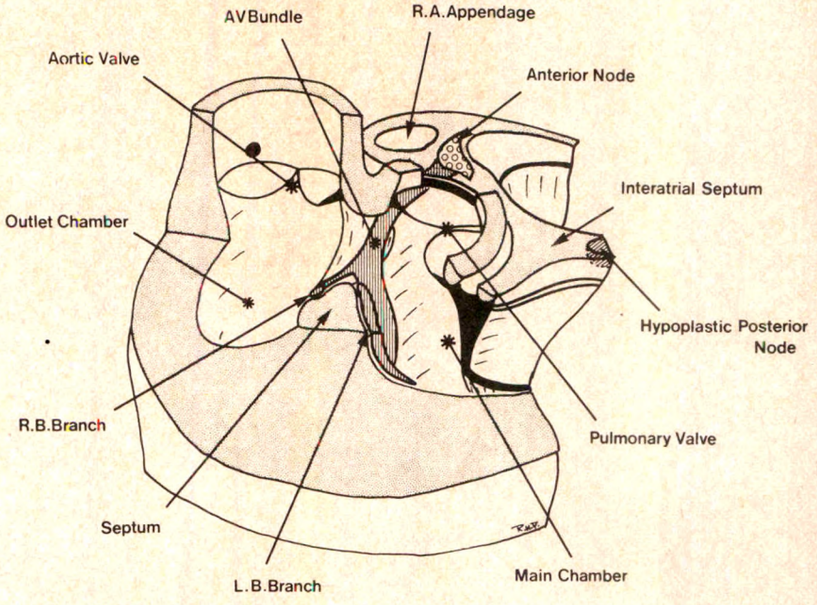

FIGURE 4. Diagrammatic representation of the position of the atrioventricular specialized tissue in the hearts studied. AV = atrioventricular; L.B. = left bundle; R.A. = right atrial; R.B. = right bundle.

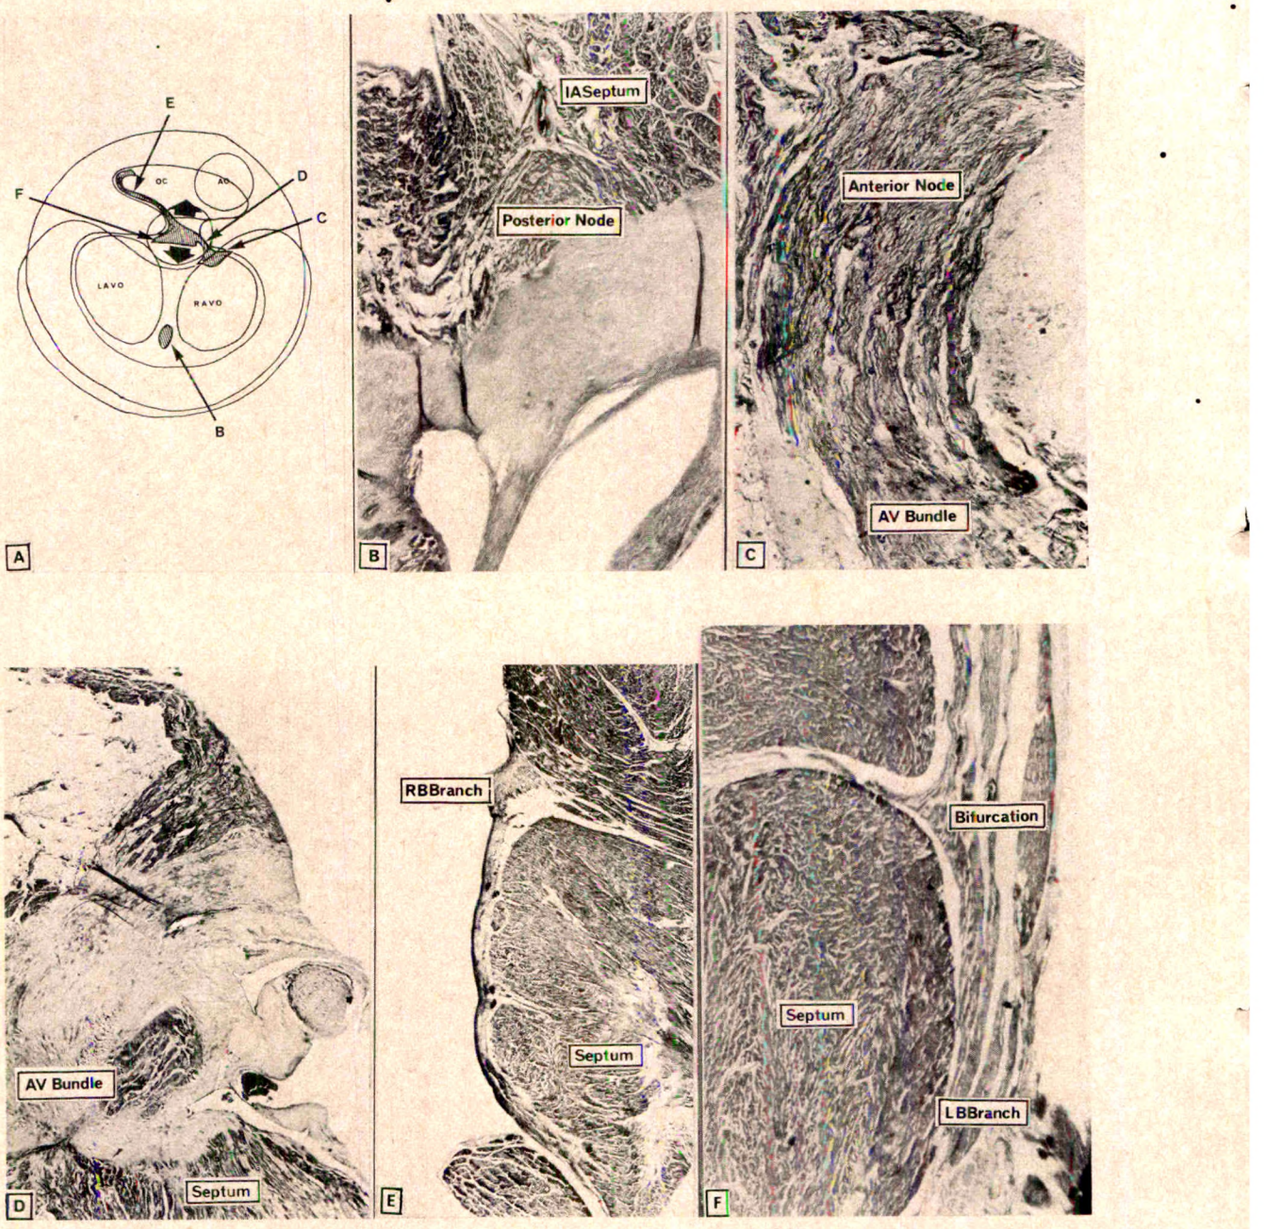

FIGURE 5. Case 2 (D-loop and D-transposition). Disposition of specialized tissue. **A,** diagrammatic cross section. **B** to **F,** photomicrographs taken from the appropriate points indicated in **A.** AO = aorta; AV = atrioventricular; IA = interatrial; LAVO = left atrioventricular orifice; LB = left bundle; OC = outlet chamber; RAVO = right atrioventricular orifice; RB = right bundle. **Arrows** indicate the foramen beneath the pulmonary artery; conducting elements are indicated by **cross hatching.**

was the only atrioventricular connection identified. We refer to this anterior collection of specialized tissue as the anterior node.

3. Atrioventricular bundle (Fig. 5d, 6d). This structure was directly continuous with the basal layer of cells in the anterior node. Having pierced the fibrous ring alongside the pulmonary valve ring, it came into contact with the right border of the foramen between the chambers. The bundle ran an extensive course down this right rim of the foramen, being situated on an aspect facing the main chamber.

4. Bifurcation and subendocardial specialized tissue (Fig. 5e, 6e). Having reached the level of the septum, the main portion of the bundle continued into the main chamber, expanding on the smooth-walled posterior aspect of the septum into a broad sheet of cells typical of the normal left bundle branch. At the level of the septum a smaller cord-like structure could be identified arising from the main bundle. In several hearts this structure arose at a higher level and descended through the myocardium to reach the outlet chamber. In all cases, having reached the outlet chamber, the cord-like structure rapidly expand-

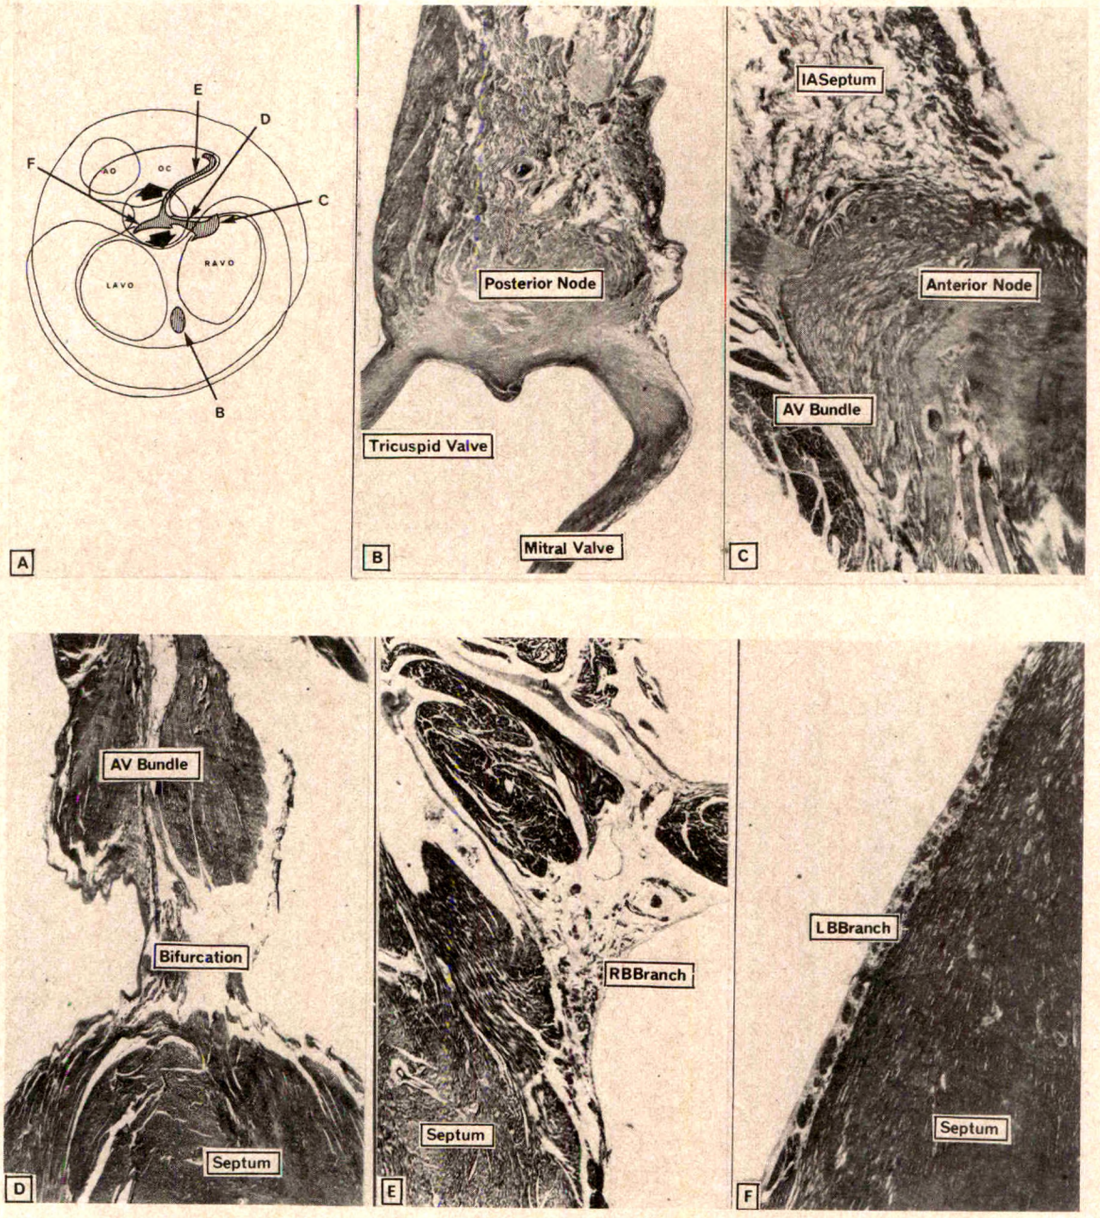

FIGURE 6. Case 10 (L-loop and L-transposition). Disposition of the specialized tissue. **A,** diagrammatic cross section; **B** to **F** photomicrographs from the appropriate points indicated in **A.** Abbreviations as in Figure 5. **Arrows** indicate the foramen beneath the pulmonary artery; conducting elements are indicated by **cross hatching.**

ed to form subendocardial ramifications. These conducting elements, typical of the right bundle branch, were identified within the outlet chambers of all the hearts studied.

Disposition in hearts with L-transposition (Fig. 4b, 6): The conducting tissue in these hearts was identical to that just described. Both posterior and anterior nodes were present, but only the anterior node made contact with the bundle. This bundle was again on the right border of the foramen, and descended in similar fashion. The left bundle-like structure passed into the main chamber, whereas the right bundle branch ran into the outlet chamber.

Hearts presenting with complete heart block: *1. Congenital.* Two hearts were in this category. In both, the general arrangement was similar to that described, but the various segments of specialized tissue were unconnected (Fig. 8). Thus, in one specimen, both atrial nodes were present, but neither made contact with ventricular myocardium. In the other specimen, which had an atrioventricular canal, a large segment of specialized tissue was confined to the atrial margin of the atrioventricular ring on its right side. In both hearts specialized tissue was identified astride the septum and in the subendocardium of both chambers. In the heart with two atrioventric-

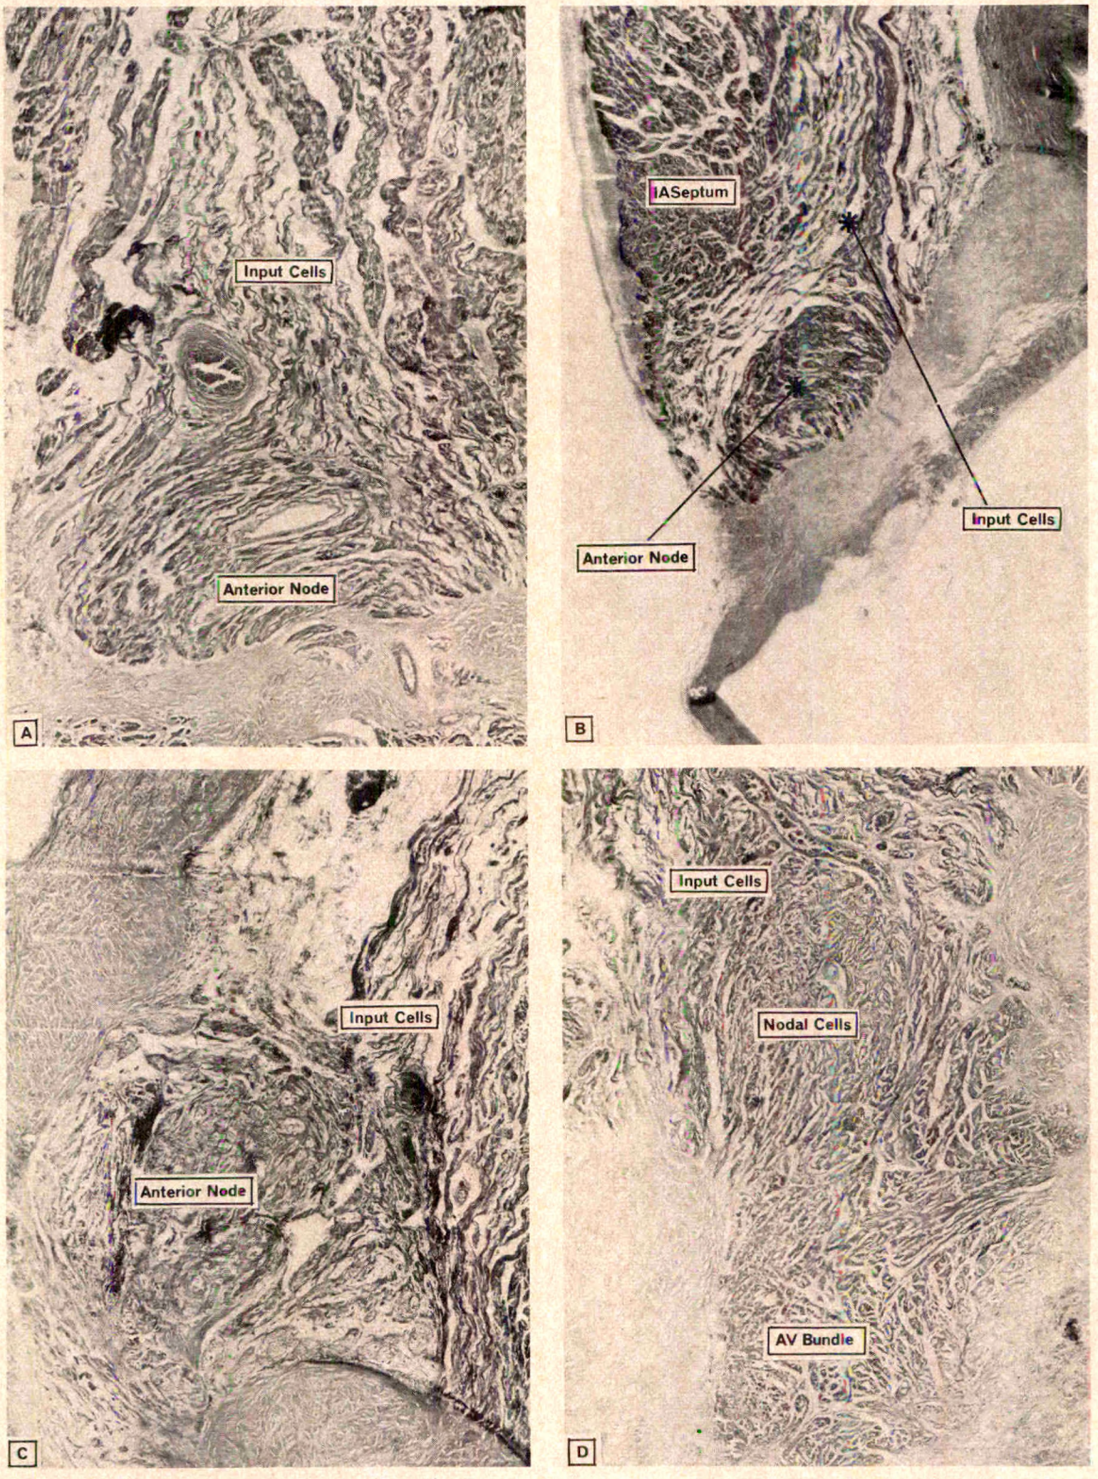

FIGURE 7: Higher power photomicrographs showing the structure of the anterior node. **A**, Case 4. **B**, Case 3. **C** and **D**, Case 14. Serial sections some distance apart. Abbreviations as in Figure 5.

ular valves it was also possible to identify atrioventricular bundles on each rim of the foramen between the chambers. However, each of these structures ended blindly, and made no contact with the atrial nodes.

2. Traumatic. The heart in which operative correction had been attempted comprised this category. L-transposition was present. As in the other hearts studied, the posterior node was identified in the interatrial septum and made no contact with the ven-

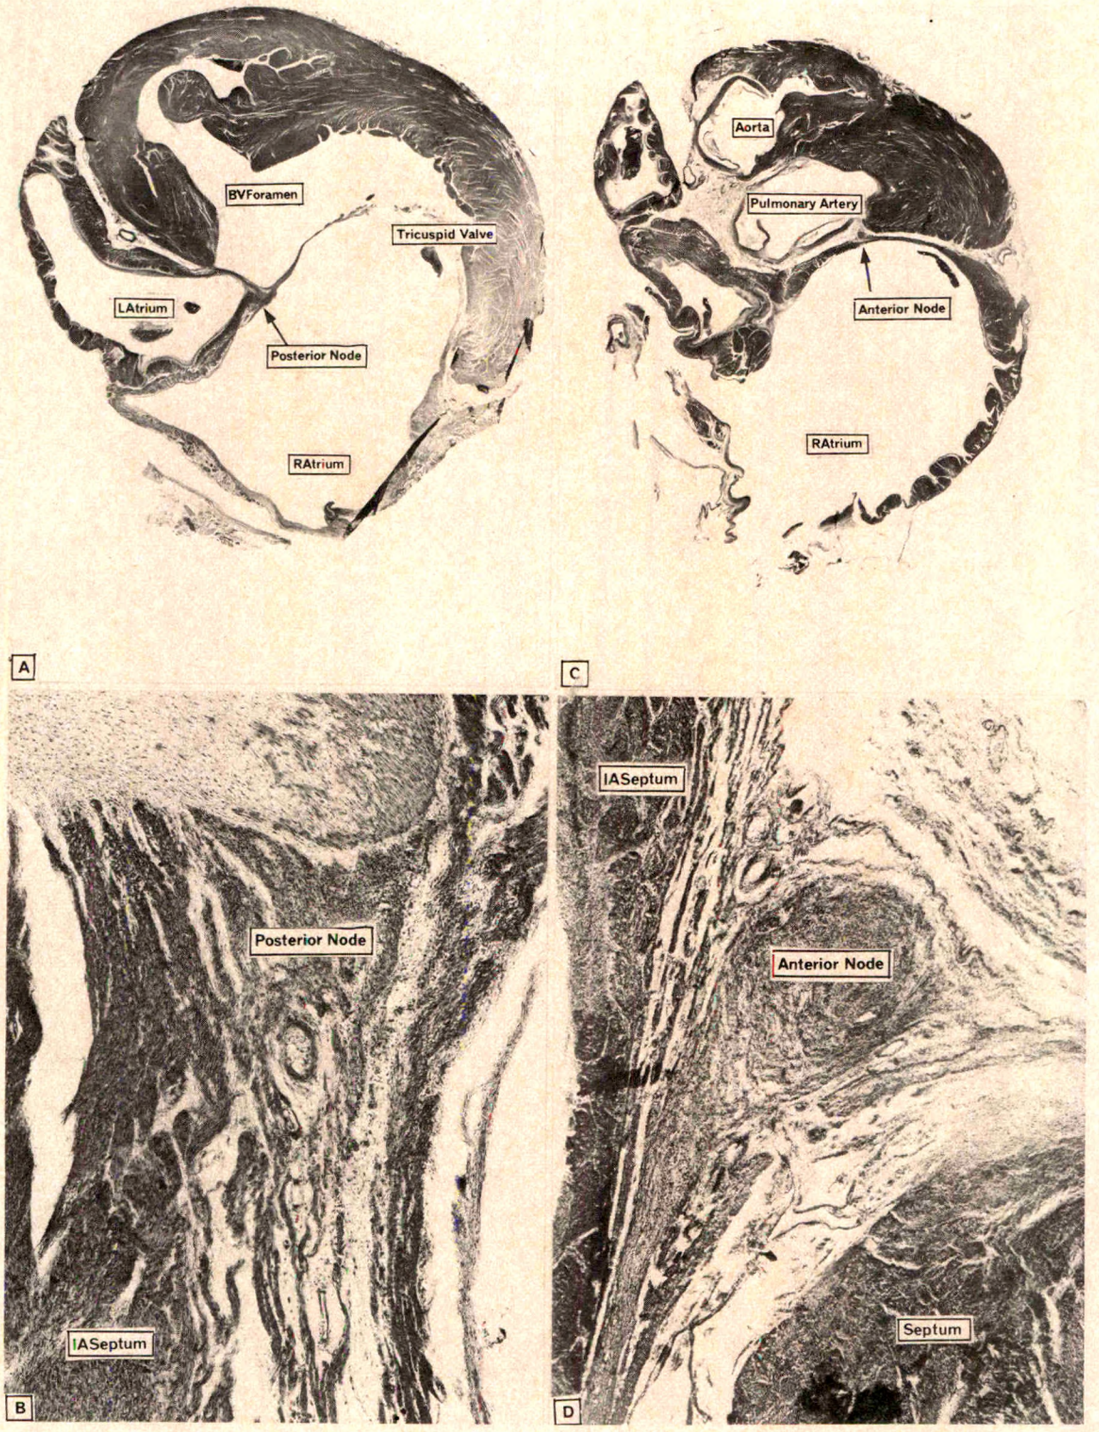

FIGURE 8. Case 12 (complete heart block). Disposition of specialized tissue. **A,** position of the posterior node (magnified in **B**). **C,** position of the anterior node (magnified in **D**). Neither node made contact with ventricular myocardium, which contained well formed specialized elements. BV = bicuspid valve; IA = interatrial; L = left; R = right.

tricular myocardium. The anterior portion of the heart was extensively traumatized, and it was not possible to identify the anterior node. However, the bundle was present, descending down the right rim of the bulboventricular foramen, and this structure bifurcated astride the septum. The conducting tissue in both chambers was extensively infiltrated with hemorrhagic exudate.

Hearts presenting with a short P–R interval and normal QRS complex: Four hearts in this cate-

gory were studied, and two had D-transposition. In each case, the specialized tissue was very well differentiated and was easy to follow. The anterior node was better developed than in most of the other specimens. Figures 5 and 6 are both taken from hearts in this group.

Heart with straddling atrioventricular orifice: One heart with this abnormality was studied. L-transposition was present. The posterior node was very poorly formed and made contact with ventricular myocardium. The anterior tissue was not identified in this specimen, but well formed bundle branches and their ramifications were present in both the main and the outlet chambers.

Discussion

Surgical implications of differentiating "single" and "common" ventricle: Our investigation has established that the specialized tissue is unexpectedly situated in hearts of the "single" ventricular type (type A of Van Praagh et al.[1]). This finding has implications for both clinical practice and the morphology of the anomaly. First, review of the literature indicates that the situation we describe differs from that previously reported by Lev[4] in single ventricular hearts. This brief report suggested that the tissue was located on a posterior muscular ridge in both "single" and "common" ventricles. Such a situation is to be expected in the "common" ventricular heart, since this malformation represents a huge ventricular septal defect, and the posterior position of conducting tissue in the bulk of such anomalies is well documented.[5-7] Our operative experience also confirms such a position in "common" ventricle. In "single" ventricle our findings show that the tissue is not situated astride a posterior ridge. Indeed, in the hearts we studied, the fused posterior papillary muscles were the only structures we could identify as approximating such a ridge. In fact, the tissue lies astride the septum, and the connecting atrioventricular bundle descends down the right rim of the bulboventricular foramen, having perforated the fibrous ring to the right of the posterior great vessel. It is therefore vital to distinguish between "single" and "common" ventricle before embarking upon corrective surgery in univentricular hearts since the area "at risk" differs in the two subgroups.

Our experience suggests that repair of the defect in "single" ventricle without suturing on the right side of the foramen is likely to prove extremely difficult when the anomaly is associated with transposed great vessels. Although we are still studying this aspect of the problem, we recommend caution in subjecting such hearts to operation, since there is every likelihood of producing complete block during the corrective procedure. However, if "single" ventricle is associated with nontransposed great vessels, as in the so-called "Holmes" hearts,[8] then it may well be possible to produce correction without impinging upon the right rim of the bulboventricular foramen. This, of course, presupposes that the specialized tissue is similarly arranged in such hearts. Clearly, the surgeon would be helped if he knew the precise type of univentricular heart he was to repair before he entered the chest. Our clinical records show that the diagnosis of univentricular heart with outlet chamber was initially difficult to make, but most of the cases were investigated several years ago, and retrospective study of the angiograms showed that the outlet chamber was visible in most hearts. With modern radiologic techniques in specialized centers, exact diagnosis should be feasible.

Mode of development of specialized tissues: We consider that from a developmental viewpoint the relevant findings of our investigation are the presence of: (1) a hypoplastic posterior node making no ventricular connection, (2) a well formed anterior node establishing atrioventricular communication, and (3) an anterior bifurcation, with the right bundle branch always present in the outlet chamber.

The posterior node is present in the interatrial septum and is related to the coronary sinus. It therefore seems reasonable to propose that this structure represents the atrophic atrioventricular node of the normal heart, which is considered to be derived from either left sinus horn tissue[9] or atrioventricular canal musculature.[10] Documentation of anterior nodes in the human heart is very rare; to the best of our knowledge the only examples are those in the case described here and in the cases cited by Lev et al.[11] No cases have been described with sole atrioventricular communication through an anterior node. However, a recent study[12] of development of human specialized tissue showed that the atrioventricular node develops in strata, and that the lowest stratum and the atrioventricular bundle are developed as one single unit. Furthermore, the development of this unit is intimately related to the development of the posterior portion of the interventricular septum, whereas the bifurcation and bundle branches are developed in relation to the anterior, bulboventricular, part of the septum.

Most important, however, was the finding that an annulus of specialized tissue was present in the distal margin of atrial musculature at its insertion into the tricuspid valve base, and that this annulus was expanded into a second node-like structure anteriorly. Although this was originally described as a lateral structure,[12] reexamination of the fetal specimens together with examination of normal human neonatal hearts (unpublished observations) shows that the anterior node is present at the junction of the anterior interatrial septum with the atriobulboventricular ledge tissue, and that it is separated from the normal bifurcation only by the fibrous annulus and some conal septal musculature (Fig. 9A). Furthermore, identical specialized tissue is present in adult rats, rabbits and guinea pigs,[13,14] and similar tissue has been previously reported in the embryonic calf.[15] Although in the normal heart this tissue does not form an atrioventricular connection, we believe that in the hearts described here it forms the abnormally situated anterior atrioventricular connection. This is because in "single" ventricle with outlet chamber

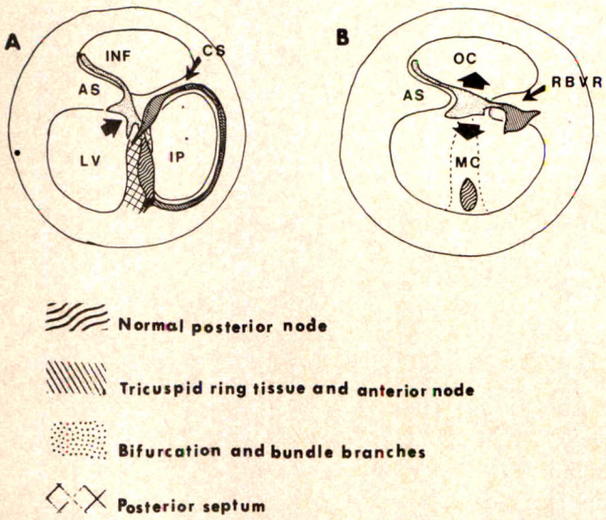

FIGURE 9. Diagrams to show postulated mechanism of production of anterior atrioventricular connection. **A,** the normal situation with the atrioventricular node astride the posterior septum, which brings it into contact with the bifurcation and bundle branches. However, the tricuspid ring tissue and anterior expansion are always present in the fetal heart. **B,** in "single" ventricle with outlet chamber, the posterior septum is either absent or malpositioned. Therefore the posterior node is unable to contact the bifurcation. The connection is effected through the anterior expansion of ring tissue which becomes the anterior node. AS = anterior septum; CS = crista supraventricularis; INF = infundibulum; IP = inlet portion right ventriculer; LV = left ventricle; MC = main chamber; OC = outlet chamber; RBVR = right bulboventricular ridge. **Thick arrow** in **A** = position of bulboventricular foramen.

the posterior interventricular septum is either absent or misplaced. The lower nodal-atrioventricular bundle unit is therefore unable to connect the posterior node with the ventricles. In contrast, the interatrial septum, atriobulboventricular ledge and anterior interventricular septum are in relatively normal positions. It is therefore easy for the embryonic anterior node to effect connection with the normally situated bifurcation and branches and produce the situation described here (Fig. 9B).

If this concept is correct, then a heart with both nodes present would be a developmental possibility, with both nodes making atrioventricular connections. We have described such an arrangement of conducting tissue in an unusual form of double outlet right ventricle, in which the two nodes formed two bundles that merged into a common bundle before bifurcating to supply the ventricles.[16] Confirmatory evidence of the validity of our concept is provided by study of hearts with classically corrected transposition. Walmsley[17] suggested that the sinistral loop of such hearts carried the ventricular specialized tissue an excessive distance away from the node, and he explained the high incidence of heart block in these cases on such grounds. The case of Lev et al.[11] and our two cases with complete block demonstrate that the anterior node, although well developed, is also unable to establish contact. However, we have also examined a case of classic corrected transposition with normal conduction tissues in which the situation of the specialized tissue was identical to that described here, with contact occurring by way of the anterior node (unpublished observations). Thus we consider that the abnormally situated tissue in "single" ventricle is an overgrowth of the specialized tissue always present in the normal heart and that this overgrowth is caused by failure of development of the posterior portion of the interventricular septum.

Morphogenesis of univentricular heart: Our morphologic and histologic findings are relevant to the morphogenesis of the anomaly, which is highly controversial and inextricably linked with the controversy surrounding the origin of the right ventricle of the normal heart. Pernkopf and Wirtinger, and Goertler (quoted by Lev et al.[2]) believed that the primitive ventricle was septated to produce the inflow portions of both ventricles, whereas the outflow tracts were formed from the conotruncus. Application of this theory to "single" ventricle suggests that the posterior interventricular septum is absent, and that the septum is either a pseudo-septum of conal ridges[18] or a persistence of the bulboventricular ridges (the latter interpretation was made by Harley[19] after an extensive review of the literature). In contrast, studies performed at the Carnegie Institute[20,21] showed that the trabeculated pouch of the right ventricle was a bulbar structure and that the entire bulboventricular septum became the interventricular septum after rightward migration of the atrioventricular canal. Thus, de la Cruz and Miller[3] consider that "single" ventricular hearts represent lack of atrioventricular canal migration—hence their term "double inlet left ventricle." Van Praagh and associates also adopt this concept, but they consider that the right ventricular sinus is absent and that the outlet chamber is infundibulum. They do believe that the septum is true interventricular septum.

Both Lev et al.[2] and Van Praagh et al.[1] suggest that study of conducting tissue can elucidate this problem. However, either concept can explain the disposition described because the conducting elements are normally formed astride the anterior septum, and this is a bulboventricular structure in either concept of development. Similarly, the continuity between posterior node and bifurcation may be lacking either because the posterior septum is not formed or because it is misplaced. The presence of the atrioventricular bundle on the right edge of the bulboventricular foramen tends to favor the concept of lack of migration.

Review of our morphologic findings is also inconclusive. The presence of different trabeculated patterns on either side of the main chamber and normal attenuation of the atriobulboventricular ledge with centralization of the posterior great vessel favor the hypothesis of Lev[2] and Harley.[19] However, the presence of valvular elements in the outflow chambers of some hearts, together with trabeculation of these chambers, supports the concept of de la Cruz and Miller.[3] On examination of embryos and other malformed hearts we find no evidence of separate growth

of anterior and posterior portions of the ventricular septum; absence of such evidence contends against the ventricular septation hypothesis. On theoretical grounds we are also unable to understand how the right atrioventricular canal migrates to contact the bulbus without a sleeve of ventricular myocardium being incorporated into the right ventricle. Thus, on the evidence available, we are unable to decide which hypothesis is correct. We are now investigating a series of hearts with juxtaposition of the atrial appendages, generally agreed to indicate a primitive state of the bulboventricular loop. These hearts may provide vital evidence. In addition, we believe that accurate study of embryos in horizons XIII to XVI would elucidate the mode of migration of the atrioventricular canal. Accurate illustration and description of this event is singularly lacking in the account of de Vries and Saunders.[21]

In conclusion, we endorse the opinion of Lev et al.[2] that in our present state of knowledge it is preferable to refer to these hearts simply as "primitive" ventricles. We also believe that it is necessary to indicate whether there is an outlet chamber since presence of this feature indicates that the specialized tissue will occur in the abnormal situation described.

Acknowledgment

We acknowledge with gratitude the help received from Professor J. D. Hay and Dr. J. Shackleton, and their kind permission to study cases previously in their care. We are also indebted to Dr. A. E. Becker of Wilhelmina Gasthuis, Amsterdam, who kindly read and criticized an earlier manuscript. The technical procedures were excellently and carefully performed by Mrs. A. Smith, and photographic material is the work of Messrs. K. Walters and R. Wylie.

Updating Sphygmomanometry

LEONARD STEINFELD, MD, FACC
HAROLD ALEXANDER, PhD
MYRON L. COHEN, PhD

New York, New York
Hoboken, New Jersey

The measurement of systemic blood pressure using a sphygmomanometer and stethoscope is well entrenched in medical practice. As a noninvasive tool for the rapid determination of intraarterial pressure, the technique has proved accurate and reliable most of the time—that is, if one has no interest in the obese, the very young, those with shock or those whose upper limbs are unusually conically shaped and thus adapt poorly to standard cuffs. With the exploding technology of the past two decades one would have expected a more precise technique to have evolved for the noninvasive assessment of systemic blood pressure. But except for a few abortive flourishes in automation, blood pressure measurements are obtained in much the same manner as in grandfather's day. Today, needless to say, the errors inherent in the technique are no less nettlesome.

In the generally accepted procedure of sphygmomanometry, after inflation of the pneumatic bladder, the intrabladder pressure, as measured by either an aneroid or mercury manometer, is assumed to be identical to pressure applied to the artery wall by the compressed tissues. After deflation of the bladder, the onset of tapping sounds (Korotkoff sounds[1]) heard through the stethoscope is taken as a sign of peak systolic brachial pressure and the cessation or muffling of the sounds is the sign of end-diastole. Too often, unfortunately, these signs fail to signal true systole and diastole. On closer examination of the procedure, we find that this error stems from two principal sources: (1) inaccurate transmission of bladder pressure to the artery wall due to the design of the cuff-bladder assembly and, (2) lack of understanding of the relation of Korotkoff sounds to the systolic and diastolic end-points, resulting in their improper detection. Although faulty instrumentation and clumsy technique cannot be ignored as frequent causes of error, their elimination is simpler than elimination of the problems of cuff and sound, which requires a better understanding as a prerequisite.

Von Recklinghausen[2] in 1901 is reputed to have been the first to propose changing the design of the sphygmomanometer cuff to improve accuracy in blood pressure measurement. However, after 70 years of attention focused on the problems surrounding the choice of the ideal sphygmomanometer cuff, a satisfactory and universally acceptable product has not been developed. The principal reason for this failure is the lack of information on the conditions necessary for the accurate transmission of bladder pressure to the artery wall; consequently, a blood pressure cuff that can reliably satisfy these conditions has not been designed. The 1967 American Heart Association recommendations for human blood pressure determination[3] proposed a pneumatic bag 20 percent wider than the diameter of the limb on which it is to be used. With respect to length, it was suggested that the bag should go halfway around the limb, but be placed directly over the compressible artery. These recommendations have not been updated although there is now convincing evidence that a revised set of standards for the pneumatic bag are in order.

Recommendations for occlusive cuff and pneumatic bag: From a series of experiments performed in our laboratory on an upper arm-brachial artery hydromechanical analog,[4] and from analytic studies,[5] we have concluded that intrabladder pressure is transmitted with least decay to the underlying compressible artery when the length of the pneumatic bag is such that it completely encircles the model arm. The conclusions drawn from these studies have substantial support in data derived from human studies in a number of laboratories, including our own. The results of studies carried out by King,[6] Karnovin[7] and others[8-10] support the view that a completely encircling pneumatic bladder is preferable to any abbreviated version. The compromise that we indulge in today of employing a short inner bladder and an outer sleeve of so-called stiff fabric seems to be less of a compromise than an open invitation to error.

From the Division of Pediatric Cardiology, Mount Sinai Hospital, New York, N. Y. and the Stevens Institute of Technology, Hoboken, N. J. Manuscript accepted June 14, 1973.

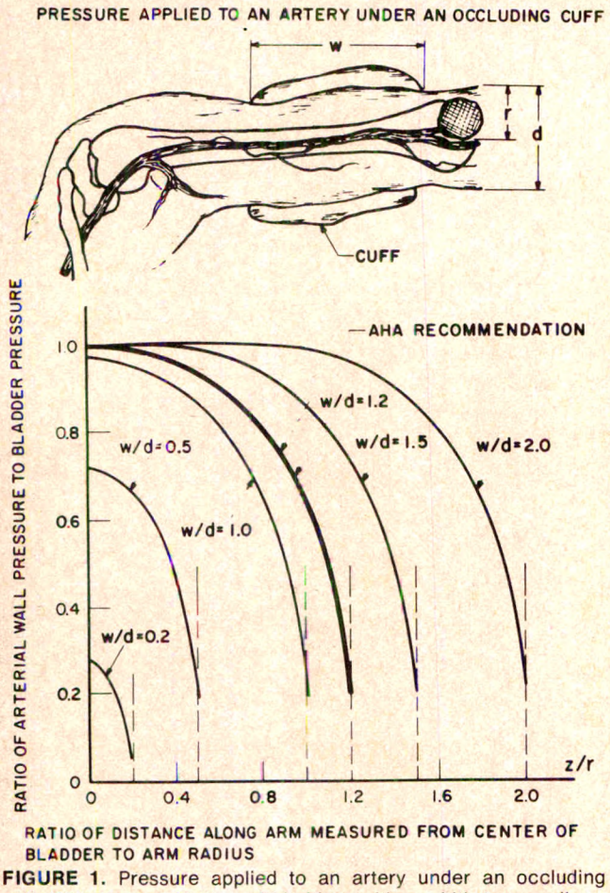

FIGURE 1. Pressure applied to an artery under an occluding cuff. With the application of bladders with a width to arm diameter ratio (w/d) ranging from 0.2 to 2.0, it is found that at w/d = 1.2 the arterial wall pressure reaches the bladder pressure value at one point on the artery under the center of the cuff (z = 0). As w/d is increased, a longer length of the artery is exposed to the full cuff pressure, but no segment of artery is ever subjected to a pressure greater than the bladder pressure. Analytic studies, therefore, negate the view that wide bladders cause underestimation of arterial pressure. d = diameter of arm; r = radius of arm; w = width of bladder; z = distance along arm measured from center of bladder.

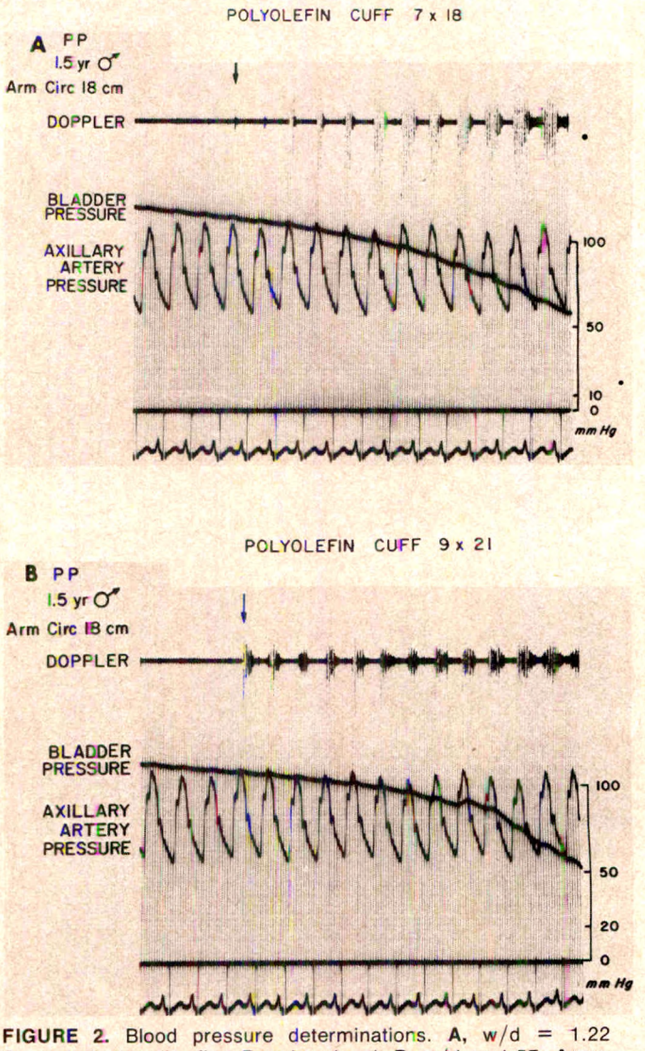

FIGURE 2. Blood pressure determinations. **A,** w/d = 1.22 **Arrow** indicates the first Doppler signal. **B,** w/d = 1.57. **Arrow** indicates the first Doppler signal. d = arm diameter; w = bladder width.

With respect to determining the optimal width of the pneumatic bag, it has been well documented in clinical studies that very narrow bladders yield inordinately high systolic and diastolic values at all age levels. However, no physically sound explanation has been previously presented for this phenomenon. Recently, analytic studies[5] have determined that constraint of longitudinal arm tissue motion is associated with accurate pressure transmission to the artery wall. These studies have also predicted the minimal ratio of bladder width to arm circumference for accurate pressure transmission to at least a point on the artery under the center of the cuff. The American Heart Association recommendation of a bladder width 20 percent greater than arm diameter ($1.2/\pi$ × arm circumference) accords very well with these analytic results as a minimal requirement (Fig. 1). However, in a number of clinical experiences, for example, with the upper arm of small infants, the long thin upper arm of the tall adolescent, and the broad tapered upper arm of the very obese, bladder widths 1.2 × arm diameter yield systolic and diastolic values considerably higher than those of simultaneously recorded intravascular pressures. In our patient sampling, a bladder width that complied with the Heart Association recommendation produced a narrow cuff effect, indicating that these minimal requirements should be exceeded to ensure accurate measurement (Fig. 2). In both human and analog experiments in which wider bladder widths were tested, peak systolic values failed to show the marked discrepancies noted with narrow bladders. In the majority of instances, the correspondence between direct and indirect peak systolic pressures was identical or nearly so. In human investigations, unusually wide bladders, extending from the axilla to a level 1 or 2 cm above the antecubital crease, failed to elicit previously reported low peak

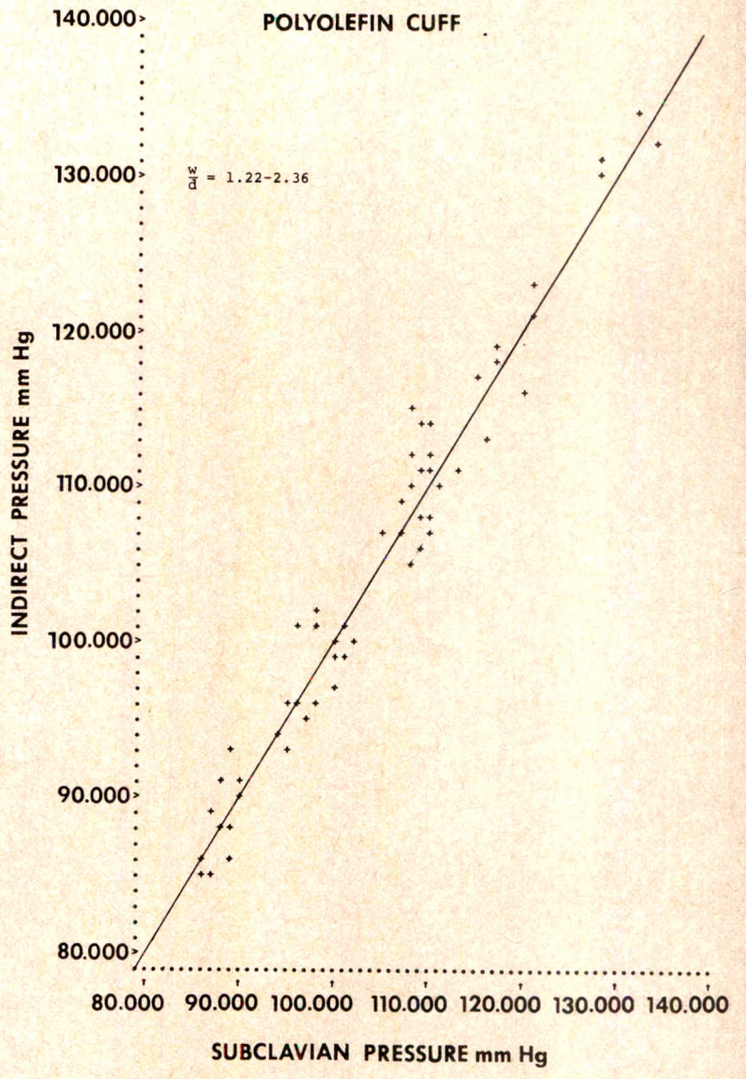

FIGURE 3. Comparison of direct and indirect use of peak systolic pressure measurements obtained with polyolefin cuffs. Indirect peak systolic pressure measurements were obtained using polyolefin cuffs with a width to arm diameter ratio ranging from 1.22 to 2.36. Arterial peak systolic pressures were measured with a catheter tip at the subclavian-axillary artery junction. The center diagonal is the line of identity, and the light parallel lines are +3 mm Hg. The seven instances in which indirect pressures were noted to exceed the 3 mm error were measurements obtained using polyolefin cuffs with a width to arm diameter ratio of approximately 1:2 (American Heart Association recommendation).

systolic values[3] when direct and indirect pressures were compared. These clinical results are in agreement with the analytic prediction of the nonexistence of the so-called "wide cuff effect."[5] Indications of the production of Korotkoff sounds in our studies, however, were sensed with a Doppler ultrasonic transducer rather than with a stethoscope. Poor signal pickup with a stethoscope may actually account for the low values previously reported with the application of wide cuffs to the upper arm.

We have come to realize that the one or two different bladder-cuff sizes used for blood pressure measurement in the adult and the few models available for infants and children are inadequate to achieve the levels of accuracy and reliability possible with this technique. The goal now would appear to be a pneumatic bladder that completely encircles the limb and that has a minimal width to length ratio of approximately 1:3, with an option for greater width to length ratios when circumstances demand. For the conically shaped obese arm or leg, the rectangular configuration should be replaced by a bladder of trapezoidal design so that, when applied to the limb, it would conform more closely to its natural contours. In effect, we are suggesting an individualized pneumatic bladder prescription which might be accomplished with the aid of a sphygmomanometer bladder kit containing a variety of bladder sizes and types. If this seems unnecessarily tedious, it is no more so than for the ophthalmologist, for example, who refracts eyes with a battery of lenses at his disposal rather than with a few choice pieces.

Relation of Korotkoff sounds to systolic and diastolic pressure levels: Unfortunately, the matter of the choice of a proper occlusive cuff is only a portion of the solution to the problem of improving the accuracy of sphygmomanometry. The relation of the Korotkoff sounds to the systolic and diastolic pressure levels must be appreciated. These sounds have at various times been attributed to a water hammer effect,[11] fluid shock wave propagation,[12] turbulent motion of the blood[13] and oscillations of the arterial wall.[14,15] It is obvious that the major component of the sounds cannot be associated with all of these

phenomena. It is necessary to determine which component of the Korotkoff sound production is of interest in blood pressure determination and how these sounds relate to the physiologic events occurring under the cuff.

Korotkoff sounds reproduced in an arm analog have been found to be virtually identical to their in vivo counterparts.[4,16] This analog has been used as a tool to investigate the probable origins of the Korotkoff sound production. Simultaneous recordings were made of the audible sounds, the oscillation of the arterial wall and the arterial blood flow velocity. This was accomplished by sensing with a crystal microphone and a Doppler ultrasound transducer in both analog and human studies. Frequency analyses of these signals have shown that the arterial wall oscillations cause the major component of the Korotkoff sounds. The first arterial wall oscillations begin at the moment intrabladder pressure drops below peak intravascular pressure and terminates when intrabladder pressure dips below end-diastolic pressure.

The vibrating arterial wall normally gives rise to sounds detectable with a stethoscope. Unfortunately, these sounds are often not discernible in human subjects because their frequency or amplitude, or both, lie below the range of human audibility. This becomes most apparent in attempts to determine blood pressure in small infants, in some obese adults and in subjects with shock. Consequently, one would prefer to sense the arterial oscillations at their source rather than listen to the sounds produced by those oscillations. A suitable filtered and properly positioned Doppler ultrasonic transducer is far more sensitive in directly detecting arterial wall oscillations than is a stethoscope in indirectly sensing these oscillations by picking up Korotkoff sounds. At present, in human studies employing the ultrasonic transducer in place of a stethoscope, extremely accurate measurements of peak systolic pressures are obtainable. The determination of end-diastolic pressure, however, is more difficult since appropriate conditioning of the ultrasonic signal is necessary to isolate the arterial wall oscillations at end-diastole from the blood flow signal which is also sensed by the Doppler system. Instrumentation now available is capable of this discrimination.

Recommended method for sphygmomanometry: In conclusion, we recommend that indirect blood pressure measurement by sphygmomanometry be performed with a properly designed and sized cuff-bladder assembly as described and an appropriate arterial oscillation sensor. A variety of such systems have been under investigation and evaluation over the past several years by many investigators. For the past 2 years, in our laboratory, we have been developing and clinically testing an integral pneumatic cuff-bladder assembly made of a heat-sealable polyolefin film. This assembly has been designed to satisfy the conditions necessary for accurate bladder pressure transmission to the artery wall. It has been made available by the manufacturer in all desired lengths, widths and configurations and can be produced sufficiently inexpensively to be disposable. A relatively inexpensive, commercially available Doppler ultrasound system has been used in our studies and has been found to be adequate to our needs. In the tests performed to date on a variety of hypotensive, normal and hypertensive patients, ranging in size from a 1,000 g premature infant to a 280 lb adult, it has been found possible to make indirect blood pressure determinations accurately and reliably in situations in which the stethoscope-commercially available cuff system is completely inadequate (Fig. 3). This method is valuable in situations in which it was previously impossible to determine blood pressure indirectly. However, it is most valuable in cases in which use of the traditional method yields inaccurate measurements.

BOOK REVIEWS

CEREBRAL VASCULAR DISEASES, 8th Conference, January 5–7, 1972, edited by F. H. McDowell and R. W. Brennan. New York, Grune & Stratton, 1973, 319 pages

As in the previous volumes of this series which began in 1954, the latest developments in the field of cerebrovascular diseases are presented. Again there are the discussions in full, and the opportunity to compare diametrically opposed conclusions from the same data. That sacred cow of medicine, the cooperative study (in this case "Joint Study of Extracranial Cerebrovascular Disease") is treated as anything but holy by several critics deploring its methods, its conclusions and its cost. Unfortunately, some discussants tend to substitute personal, unsupported opinions for the conclusions they attack. To summarize the results of the Joint Study to date: they are inconclusive and indicate only that surgery is or is not of value in the treatment of cerebral vascular lesions.

Basic research on cerebral metabolism in ischemia and some refined angiographic techniques are well presented. The gamma camera (for those who can afford it) promises to give valuable information about cerebral blood flow. The diagnosis of carotid arterial stenosis can often by made by this noninvasive method.

Four reports present the effect on cerebrovascular disease of certain drugs (chiefly aspirin and sulfinpyrazone) that reduce the adhesive and cohesive properties of platelets. As presented here (and in some subsequent reports) this work looks promising clinically—the statistics equaling those for surgery. However, there have already been two large series (referred to here but not part of the conference) in which use of these agents produced no benefit.

An article entitled "Clinical Management of Cerebral Ischemia" describes several treatments for acute stroke that the authors claim are "of value," although the evidence did not impress this reviewer and failed to convince two discussants with comparable experience in the specific methods cited.

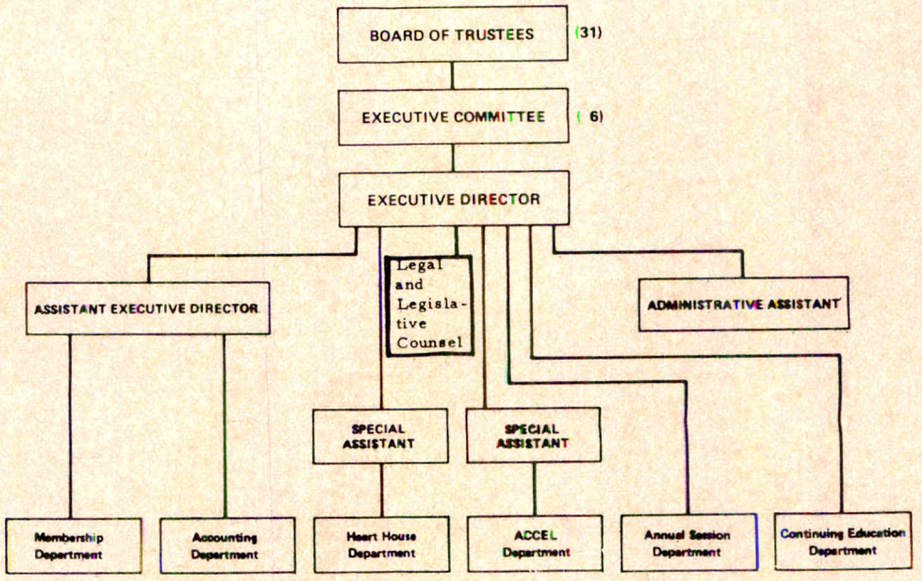
In summary, this volume documents the sad fact that we have gone another 12 months without a real breakthrough in this important but depressing medical field.

Philip S. Bergman, MD
New York, N.Y.

Report To:

The Executive Committee and The Board of Trustees

American College of Cardiology: Table of Organization



Since my last report to you, there have been several administrative changes which I have effected in our table of organization. These additions to our professional "management team" have resulted in a better distribution of work responsibilities in the American College of Cardiology Central Office and hopefully we are now in a better position to respond quickly to the needs of the Board of Trustees, committees and indeed the entire membership of the College.

It has been apparent to me for almost a year that finding an Assistant Executive Director of the College was a must. We were fortunate in attracting a most qualified professional to fill this position. Dwight Monnier joined the staff in the late summer and has brought to us many talents. He had served as Vice President of American University in Beirut for seven years.

Our HEART HOUSE Planning and Development Department is headed by Theodore G. Kummer who came with us this past summer. Ted has good credentials in the professional society management field as well as considerable background in the audio-visual field.

Albert S. Pasini, another important segment of our management team, directs the expanding ACCEL programs. In addition, in his role as Special Assistant to the Executive Director, he staffs several of our key committees and is assisting with HEART HOUSE planning needs.

The part-time Legislative Counsel in the person of Mr. Raymond D. Cotton has given us the help we sorely needed in this area. He is available at all times for advice and his contacts, both in Congress and within the federal agencies, are invaluable.

The part-time assistance of a professional health writer with our CARDIOLOGY Newsletter is essential, and I am grateful to you for the Newsletter budget which permits this assistance.

I cannot commend too highly the work of all individuals on our 25–30 person staff. They are interested, enthusiastic and totally devoted to assisting you in every way. We all consider it a privilege to work for the College. The time which each of you devote as volunteers to College activities is most appreciated.

This past year has seen a healthy growth in the College. We continue to add quality to our membership roles. With the raise in dues in January 1973 we are able to keep our finances in the black. The Leadership Conferences this past summer afforded another excellent opportunity for communication between the officers and staff of the College and the membership across the nation. I would strongly recommend that these be repeated in 1974. The Governors are asking long overdue questions about their real role in College activities. Hopefully this dialogue will result in a more meaningful role for the College Governors.

Planning for HEART HOUSE is taking a tremendous amount of staff time and Building Facilities Committee time. It is needed and will be well worth the effort. If we are not immediately available to answer your question about some matter, please have patience with us. We'll respond as rapidly as humanly possible.

And finally, I appreciate the time which the officers have granted to me to serve as President of the Professional Convention Management Association during 1974. The duties will not take me away from Bethesda very often and I hope that my tenure as President will reflect credit to the American College of Cardiology.

WILLIAM D. NELLIGAN
Executive Director
American College of Cardiology

Calendar of Continuing Medical Education Programs

The National Committee for Continuing Medical Education, William Likoff, MD, FACC, Chairman, announces the following calendar of programs.

Each program is designed to enlarge knowledge and clarify the endlessly changing frontiers which mark scientific achievements in the recognition and treatment of cardiovascular disease. Although the disciplined objective of each program as well as its content, format and faculty are primarily determined by the Program Director, the National Committee for Continuing Medical Education always exercises the prerogative of final review and approval, whether the program is sponsored solely by the College or in collaboration with universities, colleges, hospitals and other professional societies.

Subject matter reflects national interest and needs in the fields of patient care, research and teaching. The program structures vary in method of education.

The National Committee for Continuing Medical Education of the College earnestly solicits the interest of member and nonmember physicians alike in continuing education for the clear reason that participation provides a unique opportunity to deepen one's understanding of heart disease, the most formidable and challenging health problem of our time.

Programs and faculty are subject to change. For further information write Mary Anne McInerny, Director, Department of Continuing Education Programs, American College of Cardiology, 9650 Rockville Pike, Bethesda, Md. 20014.

JAN. 10–12 — **Non-Invasive Methods in Cardiac Diagnosis.** Ernest Craige, FACC, director. University of North Carolina School of Medicine, Chapel Hill N. C.

JAN. 11–13 — **Core Curriculum: Cardiovascular Physiology: Clinical Utilization of Invasive and Non-Invasive Measurements.** William W. Parmley, FACC, James S. Forrester and H. J. C. Swan, FACC, directors. Riviera Hotel and Country Club, Palm Springs, Calif.

JAN. 13–15 — **The Cardiac Care Unit in 1974—Integrated Medical-Surgical Care in Acute Coronary Artery Disease.** John H. K. Vogel, FACC, director. Opticon Theater, Snowmass at Aspen, Aspen, Colo.

FEB. 11–14 — **Twenty-third Annual Scientific Session.** H. J. C. Swan, FACC, president. Americana Hotel and New York Hilton, New York, N. Y.

FEB. 15–17 — **1974 Reconvened Annual Scientific Session.** Carlos E. Bertran, FACC, director. Hyatt Hotel, San Juan, P. R.

MAR. 18–22 — **Consultant's Course in Cardiology.** Simon Dack, FACC, director. Mt. Sinai Medical Center, New York, N. Y.

MAR. 21–23 — **Core Curriculum: Pathology of the Heart.** Maurice Lev, FACC, director. Palmer House, Chicago, Ill.

MAR. 25–27 — **Electrocardiographic Interpretation of Arrhythmias: A Physiological Approach.** Charles Fisch, FACC, director. Indiana University Medical Center, Indianapolis.

MAR. 28–30 — **High Blood Pressure—When and How To.** Robert S. Eliot, FACC, director. Gerald L. Wolf and Francis L. Land, co-directors. University of Nebraska Center for Continuing Education, Omaha, Nebr.

APR. 1–10 — **Cardiology for the Consultant: A Clinician's Retreat.** E. Grey Dimond, FACC, director. Rancho Santa Fe Inn, Rancho Santa Fe, Calif.

APR. 4–6 — **Advances in Clinical Cardiology.** Lawrence S. Cohen, FACC, director. Yale University School of Medicine, New Haven, Conn.

APR. 17–19 — **Core Curriculum—Vectorcardiography (A Basic Workshop).** Alberto Benchimol, FACC, director. Scottsdale Hilton Hotel, Scottsdale, Ariz.

APR. 22–25 — **Current Concepts in Cardiology—1974.** Philip R. Akre, director. Grand Hotel, Las Vegas, Nev.

MAY 6–9 — **The Treatment of Coronary Syndromes.** J. Willis Hurst, FACC, director. Royal Coach Motor Hotel, Atlanta.

MAY 9–11 — **The Ventricular Ectopic Beat: Heart-throb or Harbinger of Death.** Bernard Tabatznik, director. Urban Life Center, Columbia, Md.

MAY 15–17 — **Clinical Auscultation of the Heart.** W. Proctor Harvey, FACC, director. Georgetown University School of Medicine, Washington, D. C.

MAY 17–19 — **Core Curriculum: Rational Drug Therapy in Cardiovascular Disease.** Robert J. Lee, PhD., director. The Nassau Inn, Princeton, N. J.

MAY 23–25 — **Cardiologist's Appraisal of Operable Heart Disease.** Arthur Selzer, FACC and Keith E. Cohn, FACC, directors. St. Francis Hotel, San Francisco, Calif.

JUNE 6–8 — **Core Curriculum in Echocardiography: New Developments in Cardiac Ultrasound.** Arthur D. Hagan, director. Town and Country Hotel, San Diego, Calif.

Membership in the American College of Cardiology

The American College of Cardiology membership includes physicians and scientists working together to promote the continuing education of physicians concerned with cardiovascular disease. Its single purpose is to encourage the development of learning experiences designed to update knowledge and clinical behavior of physicians, surgeons and scientists, thereby promoting high quality health care delivery through application of new information.

The College attempts to accomplish this objective through a balanced array of programs including the *Annual Scientific Session,* consisting of reports of original research, lectures, core curricula, panel discussions, clinical demonstrations, small seminars with master teachers, films, self-assessment testing and scientific and technical exhibits; some 30 *regional scientific seminars* of 1 to 10 days' duration; the official monthly publication of the College, *The American Journal of Cardiology; ACCEL,* a multi-media journal which features a monthly audio cassette tape; *International Circuit Courses* (co-sponsored by the U. S. Department of State) presenting up-to-date information on cardiovascular disease to medical communities in foreign countries; and special *Bethesda Conferences* designed to encourage the exchange of ideas on policies concerning the practice of cardiology and matters affecting service, investigation and training relative to cardiovascular disease.

Membership in the College provides several direct advantages relating to the above objective: subscription to *The American Journal of Cardiology,* waiver of the registration fee for attendance at the annual scientific session, reduced fees for attendance at regional continuing education programs, reduced subscription rate for *ACCEL,* and receipt of *Cardiology.*

The College has three categories of membership: Fellowship, Associate Fellowship and Affiliate. Fellowship acknowledges that the individual has achieved a significant degree of professional maturity in cardiology, and that his primary medical interest is the prevention and treatment of this disease. Accordingly, election to Fellowship is recognition of achievement, not of promise. Depending upon such factors as training, acknowledgment of abilities by peers, and age, individuals are elected to membership at the Associate Fellowship or Affiliate level. Election to Associate Fellowship recognizes those individuals who have completed formal training in cardiology and are qualified for the subspecialty boards; the category of Affiliate recognizes younger individuals who exhibit an interest in cardiology by participation in a cardiology training program, as well as older individuals whose practice is predominately cardiology but who have had limited formal specialty training.

The future strength and health of the organization is largely dependent upon the quality of the young cardiologists, cardiac surgeons, cardiovascular radiologists and basic scientists who become participating members. Therefore, we encourage membership for those individuals still in training programs and hope for their active interest in College affairs.

Further information on the procedure for making application to the College can be obtained by writing Mrs. Nancy A. Bish, director, Membership Department, American College of Cardiology, 9650 Rockville Pike, Bethesda, Md. 20014.

Welcome to New York City in February

You are cordially invited to attend the 23rd Annual Scientific Session of the American College of Cardiology in New York City, to be held on February 11–14, 1974. It is particularly appropriate to hold this 25th anniversary meeting in New York City because the College was founded here in 1949. The founders and New York members will do their utmost to make this meeting an outstanding event.

New York City is an exciting place to hold a College meeting. The attractive New York Hilton and Americana Hotels, located across the street from each other, will house most of the registrants. The technical and scientific exhibits, scientific sessions, fireside conferences, luncheon panels and all other ancillary programs will be held in the meeting rooms of these two hotels. They are conveniently located close to all amusement, educational and business centers of our city.

The scientific sessions, organized by Eliot Corday and his Scientific Program Committee, are oriented for the clinical cardiologist. They will be preceded by the popular Cardiac Clinics which are sponsored by the divisions of cardiology of seven metropolitan medical schools and their affiliated teaching hospitals. The faculty includes teachers, clinicians and investigators in the forefront of cardiology in the New York area who will review advances and current problems in clinical diagnosis and medical and surgical treatment of heart disease, by the use of lectures, patient demonstrations and graphic methods.

The Cardiac Clinics begin at 9 AM on Monday, February 11. Buses will pick up the registrants at 8 AM. Please try to check into your hotel on Saturday or Sunday, February 9 or 10 and preregister for the Cardiac Clinics with your advance registration form, or on arrival at your hotel.

The various convention committees and the Ladies Entertainment Committee will do their best to make the New York meeting a pleasant, exciting and educational experience.

Simon Dack, MD, FACC
General Chairman

Ayerst Laboratories

is pleased to offer you and a member
of your family—with your permission—

Five good reasons why Brush biomedical recording systems are your best buy.

1. Brush has a complete line of biomedical signal conditioners and recording systems.

We make a recorder/signal conditioner system to meet any biomedical recording need you may have.

For research monitoring OR, and Cath Lab you can choose from 1 to 8 channels on high performance direct writing recorders, XY recorders, 4 and 8 channel monitoring oscilloscopes, a light beam oscillograph with up to 16 channels.

Our engineered systems include all transducers, interconnecting cables, signal conditioning, recorders and direct display readouts.

2. The Brush pressurized inking system gives you the highest quality traces.

Brush traces are the standard of the industry. Our pressurized inking system eliminates smudges, smears, skips and puddles because the traces are actually forced into the paper. The record you get is crisp, clear and permanent.

3. Brush guarantees better than 99.5% linearity.

There are two reasons why we can guarantee such a high degree of accuracy. First, our Metrisite® non-contact servo-loop feedback device moves freely in an enclosed air gap. Second, our recorders have a rectilinear presentation rather than a curvilinear one. This eliminates geometric errors inherent with the conventional system.

4. Brush biomedical recording systems give you trouble free operation.

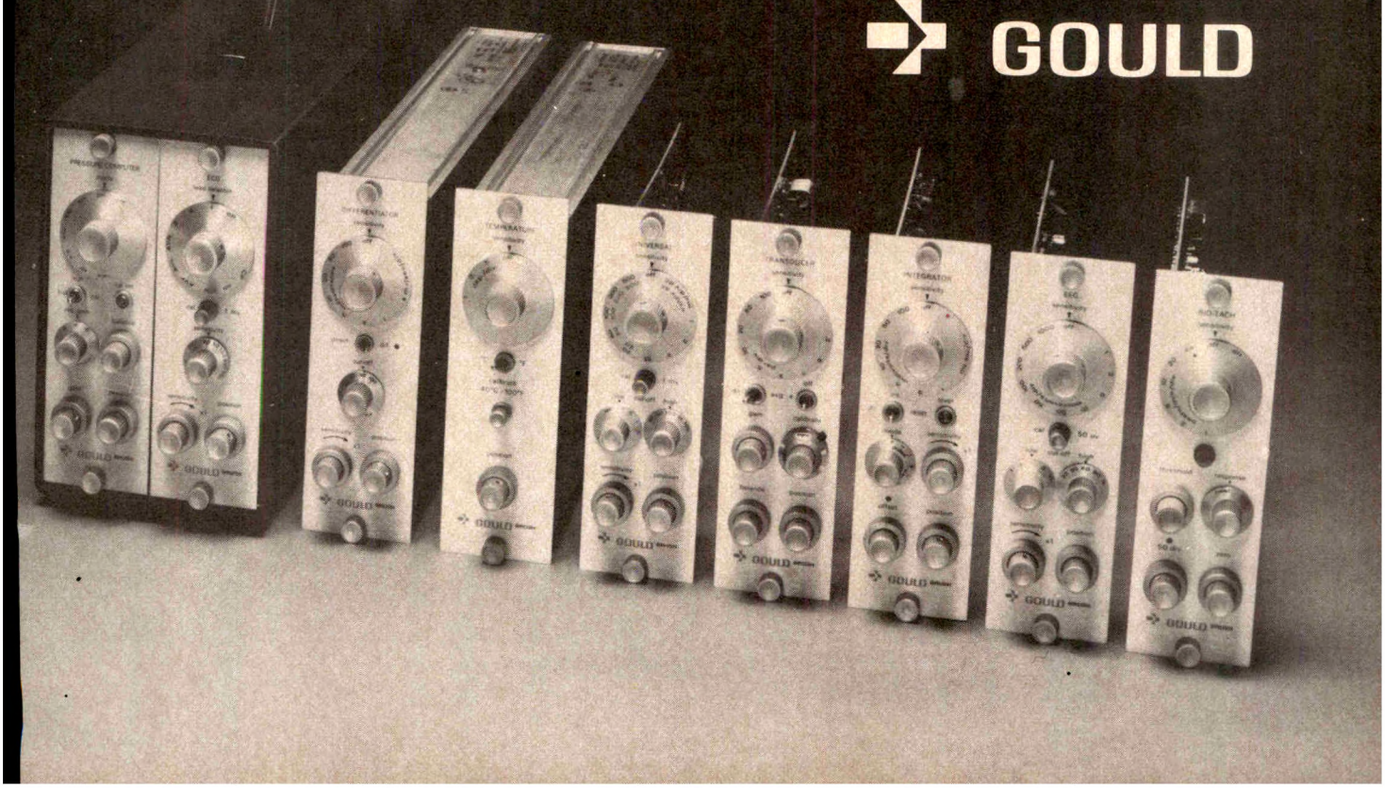
All of our instruments require minimal maintenance. For example, our disposable ink cartridge provides for a year's worth of recording. Our Metrisite tracing system eliminates slide wires and all the problems that go with them. And all of our electronics are solid state.

5. A Brush system is one of the easiest to operate.

All systems are self calibrating. Our controls are conveniently placed to give you maximum flexibility. Chart paper can be replaced in seconds. Switching signal conditioners is a snap. And Brush service technicians and engineers are readily available when and if you do need assistance.

Send for our free full color catalog. Write Gould Inc., Instrument Systems Division, 3631 Perkins Avenue, Cleveland, Ohio 44114. Or Kouterveldstraat Z/N, B 1920 Diegem, Belgium.

GOULD



System 80.

The Second Generation Intra-Aortic Balloon Pump. It Has The Gas, The Balloon, And The Logic.

The Datascope System 80. Our system for Intra-Aortic Balloon Pumping. It uses CO_2 to pump the intra-aortic balloon. Not Helium. And because the intra-aortic balloon connects to a slave balloon in a Safety Chamber, the gas system is closed. Not open. Which means only a fixed volume of CO_2 is transferred from one balloon to another.

Our intra-aortic balloon* is unique. The Dual-Chamber Intra-Aortic Balloon. It pumps blood preferentially towards the heart during balloon inflation. Experimental data[1] show an average increase of 66-100% in coronary blood flow over and above that obtained with a single-chamber balloon.

Our system also offers you superior pumping logic. Complementary Pulse Logic. Something like turning a lamp off first instead of on. The R-wave triggers *deflation* of the balloon at the onset of systole following *that* R-wave; inflation follows systole and automatically adjusts itself for the duration of diastole. Which means our system tracks irregular rhythms.

Our system is also complete. Modular and Mobile. With Battery-powered, synchronized** monitoring of ECG and aortic pressure. And optional battery-pack for pumping without external power.

Call us at area code 201-845-7650. Or write to Datascope Corporation, 520 Victor Street, Saddle Brook, New Jersey 07662. We'll be happy to send you reprints of published clinical experience with our system, information on clinical evaluation and experimental studies now in progress and a Guidebook to Intra-Aortic Balloon Pumping which describes System 80 in detail.

Besides Intra-Aortic Balloon Pumping, we might also mention that our system will perform in a variety of pneumatically powered procedures for assisted circulation. That's logical too.

*patent pending

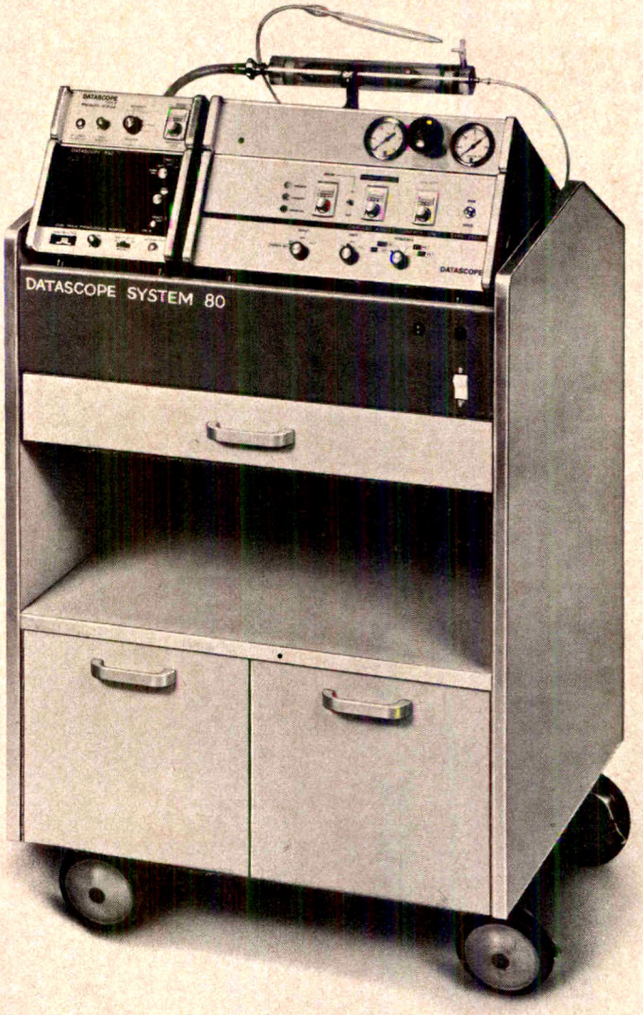
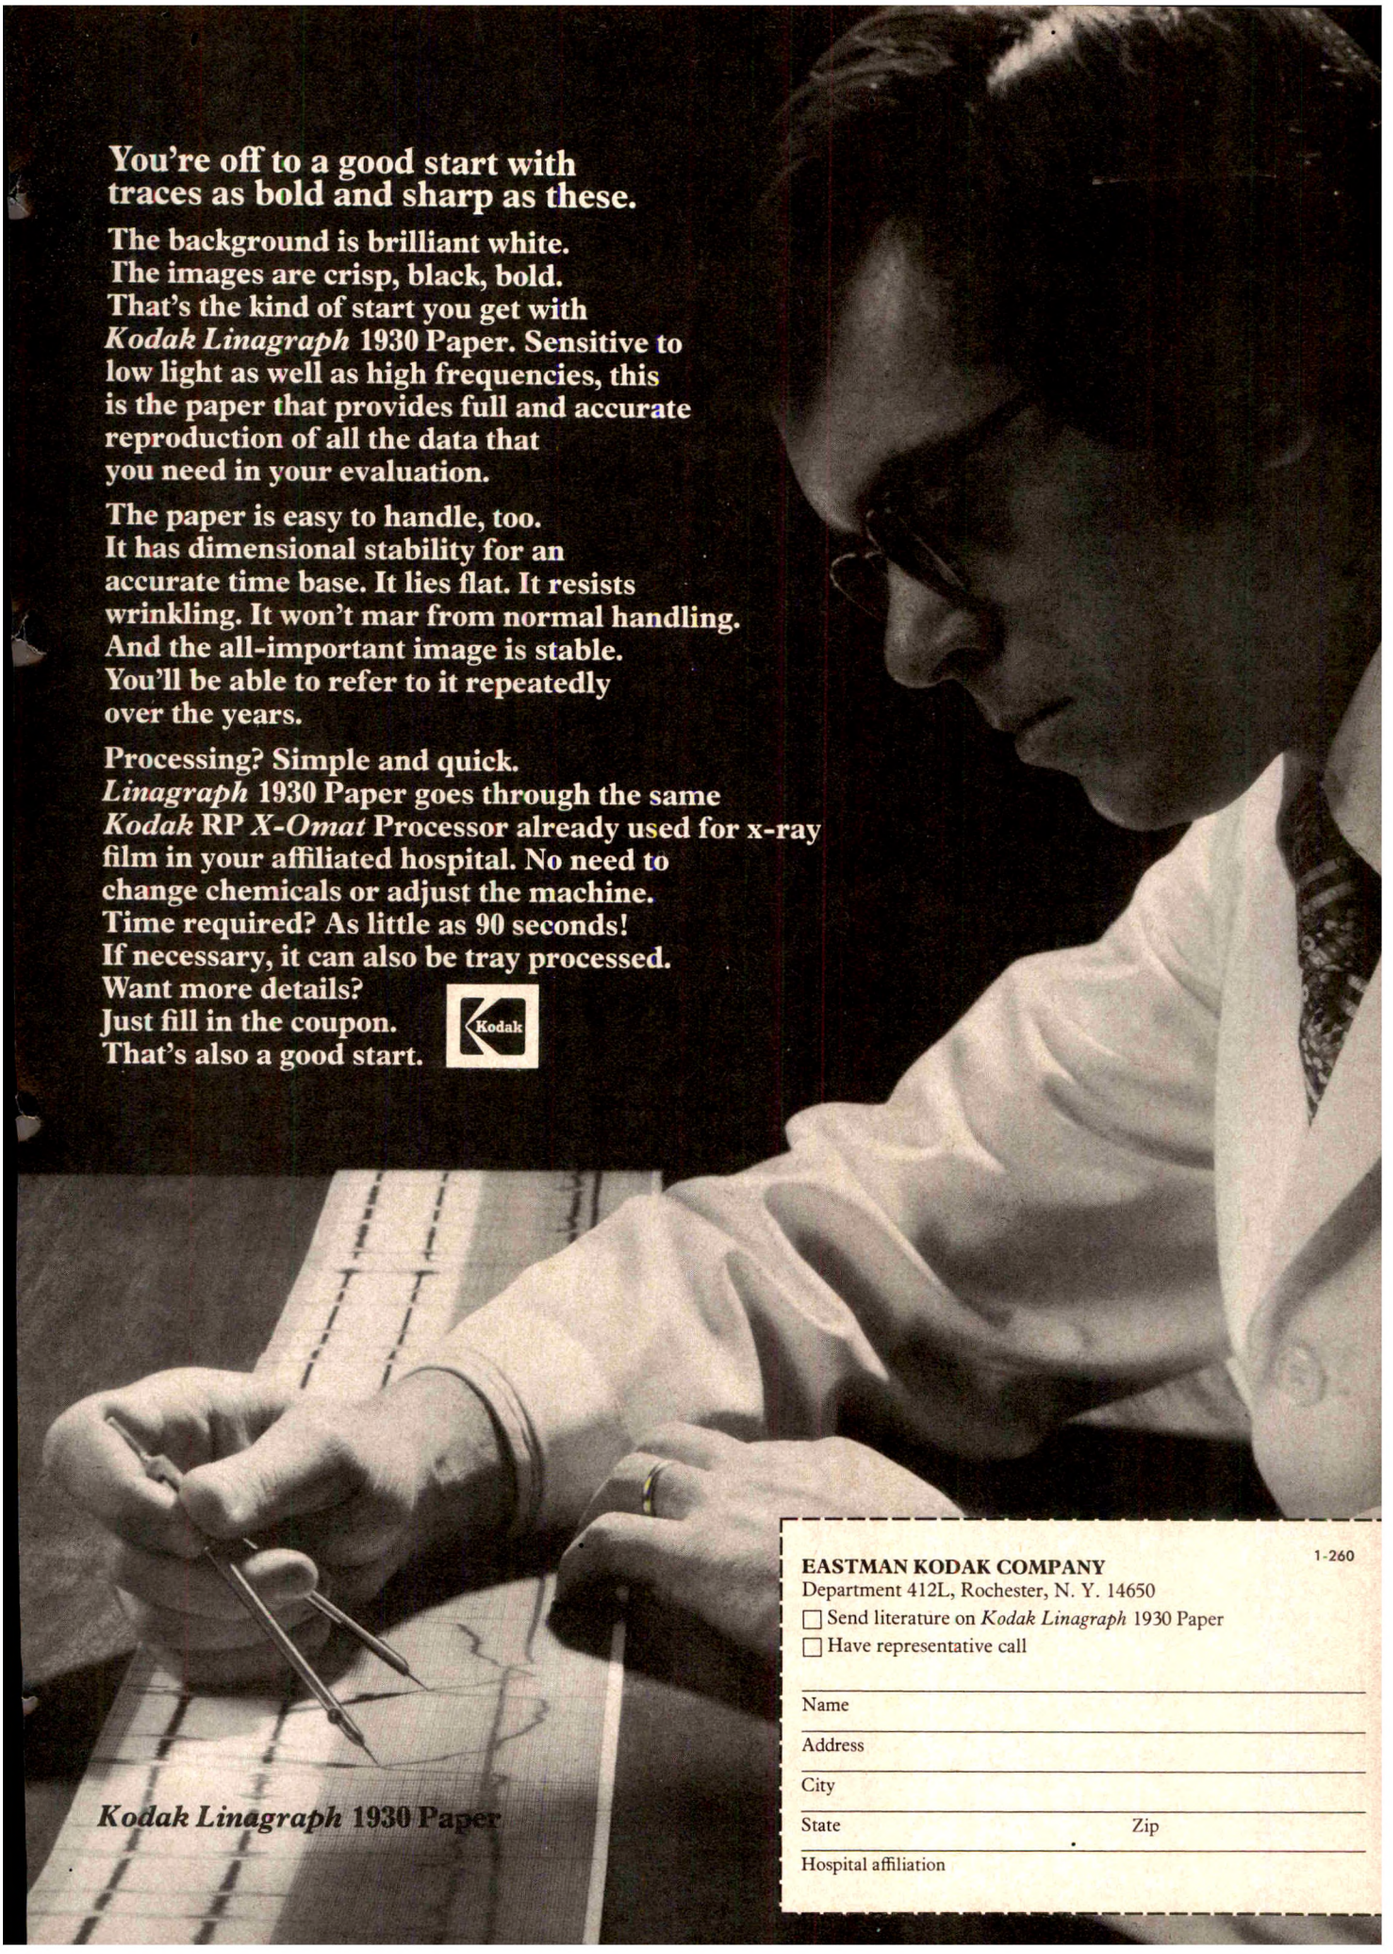
Datascope System 80





You're off to a good start with traces as bold and sharp as these.

The background is brilliant white. The images are crisp, black, bold. That's the kind of start you get with *Kodak Linagraph* 1930 Paper. Sensitive to low light as well as high frequencies, this is the paper that provides full and accurate reproduction of all the data that you need in your evaluation.

The paper is easy to handle, too. It has dimensional stability for an accurate time base. It lies flat. It resists wrinkling. It won't mar from normal handling. And the all-important image is stable. You'll be able to refer to it repeatedly over the years.

Processing? Simple and quick. *Linagraph* 1930 Paper goes through the same *Kodak* RP *X-Omat* Processor already used for x-ray film in your affiliated hospital. No need to change chemicals or adjust the machine. Time required? As little as 90 seconds! If necessary, it can also be tray processed. Want more details? Just fill in the coupon. That's also a good start.

Rheumatic fever prevention.
Here's true convenience for patients who must receive prophylactic penicillin indefinitely. A prolonged-action penicillin—benzathine penicillin G. Recommended as the method of choice* to prevent streptococcal infection and possible recurrence of rheumatic fever. A single monthly injection (1,200,000 units) offers continuous prophylaxis in most patients.

Action against strep.
In therapy of mild to moderate group A streptococcal pharyngitis (without bacteremia), prolonged action again commends this penicillin, named by authorities a method of choice.* Just one injection (600,000 to 900,000 units in children and 1,200,000 units in adults) usually maintains serum concentrations for the ten days considered necessary to eradicate the streptococci and preclude the initial onset of rheumatic fever.†

*Rheumatic Fever Committee of the Council on Rheumatic Fever and Congenital Heart Disease of the American Heart Association.

Indications: In treatment of infections due to penicillin G-sensitive microorganisms susceptible to the low and very prolonged serum levels common to this dosage form. Therapy should be guided by bacteriological studies (including sensitivity tests) and clinical response.
The following infections usually respond to adequate dosage of IM benzathine penicillin G.
Streptococcal infections (Group A—without bacteremia). Mild to moderate upper respiratory infections (e.g., pharyngitis).
Venereal infections—Syphilis, yaws, bejel, and pinta.
Medical Conditions in which Benzathine Penicillin G Therapy is indicated as Prophylaxis:
Rheumatic fever and/or chorea—Prophylaxis with benzathine penicillin G has proven effective in preventing recurrence of these conditions. It has also been used as followup prophylactic therapy for rheumatic heart disease and acute glomerulonephritis.

FOR DEEP INTRAMUSCULAR INJECTION ONLY.
Contraindications: Previous hypersensitivity reaction to any penicillin.
Warnings: Serious and occasionally fatal hypersensitivity (anaphylactoid) reactions have been reported. Anaphylaxis is more frequent following parenteral therapy but has occurred with oral penicillins. These reactions are more apt to occur in individuals with history of sensitivity to multiple allergens. Severe hypersensitivity reactions with cephalosporins have been well documented in patients with history of penicillin hypersensitivity. Before penicillin therapy, carefully inquire into previous hypersensitivity to penicillins, cephalosporins and other allergens. If allergic reaction occurs, discontinue drug and treat with usual agents, e.g., pressor amines, antihistamines and corticosteroids.
Precautions: Use cautiously in individuals with histories of significant allergies and/or asthma.
Carefully avoid intravenous or intraarterial use or injection into or near major peripheral nerves or blood vessels, since such injection may produce neurovascular damage.
†In streptococcal infections, therapy must be sufficient to eliminate the organism, otherwise the sequelae of streptococcal disease may occur. Take cultures following completion of treatment to determine whether streptococci have been eradicated.
Prolonged use of antibiotics may promote overgrowth of nonsusceptible organisms including fungi. Take appropriate measures if superinfection occurs.
Adverse Reactions: Hypersensitivity reactions reported are skin eruptions (maculopapular to exfoliative dermatitis), urticaria and other serum sickness reactions, laryngeal edema and anaphylaxis. Fever and eosinophilia may frequently be only reaction observed. Hemolytic anemia, leucopenia, thrombocytopenia, neuropathy and nephropathy are infrequent and usually associated with high parenteral doses.
As with other antisyphilitics, Jarisch-Herxheimer reaction has been reported.
Composition: (units benzathine penicillin G as active ingredient): 300,000 units per cc.—10-cc. multi-dose vial. Each cc. also contains sodium citrate buffer, approximately 6 mg. lecithin, 3 mg. polyvinylpyrrolidone, 1 mg. carboxymethylcellulose, 0.5 mg. sorbitan monopalmitate, 0.5 mg. polyoxyethylene sorbitan monopalmitate, 0.14 mg. propylparaben and 1.2 mg. methylparaben.
600,000 units in 1-cc. TUBEX® (sterile cartridge-needle unit) Wyeth, packages of 10.
1,200,000 units in 2-cc. TUBEX, packages of 10, and in 2-cc. single-dose disposable syringe.
2,400,000 units in 4-cc. single-dose disposable syringe.
Each TUBEX or disposable syringe also contains sodium citrate buffer and, as w/v, approximately 0.5% lecithin, 0.4% carboxymethylcellulose, 0.4% polyvinylpyrrolidone, 0.01% propylparaben and 0.09% methylparaben.

Injection BICILLIN® LONG-ACTING (sterile benzathine penicillin G suspension)

Month-long rheumatic fever prophylaxis gives freedom from daily dosage.

Make Life Easier For You And Your Pacer Patients

Now, with the advent of the ESB Medcor Pacer-Check* system, it is possible for your office to conduct regular, accurate recordings of heart pacer patient's ECG and pacer rates by telephone.

Both you and your patients benefit. Now, with no more than a phone call, you can have information which permits elective decisions on replacement rather than emergency or prophylactic replacements. (By using a regular patient checking program, maximum pacer life can be realized.) Your patient and you have flexibility and safety at the same time.

This two-component system operates simply, requiring minimal training to both your personnel and patients.

The Medic Unit, at left, is the central component and is usually located in the hospital or clinic. It receives ECG and pacer rate input via unaltered telephones from the Patient Unit which is usually located in the patient's home. ECG data, produced on a standard paper chart, indicates the relationship between the QRS complex and pacer artifact to ascertain pacer capture. Pacer rate is shown continuously by illuminated numbers on the front panel. This is the first system available to physicians that records ECG and simultaneously displays pacer rate.

The Patient Unit is lightweight and battery powered. It is capable of transmitting from any telephone to your office. Transmissions have been successfully made from such great distances as Tokyo to New York. To operate, the patient places the telephone headset in the receiving cradle and then slips the two expandable bracelets over his forearms. Transmission begins immediately.

The Pacer-Check* system, approved for reimbursement by Medicare, has proven itself a useful and self-supporting method of maintaining a desirable pacer program.

If the unique qualities of the Pacer-Check* system interest you, contact ESB Medcor, Inc., Dept. 373, 5920 Rodman St., Hollywood, Florida 33023. Toll free call: (800) 327-9780, Ext. 373.

ESB Medcor™

Sentry 75
ventricular inhibited pulse generator

GENERAL ELECTRIC

Sentry 75... one generator that meets long-term pacing demands

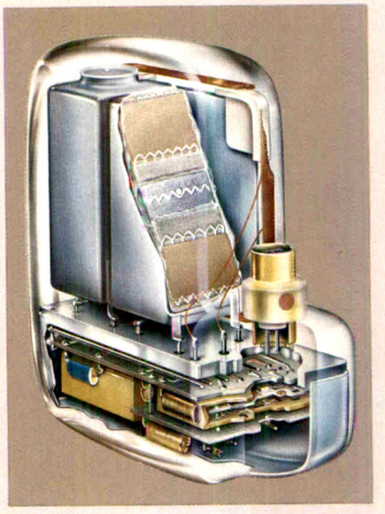
The Sentry 75 ventricular inhibited pulse generator maximizes the potentials of a proven power source to deliver extended pacing life to most patients, regardless of threshold value.

It is General Electric's positive response to the medical profession's demand for a simple, extended-life pacing system to serve the large majority of patients.

The Sentry 75 presents no alterations in implant technique or patient management. It is compatible with all GE electrodes, and the long reliable service life can be monitored easily by both patient and physican.
The Sentry 75 is powered by the industry's first mercury/zinc cells specifically designed for implantable pulse generator applications. A complete redesign of both this power cell and circuitry now make possible a pulse generator which can be expected to deliver a 4 to 6 year life, with an assurance factor greater than generators using normal mercury/zinc batteries.

Your GE representative can provide you with information regarding patient testing, warranties, and availability in your area.

Optimized power source capability.



Redesigned power cells. The mercury/zinc battery is a long proven power source familiar to the medical profession. Its chief liability has not been in the chemical composition, but in its construction. GE design aims were to maximize power utilization and reduce internal losses to produce a power cell capable of far longer and more reliable service life.

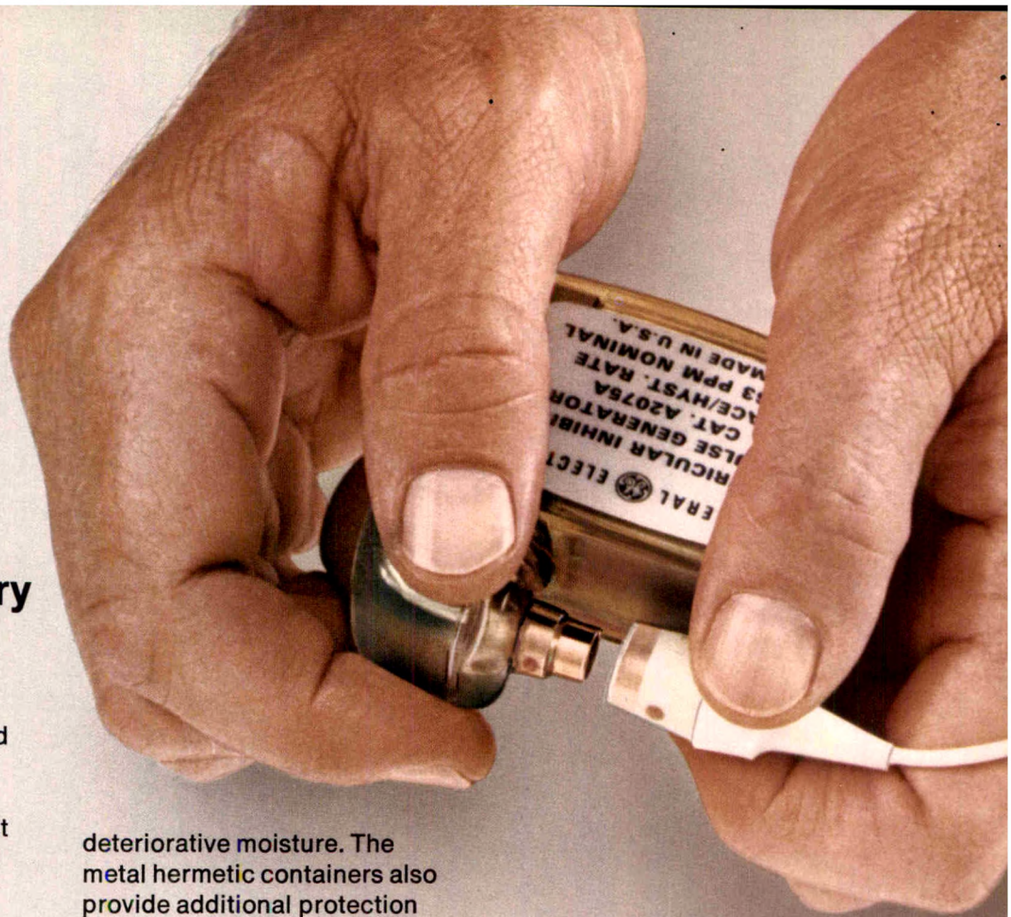
Note the new GE power cell is rectangular. It displaces the same volume as 2 circular batteries, yet contains 50% greater capacity (3000 mA hours vs. 2000) than 2 circular batteries operating in parallel. Two of these high-capacity cells, connected in series, power the pulse generator.

Internal discharge, a problem with previous batteries resulting from shorting electrodes, has been virtually eliminated by 6 wraps of a new non-degradeable separator. These multi-wraps replace the single-wrap separator presently used in mercury/zinc batteries.

The power cell case is solid nickel to prevent case-to-electrolyte reaction, another potential source of self-discharge.

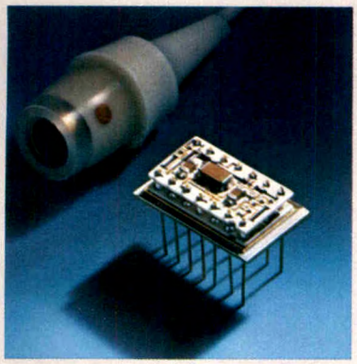
Welded internal contacts to electrodes preclude the possibility of "open" contacts, a design shortcoming with ordinary pressure contacts.

The negative terminal is isolated from the cap through a hermetic ceramic-to-metal seal, and the cap is welded to the top of the cell to prevent electrolyte seepage across the 2 terminals. And as one last safety precaution, the positive pressure vent is located at the end of the cell, remote from the terminals.



Simplified circuitry for reliability.

New circuit efficiencies. Through the development and adaptation of thick-film hybrid circuitry, born of aerospace technology, almost one-half the normal electrical interconnections are eliminated. The new circuits improve electrical efficiency by 45% (135 micro-watts of power drain vs. 244 micro-watts formerly).



The new micro-circuitry in both the sensing and pacing circuits—plus the rectangular power cells—allow a 25% reduction in the volume of the generator. Thus, while generator size is reduced, power capacity is increased 50%.

Hermetic sealing of these critical hybrid circuits, plus a second overall hermetic sealing of the complete circuitry, virtually locks-out deteriorative moisture. The metal hermetic containers also provide additional protection from electromagnetic interference (EMI).

In addition, patient defibrillation can be conducted without damaging the generator.

Adapts to electrodes.

Implant procedures are not altered because the Sentry 75 is compatible with all existing GE electrodes which feature simple self-sealing, push-pull connectors. It is also adaptable to the electrodes of other manufacturers.

The pulse generator is provided as a bipolar system which, at implant, can be converted to unipolar pacing if desired. This is accomplished by simply removing the insulating label covering the metallic plate electrode on the generator's surface, and attaching it to a unipolar electrode, or to a bipolar electrode adapted for unipolar pacing.

Standardized output.

Choice of rates. Two models of the Sentry 75 pulse generator are presently available with two additional models scheduled for subsequent availability. Models differ only in pacing and hysteresis rates.

Model	Pace Rate	Hysteresis (Escape Rate)
A2075A/AD	73	63
A2075B/BD	80	70
A2075C/CD*	85	80
A2075D/DD*	73	71

*Available second quarter of 1974.

GENERAL ELECTRIC

Patient management.

The Sentry 75 pulse generator has a built-in service-life indicator that is simple and easy to use. The pulse generator's pacing rate is highly dependent upon battery voltage; thus as battery voltage begins to fall near end-of-life, pacing rate will decrease. This change in rate can be easily and accurately monitored when a GE patient sensor and rate-interval computer are used. The latter is a desk-top unit which, used in conjunction with the patient sensor, enables the physician to check the patient's pacemaker over the phone between regular office visits. The patient can also be instructed to check his own rate with the sensor.

Clinical evaluation.

Laboratory tests of the Sentry 75 components were conducted for 2 years before any implants in humans were undertaken. Clinical evaluations began on a worldwide basis in November, 1972. Physicians representing more than 15 major hospitals and medical centers are participating in the program.

DONTI T.M. The Pulmonary Performance Analyzer that makes every second count

In the few seconds required for a patient to perform a forced exhalation, the DONTI T.M. Pulmonary Performance Analyzer records and instantaneously displays a complete battery of sensitive spirometric parameters:

- Forced vital capacity
- FEV_1
- FEV_3
- Peak flow
- $FEV_{1\%}$
- $FEV_{3\%}$

With 10 more seconds of patient participation, the DONTI T.M. Pulmonary Performance Analyzer measures and expresses maximum voluntary ventilation (MVV) in liters per minute.

The DONTI T.M. Pulmonary Function Recorder:

- Produces simultaneously a meaningful record for patient histories.
- Provides a basis for easily determining $FEF_{200\text{-}1200}$ and $FEF_{25\%\text{-}75\%}$.

The functional integration of the circulatory and respiratory systems makes it inevitable that disturbances in one will profoundly affect the other.

It has been noted that good spirometry can supply the clinician with most of the information he wishes to know about airway obstruction, much about restriction of the expansion of the lungs and how to distinguish these two types of physiologic defects from each other.

Spirometry has been employed as a routine presurgical procedure for assessing potential complications.

The Donti system simplifies the mechanical aspects of testing and allows the clinician to focus on the patient and proper testing technique — with no diversion to preparing the instrument or to time-consuming calculations.

HARNESSING THE INFORMATION EXPLOSION:

The Heart
THIRD EDITION

To transform the latest research findings into practical therapeutic resources for those tending the sick, the editors have massively updated and revised this classic treatise. The new Third Edition introduces the problem-solving approach. It thoroughly integrates physiology, pathology, history, and physical and laboratory examinations with medical and surgical treatment of the patient.

You will find every chapter updated, many changed considerably. Of particular interest are the new chapters covering Non-Invasive Graphic Methods, Surgical Treatment of Coronary Atherosclerotic Diseases, and Errors Made in the Recognition and Treatment of Heart Disease. Numerous internationally known authorities contribute their specialized expertise.

Editor-in-Chief: J. Willis Hurst, M.D. *Editors:* R. Bruce Logue, M.D.; Robert C. Schlant, M.D.; and Nanette K. Wenger, M.D.; all of Emory University School of Medicine

Harrison's Principles of Internal Medicine
SEVENTH EDITION

The thoroughly updated Seventh Edition offers you an important new chapter on the Problem Oriented Record. Other new chapters detail the latest findings on the Principles of Neoplasia and Neoplastic Diseases, Antimicrobial Therapy, Septic Shock, Sudden Cardiovascular Collapse, Electrocardiography, Cardiac Arrhythmias, and Hypertension. Further revisions include Skin Manifestations of Disease, Nutrition and Nutritional Deficiencies, Psychiatry, Clinical Immunology, and Respiratory Disorders.

The Editors: Maxwell M. Wintrobe, M.D.; George W. Thorn, M.D.; Raymond D. Adams, M.D.; Eugene Braunwald, M.D.; Kurt J. Isselbacher, M.D.; and Robert G. Petersdorf, M.D.

EKG EXERCISE SYSTEM

- New digital rate meter rejects noise, tremor, and tall T waves to provide precise 1% easily read rate display.
- Adjustable and automatic recording sequencer eliminates operator error and consequent need for stop watch.
- New Exercise Cable with buffer amplifiers provides noise free tracings.
- Complete 12-lead electrocardiogram in 10 seconds or classical/orthogonal in just 20 seconds before, during, and after exercise.
- Total patient safety under configurations currently specified by AAMI, N.F.P.A., U.L. and C.S.A.
- PRESSURE-SCRIBE ™ dry ink recording provides EKG's of superior readability with lowered cost per tracing.

Is Sublingual Nitroglycerin still the drug of choice for acute angina?

Most physicians agree that of the nitrates available for the relief of acute angina pectoris, sublingual nitroglycerin remains the drug of choice. However, nitroglycerin is an unstable compound that can migrate from tablet to tablet, from tablet to cotton packing, from tablet to air.

And your patient may end up with too little nitroglycerin—just when it's needed most. To help solve this problem, Parke-Davis has developed Nitrostat, a stabilized sublingual nitroglycerin.

Nitrostat offers these important benefits:

- Rapid relief of pain
- Predictable patient response
- Uniform potency from tablet to tablet
- Stable sublingual dosage
- Reliable in clinical confirmation of angina pectoris

So whenever you're confronted by a patient with acute angina, *think* nitroglycerin. But *write* Nitrostat.

NITROSTAT®...the dependable nitroglycerin
(nitroglycerin tablets, USP)
Sublingual Tablets

Twenty-Third Annual Scientific Session American College of Cardiology New York, New York, February 11 to 14, 1973

Method and Criteria of Selection of Abstracts

A record number of 860 abstracts were submitted to the College for consideration for presentation at the 23rd Annual Scientific Session. Each abstract was reviewed by a dual process which included review by teams of experts in 24 different areas of cardiology as well as by general cardiologists, thereby insuring that the presentations will deal with topics of current interest to a broad audience. The abstracts were graded objectively and independently from 1 to 10 with 10 being the highest score. Independent results were returned by each grader to the Bethesda office of the College. When an abstract came from a reviewer's institution, an abstention was recorded.

The scores of each abstract were then averaged by the College staff, and all abstracts receiving a grade of 7.3 and above by both expert and generalist teams were accepted for presentation. Those rated above 7.3 by one team but receiving a lower level of priority by either the generalists or the experts were individually reviewed by members of the Committee.

This year, because of the excellence of the abstracts and the augmented facilities of the program, it was possible to select a total of 235 for the final program, an increase of 15 percent over any previous year.

Eliot Corday, MD, FACC
Scientific Program Chairman

NATURAL HISTORY AND TREATMENT IN MUSCULAR SUBAORTIC STENOSIS*

Allan G. Adelman, MD; E. Douglas Wigle, MD; Clarence H. Felderhof, MD; Allan S. Trimble, MD; Wilfred G. Bigelow, MD, Divisions of Cardiology and Cardiovascular Surgery, Toronto General Hospital, Toronto, Ontario.

Some authors have suggested that surgery is rarely indicated in muscular subaortic stenosis (MSS). Others, who favour surgery, advocate mitral valve replacement rather than ventriculomyotomy or muscle resection.

Study of the natural history of 26 patients (pts.) with MSS untreated over 4 years revealed that 11 of 17 (65%) in NYHC I or II, and all 9 in NYHC III or IV deteriorated or died.

Propranolol was given to 32 pts. who were followed 3 years. All 10 pts. with latent outflow tract obstruction improved. Of 22 pts. with outflow tract obstruction at rest, only 8 (36%) improved. Of the remaining 14 pts., 1 (5%) was unimproved, 9 (41%) deteriorated and 4 (18%) died. Seven of the 9 pts. who deteriorated have undergone ventriculomyotomy.

Ventriculomyotomy was performed in 39 pts. with 3 deaths (mortality 8%). No deaths have occurred in the last 25 operations. Of 36 pts. surviving surgery, 29 (80%) improved symptomatically. Post-operative studies in 19 pts. revealed that a successful ventriculomyotomy abolished the abnormal systolic movement of the anterior mitral leaflet, the outflow obstruction and related mitral regurgitation. Left ventricular end-diastolic pressure decreased in 15 of 19 pts.

Ventriculomyotomy is a very effective operation in MSS and is indicated in symptomatic pts. not responding to Propranolol.

* Abstracts are listed alphabetically by first author.

PERSISTENT DEPRESSION OF MYOCARDIAL FUNCTION AFTER EXPERIMENTAL COXSACKIEVIRUS B3 VIRAL MYOCARDITIS

Christa O. Adesanya, MD; William P. Phear; Alan H. Goldberg, MD; Nathaniel A. Young, MD; Walter H. Abelmann, MD, FACC, Thorndike, Anesthesia and Channing Laboratories and Harvard Medical Unit, Boston City Hospital, Boston, Massachusetts

To test the hypothesis that chronic idiopathic cardiomyopathy might be a sequela of previous viral myocarditis, 35 suckling golden hamsters were inoculated i.p. with 10^6 plaque forming units of coxsackievirus B3. Twelve sham inoculated hamsters served as controls (C). Most animals sacrificed within 7 days of inoculation showed histological evidence of myocarditis, infectivity of myocardium exceeded that of serum on day 3, and 80% of inoculated animals developed neutralizing antibody titers<1:40. Ninety days later, surviving inoculated (I) animals appeared clinically healthy, showed few histologic lesions and no cardiac hypertrophy.

Left ventricular trabeculae carneae muscles were isolated and suspended in a muscle bath. Experiments were performed with the preparation contracting isometrically at a rate of 0.25/sec at 32°C. Results are summarized below:

	N	L_i (mm)	L_{max} (mm)	peak dev. tension (gm/cm^2) $[Ca^{++}]$2.2mM	$[Ca^{++}]$3.3mM
C	6	5.44±0.21	7.28±0.10	112.3±5.4	154.0±17.6
		NS	(P<0.001)	(P<0.001)	(P<0.001)
I	10	5.27±0.25	6.72±0.10	64.2±9.9	74.2±11.7

L_i = muscle length at minimal resting tension, L_{max} = muscle length at peak developed tension. Cross-sectional areas were similar. In I diminished L_{max} and developed tension at both $[Ca^{++}]$ suggests decreased compliance and depressed myocardial function. This dysfunction appears to persist for at least 90 days after subclinical viral myocarditis.

PAROXYSMAL A-V NODAL REENTRANT TACHYCARDIA FOLLOWING ATROPINE

Masood Akhtar, MD, Anthony N. Damato, MD, William Batsford, MD, Anthony N. Caracta, MD, Jeremy N. Ruskin, MD, Sun H. Lau, MD, U.S. Public Health Service Hospital, Staten Island, New York

It is well known that a critical A-V nodal conduction delay is required for the initiation of paroxysmal A-V nodal reentrant tachycardia (PAT). This critical A-V nodal delay can be achieved by appropriately timed premature atrial beats occurring within the relative refractory period of the A-V node or during A-V nodal Wenckebach cycles produced by rapid atrial pacing. Using His bundle recordings and premature atrial stimulation techniques four patients (pts) were studied before and after small doses (0.5 mg I.V.) of atropine, at comparable preceding atrial cycle lengths (A_1-A_1) and atrial premature coupling intervals (A_1-A_2), up to the point of atrial refractoriness. Before atropine, 3 pts demonstrated single atrial echo beats and 1 pt had no atrial echo beats. After atropine, sustained PAT occurred in all 4 pts. In 3 pts, PAT occurred at the same A-V nodal delay which before atropine produced only single echo beats and in the 4th pt, atropine permitted the attainment of a greater and requisite A-V nodal for PAT. PAT due to A-V nodal reentry could be distinguished from sinus tachycardia and sinus node reentrant tachycardia. It is postulated that atropine which shortens the effective and functional refractory periods of the A-V node and shortens antegrade and retrograde A-V nodal conduction time caused a critical and necessary balance between conduction within the antegrade and retrograde limbs of the reentrant circuit so that PAT could be sustained.

DOSE-RESPONSE EFFECTIVENESS OF PROPRANOLOL FOR THE TREATMENT OF ANGINA PECTORIS

Edwin L. Alderman, M.D., F.A.C.C., Mario Lopes, M.D., Donald C. Harrison, M.D., F.A.C.C., Cardiology Division, Stanford University School of Medicine, Stanford CA

A clinical trial of 10 months duration in 17 patients(pts) evaluated the response of angina to propranolol in 4 divided daily doses of placebo, 20, 40 and 80 mg, in relation to drug blood levels. Pts entered the double-blind portion of the study only after the frequency of anginal episodes was greater than 5/week during a 3 month period of single-blind placebo medication. Pts then entered 4 6-week double-blind periods, receiving each of the 4 dose levels in a random sequence. Angina frequency and nitroglycerin consumption were recorded by pts on personal diaries collected biweekly. Average exertional angina episodes per week were reduced from 8.2±2.4 during placebo medication to 5.2±1.0 (N.S.) while taking 80 mg/day, 4.8 ±1.3 ($p<0.5$) while taking 160 mg/day, and 3.3±1.2($p<.01$) while taking 360 mg/day. Physician evaluations at biweekly intervals and exercise testing during each dose period confirmed the statistical significance of the clinical response. Mild adverse effects were noted in 8 of the 17 pts and in some pts rebound withdrawal symptoms from propranolol occurred. Propranolol blood levels obtained between 100 and 180 minutes after the last tablet correlated highly with the dose and the clinical response. Propranolol doses of 80 mg/day were clinically ineffective and generally achieved blood levels below 30 ng/ml,whereas daily doses of 160 and 320 mg achieved blood levels above 40 ng/ml and were effective in reducing angina frequency and nitroglycerin consumption, and in increasing pain-free days and treadmill exercise tolerance.

EVALUATION OF THE EFFECTS OF ANTITHROMBOTIC THERAPY ON SURVIVAL FOLLOWING AORTOCORONARY BYPASS SURGERY

Mahdi S. Al-Bassam, MD; Robert J. Hall, MD, FACC; Efrain Garcia, MD, FACC; Robert D. Leachman, MD, FACC; Louis L. Leatherman, MD; Grady L. Hallman, MD, FACC; Denton A. Cooley, MD, FACC; Texas Heart Institute, St. Luke's Episcopal Hospital, Houston, Texas

Various antithrombotic regimes used emperically by various consulting Cardiology Sections of this Institute were evaluated 6 to 40 months postoperatively to determine effects on late survival (after 1 month). Coumadin (C) was favored in the early period while Persantine (P) and aspirin (A) were used alone or in combination, more frequently in the last 2 years. Therapeutic regimes were continued for a sufficient period assuring comparable patient enlistment into each therapeutic group. Charts, letters to patients and information from private doctors were reviewed to collect data on C, P, & A regimes. Of the 1404 patients operated at this Institute from August 1969 to September 1972, adequate follow-up drug data were available on 1078 patients, 60 of whom died in the follow-up period. The "life survival curve" (Cutler) of the 1078 subgroup was closely similar to the curve for the total series of 1404 patients. Therapy prescribed, singly or in combination, was as follows: C, 557 patients; P, 430; A, 358; and no C, P, A, 243.

Follow-up	C	P	A	No CPA	All Pts
6 mo.	99.1%	99.1%	99.7%	94.6%	97.9%
18 mo.	95.6%	96.6%	97.4%	91.7%	94.9%
30 mo.	93.1%	94.2%	96.2%	89.0%	92.2%

All percentages are related to cumulative survivals. Higher survival was associated with A alone or in any combination while C and P were close to the average rate of attrition. No antithrombotic therapy was associated with a decreased survival in the observed group.

ENDOMYOCARDIAL BIOPSY: ITS CLINICAL APPLICATION.

Ali, N. Ferrans, V.J., Banks, T., and Roberts, W.C. D. C. General Hospital and National Heart & Lung Institute, Bethesda, Maryland.

Fifty patients (pts) with (c) suspected cardiomyopathy (CM) in the presence or absence of a systemic disease were selected for endomyocardial biopsy in an attempt to clarify the etiology of the CM. The primary diagnoses included myocarditis (viral), bacterial endocarditis, sarcoidosis, sickle cell disease, eosinophilic leukemia, systemic sclerosis, myxedema, throtoxicosis and chronic alcoholism. Three techniques were used i.e. Konno's Bioptome in 25 pts, GFB biopsy catheter either alone in 20 or introduced through an end hole catheter in 5. Two to 5 specimens were obtained. Overall success rate was 92%. Complications included ventricular tachycardia (TV) in a pt c sarcoidosis and recurrent VT, ST-T changes in 1 pt and right bundle branch block in 4. All the changes were transient. No other immediate or late complications secondary to the procedure were noted. The structural changes observed were: interstitial fibrosis, cellular hypertrophy and degenerative changes of edema, lipid deposition, myofibrillar loss, sarcoplasmic reticular dilatation & mitochondrial damage. The degree and extent of these changes correlated c the duration and severity of heart disease. No viral particles but nuclear & nucleolar alterations were found in 2 pts from whom Coxsackie B viruses were isolated. Tuboreticular structures were found in a thyrotoxic pt. Alcoholic & non-alcoholic pts c CM could not be distinguished morphologically.

THE EFFECTS OF ATRIAL PACING SITE ON A-V NODAL FUNCTION
Fernando Amat, MD; Pablo Denes, MD; Delon Wu, MD; Raymond J. Pietras, MD, FACC; Kenneth M. Rosen, MD, FACC, University of Illinois, Chicago, Ill.

The effects of atrial pacing site on A-V nodal function was evaluated in 14 patients. Three sites were tested: 1) High lateral right atrium (HRA); 2) Low lateral right atrium (LRA), and 3) Mid-coronary sinus (CS). His bundle (H) electrograms were measured using electrode catheters. The atrial electrogram (A) on the H recording was considered to reflect activation of low septal right atrium (LSRA). A-H was compared at a paced rate of 90/min. A-H (mean ± SEM) with HRA, LRA, and CS pacing was respectively 154 ± 21 msec, 148 ± 17 msec, and 114 ± 14 msec. A-H was significantly shorter during CS pacing when compared to both HRA and LRA pacing ($p < 0.01$). The mean paced rate inducing type 1 block proximal to H was 143 ± 8 beats/min with HRA pacing, 145 ± 9 beats/min with LRA pacing, and 146 ± 10 beats/min with CS pacing (NS). Mean A-V nodal effective and functional refractory periods, measured at identical cycle lengths, were respectively 436 ± 75 and 504 ± 47 msec from the HRA, 450 ± 79 and 502 ± 53 msec from the LRA, and 457 ± 73 and 490 ± 42 msec from the CS. These were not significantly different. In conclusion, A-H interval was shorter with CS pacing when compared to HRA and LRA pacing at equivalent rate. This shortening did not appear to reflect a decrease in A-V nodal conduction time, since other indices of A-V nodal function were identical when comparing the three pacing sites. The short A-H during CS pacing may reflect simultaneous activation of LSRA and A-V node from depolarization proceeding from the CS. The site of impulse formation must be considered when evaluating A-V nodal function using A-H interval.

K^+ MEDIATED RELEASE OF OUABAIN FROM PURKINJE CELLS
Gary J. Anderson, MD, Indiana University School of Medicine, Indianapolis, Indiana.

The purpose of this study was to determine 1) the effect of elevating potassium concentration ($[K^+]_o$) on the binding of ouabain (OUA) to canine Purkinje fibers and 2) the electrophysiological consequences of changes in OUA binding subsequent to elevation of $[K^+]_o$. Conventional microelectrode and scintillation counting techniques were utilized. In 10 experiments, Purkinje cells were initially exposed to tritiated OUA (H^3-OUA) (0.3×10^{-6} M) until phase 4 depolarization and a reduction in maximal diastolic potential occurred. The preparation was then exchanged with an identical solution containing non-labelled OUA and exposure was continued until the cells depolarized to 47.1 ± 4.3 mV. After elevation of $[K^+]_o$ from 2.7 mEq/l to 5.4 mEq/l membrane potential increased to 61.2 ± 1.3 mV. Concomitant with this increase in membrane potential, mean H^3-OUA concentrations from the tissue bath effluent rose 49.14% (range 21.7%-198.7%) within 2 minutes indicating release of previously bound H^3-OUA. Despite continued superfusion with non-labelled OUA bath concentrations of H^3-OUA remained above expected values calculated from standard dilution curves, indicated continued release of H^3-OUA. This potentiated release of H^3-OUA paralleled the time course of increase membrane potential. Similar studies conducted on metabolically inactive cells failed to demonstrate the potentiated release of H^3-OUA from Purkinje cells in response to elevation of H^3-OUA. It is concluded that reversal of digitalis toxic manifestations of OUA are reversed by elevation of $[K^+]_o$ and may be causally related to cellular release of ouabain.

EARLY SURGICAL INTERVENTION FOR COMPLICATED ACUTE MYOCARDIAL INFARCTION: INITIAL AND LONG-TERM RESULTS.
Ezra A. Amsterdam, MD, FACC; James L. Hughes, MD; Richard R. Miller, MD; Albert Iben, MD; Edward Hurley, MD; Robert Zelis MD, FACC; Dean T. Mason, MD, FACC, Univ. Calif., Davis, Calif.

The high mortality associated with the early, severe complications of acute myocardial infarction (AMI) has stimulated increasingly aggressive treatment of these syndromes. Direct cardiac surgery now provides a rational approach to complicated AMI intractable to medical therapy. We have performed corrective cardiac surgery on 9 patients (pts) within 14 hrs-8 days (mean 4 days) of occurrence of complication. Complications of AMI in these pts were: cardiogenic shock (n=5), recurrent ventricular tachycardia (VT)(n=2) and threatened extension of established AMI (n=2), all of which were unresponsive to conventional medical therapy. Diagnostic evaluation, consisting of left heart catheterization, left ventriculography and selective coronary arteriography, was performed in all pts without the aid of mechanical circulatory assist to identify any surgically remediable lesions. Catheterization incurred no morbidity or mortality. As a result of angiographic evaluation, the following surgical procedures were performed: for shock- closure of ventricular septal defect (VSD) 2 pts, combined closure of VSD and infarctectomy 1 pt, infarctectomy 2 pts; for recurrent, intractable VT- aorto-coronary saphenous vein bypass grafts (CBG) 2 pts; for threatened extension of AMI- CBG 2 pts. Results: Complete reversal of AMI complications in 7 pts (78%)(4/5 shock, 2 VT, 1 threatened extension of AMI), 1 operative death, 2 intraoperative infarctions. There are 8 long-term survivors (89%)(mean follow-up 13 mos, range 1-38 mos) 7 of whom have returned to full activity. Early evaluation and direct surgical intervention are feasible for complications of AMI.

REGIONAL ISCHEMIC FREE FATTY ACID METABOLISM WITH ANGINA.
Carl S. Apstein, MD, Susan Kline, MD, Nadya Keller, PhD, Norman Brachfeld, MD, FACC, Cornell Medical Center, N.Y., N.Y.

Sixteen patients with angiographically proven coronary disease were paced to provoke angina pectoris with concurrent simultaneous coronary sinus (cs), and arterial (art.) metabolic sampling. Thirty-eight samplings demonstrated cardiac lactate production and were considered to be the efflux from ischemic regions; 96 samplings showed lactate extraction and were classified as non-ischemic efflux. Fractional free fatty acid (FFA) extraction $((FFA_{art.})-(FFA_{cs}))\div(FFA_{art.})$ at rest was 0.19±.02. With pacing, ischemic fractional FFA extraction decreased by 37% to 0.12±.01 ($p < .05$), but non-ischemic FFA extraction did not change. FFA oxidation was measured by infusing a tracer amount of ^{14}C-FFA (^{14}C-palmitate bound to human albumin) to achieve an arterial steady-state level, and quantitatively collecting $^{14}CO_2$ in the coronary sinus samples. Fractional ^{14}C-FFA oxidation, $((^{14}CO_{2cs})-(^{14}CO_{2art.}))\div((^{14}C\text{-}FFA_{art.})-(^{14}C\text{-}FFA_{cs}))$, in the resting state was 0.54±.03. With pacing, regional ischemic efflux demonstrated a 31% increase in fractional ^{14}C-FFA oxidation to 0.71±.05 ($p < .01$) but non-ischemic FFA oxidation was unchanged. Thus, the regional ischemia associated with pacing-induced angina results in a significant decrease in fractional FFA extraction with an increase in fractional FFA oxidation, making myocardial lipid deposition unlikely. These clinical results stand in sharp contrast to isolated hypoxic animal heart experiments, where marked FFA and triglyceride tissue accumulation occurs.

PACEMAKER CURRENT IN CARDIAC PURKINJE FIBERS: EVIDENCE FOR DEPENDENCE ON THE NA-K PUMP

Ronald S. Aronson, MD; Jeremiah M. Gelles, MD; Brian F. Hoffman, MD, College of Physicians & Surgeons of Columbia University, New York, New York.

We have previously shown that ouabain greatly diminishes or abolishes the current (IK2 or pacemaker current) presently considered to be responsible for spontaneous diastolic depolarization in Purkinje fibers of the sheep. Since ouabain is a relatively specific inhibitor of the Na-K pump we were led to test the effect of other pump inhibitors on IK2. The effects of substitution of Li for Na and of 2,4-dinitrophenol (DNP) on IK2 were studied using a two-microelectrode voltage clamp technique in shortened cardiac Purkinje fibers of the sheep. Isolated fibers were perfused with Tyrode solution (K, 4.0mM, T, 36°C) the Na of which was isosmotically replaced with Li (except for 12mM $NaHCO_3$) or to which DNP, 0.2mM, was added under test conditions. Exposure to Li Tyrode solution greatly reduced or abolished IK2. This current reappeared on readmission of Na Tyrode solution. DNP also greatly attenuated IK2. Action potentials which under control conditions showed spontaneous diastolic depolarization did not show such activity after exposure to Li Tyrode solution or to DNP. The dramatic reduction or abolition of the pacemaker current under various conditions that inhibit the Na-K pump suggests that the integrity of this pump is in some way necessary for the generation of this current.

CRITERIA FOR THE VALIDITY OF THE RISE IN LEFT VENTRICULAR END DIASTOLIC PRESSURE FOLLOWING PACING INDUCED ANGINA

Raphael Balcon, MD, FACC; Roger Wilkinson, MB; Warren Walsh, MB, MRACP; Anthony Rickards, MB, MRCP. London Chest Hospital, London, England.

85 patients being investigated for angina have been studied at cardiac catheterisation. With continuous measurement of LVEDP the heart rate (HR) was increased by pacing from an initial rate of 100 bpm, increasing by 10 bpm each minute. If AV block occurred during RA pacing, the catheter was advanced to the RV and the test continued until either the maximum rate of 180 bpm was reached or the patient complained of cardiac pain. At the end of each minute the pacemaker was switched off and LVEDP recorded for 10 beats in sinus rhythm. 4 patient groups were identified. A (47 patients) with CAD who developed angina during pacing, B (12 patients) with CAD without induction of angina, C (13) and D (13) had no CAD but group C complained of pain during pacing. Group D were considered normal. No differentiation between the groups was apparent from LVEDP during pacing. Following switch-off of pacing the RR interval, pre a, a wave and post a pressures were measured in each patient. The relationship between pre a and a ($r=0.96$) and pre a and post a ($r=0.95$) remains constant for any individual. With increased HR there was no significant change in LVEDP from control in groups B, C, D. Only in group A at the induction of angina (p 0.001) and 10 beats before (p 0.05) did LVEDP rise significantly. The magnitude of the rise in LVEDP is proportional to the HR attained before switch off of pacing. Thus a rise of 1mm Hg at 100-120 bpm, 3mm Hg at 130-150 bpm and 5mm Hg at 160-180 bpm was seen in 70% of group A and only 23% of group D (normal). These figures provide more accurate guidelines for the definition of an abnormal LV response to pacing.

RELATION OF EARLY POSTOPERATIVE MYOCARDIAL INFARCTION TO PATENCY OF AORTOCORONARY BYPASS GRAFTS AND TO UNGRAFTED CORONARY ARTERIES

Jose L. Assad-Morell, MD; Gerald T. Gau, MD, FACC; Robert L. Frye, MD, FACC; Daniel C. Connolly, MD, FACC; George D. Davis, MD; Gordon K. Danielson, MD, FACC, Mayo Clinic and Mayo Foundation, Rochester, Minnesota.

To study the incidence of early transmural myocardial infarction (TMI) after saphenous-vein bypass graft and its relationship to graft patency and diseased ungrafted coronary arteries, we analyzed the preoperative and postoperative (PO) electrocardiograms (ECG) and vectocardiograms (VCG) of 572 patients (pts) operated on from 1969-1972 inclusive. Standard ECG and VCG criteria for diagnosis of TMI were used, and the angiograms of pts with early PO-TMI were reviewed. TMIs occurred in 67 (12%) of the pts. Nearly all of them were documented within 24 hours after operation, and the rest within 72 hours. The pts comprised 15 (5%) of the 295 who had had TMI prior to surgery and 52 (19%) of the 277 who had not. There were 47 TMIs within the distribution of the grafted vessels and 17 in the distributions of vessels that had been severely diseased but not grafted. (Three were in the distributions of angiographically normal vessels.) Repeat angiography, performed in 36 of the 67 cases of early PO-TMI, showed that 32 of the infarcts in this group were within the distribution of the grafted vessel. The grafts were patent in 16 of these pts and there was graft occlusion in 16. The 12% risk of early postoperative TMI is substantial. Clearly, the occurrence of early PO-TMI is not a reliable indication of graft occlusion, for 25% of all TMIs were in the distribution of diseased but ungrafted arteries, and among the group of 32 who developed TMI in the distribution of the grafted artery and were studied angiographically afterward, as many grafts were patent as occluded.

EFFECTS OF NITROGLYCERIN ON REGIONAL LEFT VENTRICULAR LENGTH-TENSION RELATIONS AFTER CORONARY OCCLUSION

Vidya S. Banka, MD; Monty Bodenheimer, MD; Richard H. Helfant, MD, FACC, Presbyterian-University of Pennsylvania Medical Center, Philadelphia, Pennsylvania

Controversy has existed concerning the value of nitroglycerin (TNG) in acute coronary disease. To better define this issue, the effects of TNG (30ug/Kg intravenously) on local tension and length characteristics of the ischemic (IZ), border (BZ) and nonischemic (NZ) zones of the left ventricle were studied in 10 open chested dogs using Walton-Brodie strain gauges and mercury-in-silastic segment length gauges. In the BZ, the pre-ejection tension (PET) increased by 30.9 ± 10.9%, ejection tension (ET) by 44.0 ± 8.5% and the rate of tension rise (DT/dt) by 41.7 ± 7.0% ($p<0.01$) in all observations recorded 15 minutes (min), 30 min., one, two and three hours after anterior descending coronary ligation (CL). NZ exhibited a parallel increase in all tension parameters. Segment length (SL) in the BZ decreased by 24.5 ± 1.3% at 15 and 30 min of CL and by 12.7 ± 1.6% after 1-3 hours of CL ($p<0.01$). NZ demonstrated a consistent decline of 23.3 ± 2.4% in SL regardless of the duration of CL. Maximal response to TNG both in tension and length parameters was observed within 30 seconds to 1 min and was simultaneous with 26.7 ± 1.9% decrease ($p<0.01$) in blood pressure and an insignificant (7.1 ± 0.9%) increase in heart rate. IZ exhibited no significant response either in tension or length parameters. In summary, TNG improves the contractile characteristics of the nonischemic and border zones following coronary occlusion without affecting the central ischemic zone. However, the border zone exhibits a progressive decrease in length response, presumably due to decreasing compliance.

VALUE OF CORONARY COLLATERALS, PATHOLOGIC Q WAVES AND SEGMENTAL LOCATION AS DETERMINANTS OF REVERSIBILITY OF ASYNERGY IN CORONARY HEART DISEASE

Vidya S. Banka, MD; Monty Bodenheimer, MD; Richard H. Helfant, MD, FACC, Presbyterian-University of Pennsylvania Medical Center, Philadelphia, Pennsylvania

The selection of patients for aorto-coronary bypass surgery depends largely on the potential for improvement in asynergic zones. To determine which factors may predict whether or not asynergy is reversible, the response of asynergic zones to sublingual nitroglycerin (1/150 grs) was studied angiographically in 35 patients and was correlated with the presence or absence of collaterals and pathologic Q waves in the corresponding zone of asynergy. Of the 21 zones to which collaterals were demonstrable 19 (90.4%) improved and only 2 (9.6%) remained unchanged ($p<0.001$). Both of the unimproved segments were located in the inferior wall. Of the 31 zones to which collaterals were not demonstrable, 14 (45.1%) improved while 17 (54.9%) remained unchanged. Pathologic Q waves were present in 30 zones of which 22 (70.3%) were unresponsive while 8 (29.7%) improved ($p<0.001$). Of the 34 zones which did not have corresponding Q waves, 27 (73%) improved but 7 (27%) remained unchanged ($p<0.001$). The relative location of the asynergic zone also influenced the chances of reversibility. Of the 25 anterior wall segments 18 (72%) improved while 7 (28%) did not. In contrast only 7 (33%) of the 21 apical segments improved and 14 (66%) remained unchanged. Of the 18 inferior wall segments 10 improved and 8 showed no response. In summary, the presence of collaterals and the absence of pathologic Q waves in the corresponding segments appears predictive of the potential reversibility of the asynergic segment. Apical asynergy responds less frequently than anterior or inferior zones.

DIFFERENTIAL EFFECTS OF DIGITALIS ON CONTRACTION OF ISCHEMIC, BORDER AND NONISCHEMIC VENTRICULAR ZONES FOLLOWING CORONARY LIGATION

Vidya S. Banka, MD; Kul D. Chadda, MD; Monty Bodenheimer, MD; Richard H. Helfant, MD, FACC, Presbyterian-University of Pennsylvania Medical Center, Philadelphia, Pennsylvania

The effects of digoxin (priming dose 0.04 mg/Kg; 0.01 mg/minute infusion) on local tension and length characteristics following coronary ligation were studied in 20 dogs utilizing Walton-Brodie tension and mercury-in-silastic length gauges. In the nonischemic zone, digoxin augmented pre-ejection tension (PET) by 42.0 $\pm$ 5.6%, ejection tension (ET) by 60.4 $\pm$ 12.1%, and rate of tension rise (DT/dt) by 46.4 $\pm$ 9.6% when administered 15 minutes to two hours following ligation. Similarly, the border zone increased by 49.4 $\pm$ 10.8% in PET, 62.9 $\pm$ 11.5% in ET, and 40.5 $\pm$ 5.9% in DT/dt ($p<0.01$ in all parameters). In the ischemic zone, digoxin given 15 minutes after ligation produced 27.3% increase in PET and 20.0% in DT/dt with no change in ET. However, when started 30 minutes after ligation, no significant changes occurred in tension parameters and an actual 3-5% decline was observed when infused one and two hours after ligation (compared to a 5-8% decrease in control dogs). Segment lengths were essentially unchanged in all studies. In summary, digitalis uniformly increases contraction of nonischemic and border zones following coronary ligation. However, effects on both contraction and aneurysmal bulging in the ischemic zone are minimal.

AORTA-RIGHT PULMONARY ANASTOMOSIS - LONG TERM PROBLEMS AND RESULTS AFTER TOTAL CORRECTION

Rosa Barbosa, M.D.; Jane Somerville, F.R.C.P., F.A.C.C.; Donald Ross, F.R.C.S. Cardiothoracic Institute and National Heart Hospital, London, England

The results in 95 cyanotic patients one to 6 years after aorta to left pulmonary anastomosis are presented. Spontaneous closure of the shunt was rare (3%), as was chronic heart failure (2%) and pulmonary vascular disease (2%). There was an unusually high mortality after total correction in Fallot and pulmonary atresia. Seven of 36 patients died with good anatomical correction and in all the postoperative main pulmonary artery pressure at surgery was high. Lung histology did not show pulmonary arteriolar disease and the problem appeared to be caused by hypoplasia of pulmonary arteries proximal to the shunt. Factors which predispose to this serious state are the leaving of a shunt which only perfuses the right lung. This was dangerous when the operation had been performed in Fallots under the age of 3 and in pulmonary atresia under 5 years. Upward kinking of the right pulmonary artery, which is common with this anastomosis, may prevent any flow into the rest of the pulmonary tree and if the right ventricular outflow is atretic, there may be no flow to stimulate growth. The operation has definite place in therapy but early postoperative investigation is recommended, irrespective of clinical result in order to see distortion of pulmonary tree. If there is only perfusion of one side, early total correction is recommended. In the child with pulmonary atresia who may not have reached an ideal size for homograft correction, a left sided shunt may be required to ensure growth of the left pulmonary artery.

LEFT MAIN CORONARY ARTERY DISEASE--IS SURGERY ALWAYS INDICATED?

Dennis J. Battock MD; Peter P. Steele MD; Hywel Davies, MD, FACC, V.A. Hospital, Denver, Colo.

Recent reports regarding left main coronary artery disease (LMCAD) suggest that it's presence, in itself, is indication for bypass surgery. We have followed 11 operated patients (OP) and 10 unoperated patients (UP) with >50% demonstrable LMCAD from 5 to 74 mos following catheterization (C). Although average onset of CAD to C was 50 mos (1-144), all but 2 patients (pts) had C because of accelerated angina. The OP and UP were comparable in all clinical and C parameters. All pts had 2 or 3 vessel involvement. Total occlusion was present in 25 vessels. Collaterals, calcification and significant left ventricular (LV) dysfunction (ejection fraction < 40%) were present in 14, 8, and 7 pts respectively. ECG's showed infarction, LVH, or ST changes in 13, 11, and 16 pts respectively. Stress tests were markedly positive (> 3mm) in 4/4 pts stressed. The only morbidity in 25 C was one episode of ventricular fibrillation. Of the 11 OP, 5 had double and 6 triple bypass grafts. Mortality from surgery was 9% (1/11). 9 OP have been followed 11 mos (3-27). Relief of pain is complete in 6, moderate in 2 and worse in 1 pt. 4/10 died of cardiac causes 13 mos (6-24) after C. One UP died of a CVA 50 mos after C, and 5/10 are alive 35 mos (13-74) after C. Three UP are the same or worse and 2 improved. Two UP restudied at 6 and 3 year intervals showed progression of LMCAD. We conclude that even though the overall mortality is increased in UP with LMCAD, the long term followup and surgical results are not sufficient to justify prophylactic operation for this disease. The average interval in UP from onset of CAD to death or followup was 74 mos (18-166); thus, the association of incapacitating angina should be the indication for surgery.

EFFECTS OF CARDIAC ARRHYTHMIAS ON AORTOCORONARY BYPASS GRAFT BLOOD FLOW VELOCITY IN MAN

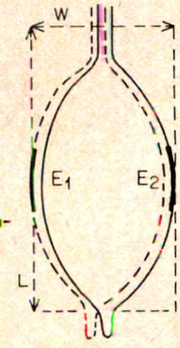
Alberto Benchimol, MD, FACC; Kenneth B. Desser, MD, Institute for Cardiovascular Diseases, Good Samaritan Hospital, Phoenix, Arizona

The influence of cardiac arrhythmias on aortocoronary saphenous vein bypass graft blood flow velocity (AGFV) has not been described. Utilizing the Doppler ultrasonic flowmeter catheter AGFV was measured in a total of 19 grafts in 16 conscious patients (pts.) during a variety of cardiac arrhythmias. Atrial (atr.) and ventricular (ventr.) premature depolarizations reduced peak AGFV by 20 to 90%, dependent on their extrasystolic coupling intervals. Post-extrasystolic sinus beats resulted in an AGFV "overshoot", with greater rebound related to longer preceding R-R intervals. Sustained atr. tachycardia (tachy.) produced an initial decline of AGFV which was followed by a gradual rise to levels greater than those recorded during the control period. Nineteen transient episodes of ventr. tachy. reduced peak AGFV by an average of 50%, (control AGFV ($\bar{X}\pm$1SD) = 28±11 cm./sec., ventr. tachy. = 14±8 cm./sec. $P < 0.001$). In the setting of sinus rhythm, atrioventricular dissociation and ventr. tachy., fusion beats and properly timed atrial systoles augmented AGFV. In 2 pts., AGFV alternation was recorded during ventr. tachy. at ventricular rates greater than 150/min. Cardiac arrhythmias influenced native coronary and AGFV in a similar manner when such measurement was obtained at these 2 respective anatomic sites in the same subject. These findings indicate the adverse influence of cardiac arrhythmias on AGFV and suggest an aggressive approach to their treatment.

A LOOP ELECTRODE SYSTEM FOR TEMPORARY RIGHT ATRIAL PACING

Stephen C. Berens, MD; Alexander Kolin, Ph.D.; Rex N. MacAlpin, MD; Max Lenz, BS. University of California, Los Angeles, California

Temporary right atrial pacing (RAP) is infrequently utilized because of the problem of maintaining a stable position of the electrodes (E). To circumvent this problem, we devised a loop-mounted E system which conforms to the walls of the RA maintaining stable contact. Its resiliency allows it to be inserted into a protective catheter in the collapsed state and thus be passed from a peripheral vein into the RA. Once extruded from the catheter, it expands as far as the RA will permit. It is constructed of a pair of insulated wires with E_1 and E_2 on either side of the loop. Width W=50 mm, length L=120 mm. An hexagonal shape has also been used, as well as different sizes. To date, it has been successfully used in 3 CCU patients (pts) for relatively long-term RAP: 2 pts for rate correction of low cardiac output, 6 and 15 days; one pt. for atrial overdrive suppression of PVCs, 9 days. It has also been used in brief RAP studies in 6 pts. RAP was essentially constant in all cases. Two additional pts could not be paced due to (a) 2 other wires and 1 catheter in the RA, and (b) anatomic variation in selected venous approach. No complications in any case.



CALCIFIC AORTIC INSUFFICIENCY

Jermiahou Ben-Zvi, MD; Frank J. Hildner, MD, FACC, Philip Samet, MD, FACC, Mount Sinai Medical Center, Miami Beach, Florida

Calcification of the aortic valve (AV) is usually associated with at least some stenosis of the valve. We have observed an unusual group of patients with pure aortic insufficiency (AI) and calcified AV. Twenty-six patients had pure calcific AI (no associated stenosis), representing 8.3% of 314 patients with AV disease of any type, and 10.7% of 243 patients with any degree of AI. Nineteen (73%) males and seven (27%) females ranged in age from 25 to 75 years (mean 51). 23% were younger than 40. Sixteen (62%) had rheumatic heart disease, one had luetic AV disease, one had congenital bicuspid valve and eight (31%) had AI of undetermined etiology. Twenty-two patients (88%) had an aortic systolic ejection murmur. AV calcification was detected by plain chest films in only four patients (17%) and by routine image intensification fluoroscopy (before catheterization) in fifteen patients (71%). The remaining 29% had the calcification of the AV detected during catheterization.

AV calcification was severe in nine patients (35%), moderate in eleven (42%) and minimal in six (22%). AI was severe in twenty patients (77%), moderate in five (19%), and minimal in one (4%). Nineteen patients (77%) had reduced left ventricular contractility. Sixteen (67%) had low cardiac index. Eighteen had normal coronary arteries and three had obstructive coronary artery disease. Aortic stenosis was misdiagnosed as the predominant lesion in fourteen patients (54%), prior to catheterization. This series demonstrates that all patients with calcified AV and ejection murmurs do not necessarily have aortic stenosis. Pure calcific AI is a distinct entity, more common that previously suspected.

PROLAPSE OF THE POSTERIOR LEAFLET OF THE MITRAL VALVE ASSOCIATED WITH SECUNDUM ATRIAL SEPTAL DEFECT

Amadeo Betriu, MD; E. Douglas Wigle, MD; Clarence H. Felderhof, MD; Michael J. McLoughlin, MD, Toronto General Hospital, Toronto, Canada.

The association of prolapse of the posterior leaflet of the mitral valve (PPLMV) with secundum atrial septal defect (ASD) has recently been reported, but the incidence and features of this association have not been defined. Analysis of right anterior oblique left ventricular (LV) cineangiograms in 54 patients (pts.) with secundum ASD revealed evidence of PPLMV in 20 (37%).

In 9 of these 20 pts. there was no clinical evidence of a mitral lesion, thus the incidence of unsuspected PPLMV with secundum ASD was 20% (9 of 43 pts.). Of the 11 pts. with clinical evidence of a mitral lesion, 9 had a pansystolic murmur and only 2 had a midsystolic click, one of whom also had a late systolic murmur.

The ECG revealed a prolonged Q-T interval in 9 pts. T wave inversion was present in leads II, III and AVF in 5 pts., and in V_5 and V_6 in 4 pts. Atrial fibrillation was present in 3 pts.

Analysis of the angiographic anatomy revealed that the prolapse was triscalloped in 4 pts., biscalloped in 11 and uniscalloped in 5. Mitral regurgitation (MR) was present in 12, including the 11 pts. with clinical signs of a mitral valve lesion. Three pts. with moderate or severe MR had triscallop prolapse. LV wall motion studies in 7 pts. with MR revealed decreased shortening of the LV basal diameter with increased shortening in the long axis.

We conclude that the association of PPLMV with secundum ASD is very common and may be present in the absence of any clinical evidence of a mitral valve lesion.

PERMANENT CARDIAC PACEMAKER FOLLOW UP

Michael Bilitch, MD, FACC; E. Betty Cassady, MA; John Lloyd, Ph.D.; University of Southern California, Los Angeles, California

Patients with permanently implanted pacemakers require constant realistic follow up in order to recognize failures of the system. Random recovery of pacemakers from the community was used as a means of identifying pacemaker patient physicians; their patterns of patient follow up were then assessed. From 475 recovered pulse generators 172 persons were identified as patients' "pacemaker physicians". 104 of these physicians were interviewed and responses to a specific series of questions were tabulated and analyzed. Interviewees included internist-cardiologist 28.9% (30), internist 25% (26), thoracic surgeon 17.3% (18), general surgeon 7.7% (8), general practicioner 19.2% (20), other 1.9% (2). Evaluation of experience showed that 57.7% (60) followed 1-8 patients, 19.2% (20) 9-24 patients, and 23.1% (24) 25-200 patients with pacemakers. Of the total group 37.5% (39/104) had a realistic follow up plan; 60% (18/30) of internist-cardiologists, 33.3% (6/18) of thoracic surgeons, and 23% (6/26) of internists had realistic plans. 62.5% (15/24) of physicians with the greatest experience used a magnet regularly while checking pacemaker function; although most pacemakers implanted today are demand type, only 5% (3/60) of physicians with the least experience used the magnet.

It is concluded that: 1) permanent pacemaker patients require more formal and stringent follow up than they receive at the present time, and 2) design characteristics of pacemaker systems should take the expertise of the physician-user into account.

THE FREQUENCY AND PROGNOSIS OF VENTRICULAR ECTOPIC BEATS IN MIDDLE-AGED MEN

Henry Blackburn, MD, FACC; Ancel Keys, Ph.D, FACC; Henry L. Taylor, Ph.D; R. Douglas Thorsen, BS; Jean L. Canner, MA; and Allen H. Womelsdorf, BS, for the International Cooperative Study on Coronary Disease Epidemiology, Laboratory of Physiological Hygiene, School of Public Health and the Department of Medicine, School of Medicine, University of Minnesota, Minneapolis, Minnesota 55455

The frequency, associations and prognostic importance of ventricular ectopic beats (VEB) were studied in 2,451 U.S. railway men and 8,319 rural European men ages 40-59 and free of coronary disease (CHD) at entry. VEB frequency in routine resting and post-exercise electrocardiograms (ECG) increased with age, and was twice as great in "high risk" men of the upper 20% of a coronary risk score (computed from the primary risk factors) ($P<.01$). VEB were also concentrated in men having other ECG abnormalities. The crude risk ratio for 5-year deaths among men having any rest or post-exercise VEB was 1.9 compared to those with no VEB. The simple univariate regression of deaths according to frequency of VEB gave a significant slope ($t = 3.1$), and it remained significantly positive after adjustment for the presence of other ECG abnormalities and primary risk factors. However, poor prognosis for CHD and death, according to the frequency of VEB, was concentrated among men having highest risk score based on blood pressure, serum cholesterol and smoking habit. We conclude that VEB are possibly significant independent harbingers of future manifest CHD and sudden death but probably only in the presence of other ECG or clinical evidence of myocardial disease, or multiple and elevated CHD risk factors. Higher grade of VEB (pairs, runs, and early beats) were too rare in short term monitoring of the general population to analyze fruitfully.

REGIONAL MYOCARDIAL BLOOD FLOW FOLLOWING CORONARY OCCLUSION IN UNANESTHETIZED NORMAL AND HYPOXEMIC DOGS.

Sanford P. Bishop, D.V.M., Ph.D. and Colin M. Bloor, M.D., FACC, University of California, San Diego, La Jolla, Ca.

Regional distribution of coronary blood flow in the immediate post-infarction period was studied in chronically hypoxemic (Hpx) and normal unanesthetized dogs. Surgical transposition of the caudal vena cava to the left atrium was produced 18-30 months prior to coronary occlusion. Left ventricle weight to body weight was not significantly changed but right ventricular weight to body weight was decreased 25% ($p<.05$). Arterial O_2 saturation was 70.0 ±4.9(SD)%. A left atrial tube and an inflatable cuff were placed around the left circumflex coronary artery in 5 Hpx and 3 normal dogs, and the left anterior descending coronary artery in 5 normal dogs. After recovery (7-14d) 15 μ tracer microspheres (TM) labeled with ^{85}Sr, ^{141}Ce, or ^{51}Cr were injected into the left atrium just prior to occlusion of the coronary cuff, 5 min and 24 h after occlusion. Gross infarct size in normal dogs was 17±7% of ventricular mass and 6±8% in Hpx dogs. The TM ratio of infarcted to non-infarcted tissue in the endocardial half of the myocardium during control, 5 min and 24 h post-infarction was 0.97±0.23 (SD), 0.16±0.04, and 0.33±0.11 respectively in normal dogs, and 0.96±0.11, 0.56±0.32, and 0.81±0.41 in Hpx dogs. In the epicardial half of the myocardium the ratios were 0.89±0.04, 0.31±0.10, and 0.61±0.17 in normal dogs and 1.07±0.33, 0.80±0.53, and 0.97±0.34 in Hpx dogs. In both normal and Hpx dogs there was significant increase in blood flow to the infarcted area at 24 h compared to 5 min post-occlusion. With chronic Hpx there was greater blood flow to the infarcted tissue resulting in smaller infarct size than in normal dogs. These findings suggest that chronic hypoxia induces myocardial changes that are protective when infarction occurs.

LEFT VENTRICULOGRAPHY IN PATIENTS WITH THE ANGINAL SYNDROME AND NORMAL CORONARY ARTERIOGRAMS

William E. Boden, BS; Harold Smulyan, MD; James Potts, MD; Lewis W. Johnson, MD; Anis I. Obeid, MD; Robert H. Eich, MD, SUNY Upstate Medical Center, Syracuse, New York

Left ventriculography, heretofore, has not been subjected to detailed investigation in patients with the anginal syndrome (AS) and normal coronary arteriograms. The left ventriculograms, obtained in the right anterior oblique (RAO) projection, of 45 patients (24 females, 21 males), mean age 47.1 years, were analyzed utilizing the one-plane cineangiographic measurement of left ventricular volume. Tracings of end-systole and end-diastole were made from the cineangiograms in the RAO projection. The ejection fraction (EF) was computed from the ratio of left ventricular systolic to diastolic volume. In addition, the percent change for both longitudinal axis (LA) and transverse axis (TA) that occurred during ventricular systole was analyzed. The EF for the 24 females in the study group ranged from 0.647 to 0.915 (mean 0.818), and for the 21 males ranged from 0.658 to 0.895 (mean 0.788). The mean percent change in the LA and TA which was observed during ventricular systole was 31.2% and 51.6% in the female sub-group, and 26.3% and 49.7% in the male sub-group, respectively. The high values for EF (mean 0.803, SD 0.0627, SE 0.0133, SEE 0.0002, ($P < .001$), compared to reported normals, suggest that hyperdynamic ventricular contraction (HVC) may be a contributing factor to the pain typical of AS in patients without angiographically demonstrable atherosclerotic lesions of the coronary arteries. In conclusion, HVC, as suggested by markedly increased EF and high degree of LA and TA shortening, could produce a state of increased myocardial oxygen consumption resulting in ischemic heart pain, and might explain the salutary effect of beta-adrenergic blockade and nitrites in some of these patients.

Q WAVES AND ASYNERGY: PREDICTIVE VALUE AND HEMODYNAMIC SIGNIFICANCE OF ANATOMIC LOCALIZATION

Monty Bodenheimer, MD; Vidya S. Banka, MD; Richard H. Helfant, MD, FACC, Presbyterian-University of Pennsylvania Medical Center, Philadelphia, Pennsylvania

To better delineate the significance of pathologic Q waves (≥.04 sec) in predicting location and functional effect of asynergy, 124 consecutive patients with asynergy were reviewed. 105 had coronary artery disease and 19 were classed as cardiomyopathy (CM) (diffuse hypokinesis and normal coronary arteriograms). 57 patients (54%) had pathologic Q waves; 27 anterior, 29 inferior and one both. Anterior Q's denoted asynergy in 27 of 27 (100%), anterior asynergy in 26 of 27 (96%) and frank aneurysm (akinesis or dyskinesis) in 22 of 27 (78%). Inferior Q's indicated asynergy in 26 of 29 (90%), inferior asynergy in 21 of 29 (78%) and aneurysm in 9 of 21 (31%). Conversely, of 47 frank aneurysms, 83% had Q's. Anterior aneurysms had Q's in 29 of 36 (80%) while inferiors had 13 of 15 (86%). Hemodynamically, the left ventricular end-diastolic pressure (LVEDP) was elevated in 15 of 27 (56%) with anterior Q's versus only 7 of 22 (31%) with inferior Q's ($p<.025$). Anterior asynergy alone was associated with an elevated LVEDP in 13 of 28 (46%) contrasted with 6 of 21 (22%) with inferior asynergy. Patients with combined or diffuse asynergy had elevated LVEDP in 43% and 45% respectively. Of the 19 patients with CM none had Q's. In summary, pathologic Q waves correlated highly with the presence of asynergy, accurately localized the site of the aneurysm and aided in predicting the degree of left ventricular dysfunction. Q's were not seen in cardiomyopathy.

BENEFICIAL EFFECTS OF LIDOCAINE ON INCIDENCE OF VENTRICULAR FIBRILLATION DURING CORONARY OCCLUSION IN DOGS.

Jeffrey S. Borer, MD; Lura Harrison, PhD; Richard Levy, MD; Kenneth M. Kent, MD; Robert E. Goldstein, MD; and Stephen E. Epstein, MD, NHLI, Bethesda, Md.

Several studies have questioned the efficacy of lidocaine in reducing the incidence of ventricular fibrillation (VF) shortly after acute myocardial infarction (AMI), when arrhythmogenic mechanisms are believed to be different from those operative several hours later. To determine whether lidocaine inhibits occurrence of early VF, open-chest anesthetized dogs were randomized into 3 groups: a control group (saline infusion); a moderate dose lidocaine-treated group (2 mg/kg bolus and 70 μg/kg/min infusion); and a high dose lidocaine-treated group (2 mg/kg bolus and 100 μg/kg/min infusion). After 10 min of infusion the left anterior descending and septal coronary arteries were occluded at their origins. Infusions continued until VF occurred or 30 min elapsed. Fourteen of 16 control dogs died in VF. Sixteen dogs received lidocaine. Of the 11 treated dogs maintaining lidocaine blood levels within the accepted therapeutic range (1.2 to 5.5 μg/ml), 6 survived ($p<.05$). Ten of these 11 received the moderate dose regimen. Five other dogs received the high dose regimen; all died, with blood levels ≥6.3 μg/ml at the time of death. Since it has been suggested that detrimental effects may result from low blood levels of lidocaine, VF threshold (VFT) was determined in 3 dogs given lidocaine to maintain blood levels ≤1.2 μg/ml. No reduction in VFT was found. We conclude that lidocaine, at blood levels ranging from 1.2 to 5.5 μg/ml, significantly reduces the incidence of VF occurring early after coronary occlusion and that no decrease in ventricular electrical stability occurs at lower blood levels. Administration of this agent therefore may be of particular value in the early phases of acute myocardial infarction.

THE EFFECT OF DIGITALIS ON SINOATRIAL CONDUCTION IN MAN

Roger C. Bond, M.D., Toby R. Engel, M.D., and Stephen F. Schaal, M.D., The Ohio State University College of Medicine, Columbus, Ohio.

Digitalis induced abnormalities of sinoatrial (SA) conduction are not recognized unless SA block is observed. The effect of digitalis on SA conduction has not been determined in man. A catheter advanced to the high right atrium was used to apply a premature atrial impulse after every eighth basic beat. When the premature beat is applied in the midzone of the basic cycle, analysis of the basic cycle interval and the interval from the atrial premature depolarization (APD) to the recovery beat allows computation of the sinoatrial conduction time (SACT). This interval represents the conduction time required for the impulse to travel to the SA node and return to the atrial recording catheter. Five normal patients were studied before and after ouabain (0.01 mg/kg). The SACT was prolonged after ouabain in all patients with an average change of 52.8 msec. The increase of the SACT correlated with the prolongation of atrioventricular conduction ($r = 0.92$). In two patients with sinus rhythym and digitalis induced SA block, application of APD's defined two separate groups of recovery intervals differing by one basic cycle length; this represented second degree SA block. This study defines a means of measuring sinoatrial conduction and demonstrates that digitalis prolongs SA conduction.

HEMODYNAMIC EFFECTS OF 1-ISOPROPYLAMINO-3-(2-THIAZOLOXY)-2-PROPANOL·HCl IN THE EXPERIMENTALLY INFARCTED DOG

Howard T. Buckley, MD, Arthur M. Strosberg, PhD, Donald C. Harrison, MD, FACC, Cardiology Division, Stanford University School of Medicine, Stanford, CA and Department of Pharmacology, Syntex Research, Palo Alto, CA

ITP (1-isopropylamino-3-(2-thiazoloxy)-2-propanol·HCl) is a selective myocardial β-stimulant with selective myocardial β-blocking activity which has previously been shown to increase (↑) myocardial contractility, cardiac output (CO), coronary blood flow, heart rate (HR); moderately decrease (↓) total peripheral resistance (TPR) and produce little or no effect on systemic blood pressure. We studied the effects of ITP (4 mg/kg, I.V. bolus), saline (0.1 cc/kg, I.V. bolus) and isoproterenol (0.1 μg/kg, I.V. infusion) administered to three groups of experimentally infarcted dogs. A 40-50% myocardial infarction of the left ventricle (LV) (measured by Evans Blue injection) was produced in each dog. Saline produced no significant hemodynamic effects. ITP produced significant ↑ in CO, 22%; LV dp/dt, 36%; stroke volume (SV), 21%; but produced no significant changes in aortic pressure, LV pressure or S-T segment elevation. TPR decreased. Isoproterenol produced greater increases in CO, SV, HR and a greater ↓ in TPR. Isoproterenol, however, appeared to ↑ S-T segment elevation to a significant degree. We conclude that ITP is effective in the treatment of myocardial failure in the dog and would seem a useful adjunct in the treatment of heart failure. Studies in humans are now underway.

SPORTS, DEATH, AND UNUSUAL HEART DISEASE

Richard S. Buddington, Charles J. I. Stahl, Hugh A. McAllister and Richard A. Schwartz, Armed Forces Institute of Pathology, Washington, D.C.

The increasing number of deaths recorded in individuals engaged in professional, amateur and recreational athletics prompted the authors to investigate the cardiovascular risk inherent in such activities. The records of the A. F. I. P. were searched and over 11,000 autopsies from the Registries of Cardiovascular Pathology and Forensic Pathology were reviewed. Cases fulfilling the following criteria were selected for further study: (1) Sudden and unexpected death in an asymptomatic individual; (2) Death or symptoms occurring during physical exercise; (3) Survival of less than 24 hours; (4) Death or symptoms witnessed by a reliable observer; (5) An adequate autopsy protocol excluding other than a cardiac cause of death; (6) Subjects 40 years or over were excluded. These criteria yielded 113 cases with an average age of 21.6 years. Besides a distribution of deaths in the expected category (i.e., coronary artery disease, myocarditis), the more unusual cases included sickle cell heart disease, congenital coronary anomalies, cardiac sarcoid, and fibroelastosis. The clinical and pathological findings and distribution of cases are reviewed.

BENIGN PROGNOSIS OF RIGHT BUNDLE BRANCH BLOCK AND LEFT ANTERIOR HEMIBLOCK AFTER INTRACARDIAC REPAIR OF TETRALOGY OF FALLOT

John A.Cairns,MD; Anthony R.C. Dobell,MD; James Gibbons, MD, FACC; Irving Tessler,MD, Montreal Children's Hospital and McGill University, Montreal, Ouebec.

Right bundle branch block and left anterior hemiblock (RBBB & LAH) occurring after intracardiac repair of tetralogy of Fallot (TOF) has been accorded an ominous late prognosis with a high incidence of late onset complete heart block (CHB) and sudden death. We studied 141 survivors of intracardiac repair of TOF operated upon between 1958-72, to document the incidence of RBBB & LAH and to study the late prognosis. RBBB & LAH occurred in 31 (22%) all of whom have complete follow-up.Transient CHB occurred post-operatively in 2 patients; there were no other significant arrhythmias. Two late deaths have occurred, neither from arrhythmia (1 at attempted VSD reclosure, 1 of progressive congestive heart failure).The remainder are well an average of 76 months post-operatively (range 144-12 months).
The absence of late onset CHB or sudden death in this series contrasts with the relatively high incidence of these events in some studies of RBBB & LAH post intracardiac repair of TOF. However in these reports a history of transient postoperative CHB(indicative of trifasicular disease in this setting) can be found in the majority of those developing late onset CHB or sudden death. We conclude that RBBB & LAH occurring after intracardiac repair of TOF does not of itself carry a bad late prognosis. The critical parameter of bad late prognosis in patients with EKG evidence of RBBB & LAH may be the history of transient post-operative CHB.

DILATATION OF THE MITRAL ANULUS: A RARE CAUSE OF MITRAL REGURGITATION

Bernadine H. Bulkley, MD; William C. Roberts, MD, FACC, National Heart and Lung Institute, National Institutes of Health, Bethesda, Md.

Many now believe that mitral anular dilatation is an infrequent cause of mitral regurgitation, but supportive studies for this belief are not available. To confirm or deny this concept, the mitral anulus was measured in patients with normal hearts and in patients with cardiac conditions associated with left ventricular dilatation with and without mitral regurgitation. The mitral anulus measured 8.0-10.5 (average [avg] 9.0) in 15 normal hearts, 9.0-12.0 (avg 11) in 20 hearts with primary myocardial disease, 9.0-13.0 (avg 11) in 10 hearts with pure mitral regurgitation due to abnormalities of leaflet or chordae tendineae, and 9.5-13.0 (avg 11) in 10 hearts with pure aortic regurgitation without mitral regurgitation. The mitral anulus in 3 patients with the Marfan syndrome without mitral regurgitation measured 8, 10, and 12 cm respectively, and in 3 patients with mitral regurgitation, 15, 15, and 17 cm. Although the mitral anulus was dilated about 20% greater than normal in patients with primary myocardial disease, and with pure aortic regurgitation and with pure mitral regurgitation, no difference in anular size between patients with and without mitral regurgitation was observed. Hence, mitral regurgitation in patients with left ventricular cavity dilatation is not due to mitral anular dilatation. An exception is the patients with the Marfan syndrome in which the mitral anulus associated with mitral regurgitation was nearly twice normal size, and also larger than in Marfan patients without mitral regurgitation. Thus, disease of the fibrous skeleton of the heart may be necessary for mitral anulus to dilate enough to cause mitral regurgitation.

EFFECTS OF NOREPINEPHRINE ON HIS ELECTROGRAMS IN THE DENERVATED HUMAN HEART

David S. Cannom, M.D., John S. Schroeder, M.D., F.A.C.C., Donald C. Harrison, M.D., F.A.C.C., Cardiology Division, Stanford University School of Medicine, Stanford, CA

The effects of norepinephrine (NE) on atrioventricular conduction determined with His bundle electrograms were studied in four patients one to three years after cardiac transplantation. Baseline A-H and H-V times were normal. NE, 4 to 8 μg/min, was infused to produce a rise in arterial pressure, while atrial donor rate, atrial recipient rate, A-H and H-V times were monitored. Concomitant with an average increase of 72 mm Hg in arterial pressure, atrial recipient rate slowed by an average of 23 beats/min, while the atrial donor rate increased by an average of 32 beats/min. The A-H interval decreased by an average of 27 msec; the H-V interval did not change. After propranolol (7 mg in two patients), NE infusion increased atrial donor rate by only 7 beats/min; A-H time did not change, but comparable increases in arterial pressure occurred. Our studies show: 1) the transplanted sinus and atrioventricular nodes are responsive to NE; 2) denervation hypersensitivity to NE was not seen; 3) the beta adrenergic effects of NE are blocked by propranolol, while the alpha effects are not; 4) the transplanted heart does not respond to reflex baroreceptor stimulation with increased arterial pressure, while the recipient atrium slows appropriately, demonstrating no evidence for reinnervation.

MANAGEMENT OF THE VENTRICULAR SEPTAL DEFECT IN TRANSPOSITION

C. Carpena, M. D., S. Subramanian, M.B., F.R.C.S.
Children's Hospital, Buffalo, New York

Forty-four patients who have undergone correction of Transposition of the Great Arteries complicated by Ventricular Septal Defect with or without pulmonary stenosis are reviewed. All except 13 were operated on with surface induced deep hypothermia and circulatory arrest. In 30 patients, the ventricular defect was closed through a right atriotomy, in 11 patients through a right ventriculotomy, and in two patients with muscular defect, through a left ventriculotomy. In one, the defect was closed through a pulmonary arteriotomy. The advantages of avoiding an incision in the systemic ventricle are emphasized.

Analysis of the results indicate that primary definitive repair of TGA with VSD and pulmonary artery hypertension is inferior (33% mortality) compared to early banding followed by early debanding and primary correction in the first year of life (0 mortality). Late debanding and correction carries a higher mortality and morbidity due to the technical difficulties associated with the band and the post-operative pulmonary problems due to extensive bronchopulmonary collaterals.

It is recommended that early banding should be followed by early debanding in this group in infancy and that the ventricular defect be closed without right ventriculotomy.

CLINICAL EXPERIENCE WITH AN IMPLANTED RECHARGEABLE TRANSVENOUS PACEMAKER

Robert D. Chambers,MD; Ronald J. Nelson, MD; James Beazell, MS; J. Michael Criley, MD, FACC; Harbor General Hospital, Torrance, California

Rechargeable battery powered fixed rate or demand pacemakers were implanted in 9 patients with symptomatic bradycardia, with or without heart block. The double hermetically sealed generator is 21% smaller and 27% lighter than any other available pacemaker, and is recharged by the patient using a portable external charging coil at home for 90 minutes weekly. A telemetry feedback loop confirms the charging current input to the implanted Ni-Cd batteries. In the event of a deficient charge, a gradual slowing in rate would be observed. The bipolar electrode readily screws without tools or adhesives into the generator casing providing 10,000 p.s.i. of electrode contact. These units continue to function normally after 2 years in dogs with experimental complete heart block and in 35 patient-months (longest implant 6 months) of clinical use. Three of the patients had prior experience with one or more conventional mercury battery generators and have stated a preference for the new unit. Rate and rhythm are monitored weekly by telephonic ECG transmission and no malfunction or decline in rate has been observed in any patient including one who did not charge the unit for 4 weeks.

The advantages of this pacemaker system include: (1) small size and light weight, (2) rapidly achieved secure electrode connection, and (3) anticipated function for over 10 years (based on accelerated in vivo testing).

DIPHENIDOL A NEW AGENT FOR THE TREATMENT OF DIGITALIS-INDUCED ARRHYTMIAS, IN MAN.

Felipe A. Cereña S., MD, Medical Services Issste-Son., University Of Sonora, Hermosillo, Son., México.

Diphenidol, a new antiemetic agent, has been shown to be effective in treating arrhytmias secondary to digitalis intoxication, exerting it's action through a shortening of the prolonged A-H time, and suppressing the enhanced ventricular automaticity. In a group of 30 patients with varied cardio-vascular pathology, and digitalis-induced ventricular arrhytmias, Diphenidol was given in a dose of 0.5 mg/kg intravenously; in the 30 patients, the return to sinus rhythm occurred in 5 to 15 minutes after the administration of the drug. In 3 patients the arrhytmia returned 3 hours after the initial dose, and the return to sinus rhythm was acomplished through a second similar dose of Diphenidol, in 5 to 15 minutes. Hemodynamic studies in these patients corroborated that the administration of Diphenidol in a dose range of 0.5 to 8.0 mg/kg had no significant effect on: Cardiac Index (liters/min/m^2) Initial: 2.8, after 10': 2.6; Total Peripheral Resistance (dynes/sec/cm^{-5}) Initial: 1930, after 10': 2200; Mean Arterial Pressure (mm. Hg) Initial: 98, after 10': 96; Stroke Index (ml/beat/m2) Initial: 30.7, after 10': 32.7; Heart Rate (beats/min) Initial: 170, after 10': 135. Diphenidol showed a significant effect on shortening the A-H time (-25.6 $\pm$ 6 percent) already prolonged in the digitalis toxic state.

MULTIPURPOSE FLOTATION ELECTRODE CATHETER - A NEW CATHETER FOR ARRHYTHMIA AND INTRACARDIAC PRESSURE MONITORING

Kanu Chatterjee, MB, FACC; H.J.C. Swan, MD, Ph.D., FACC; William Ganz, MD, C.Sc, FACC, Richard Gray, MD, John Albus, BS, Cedars-Sinai Medical Center, Los Angeles, California.

A balloon tipped flotation catheter (5F) and two sets of platinum electrodes positioned at 11 and 12 cm, and 25 and 26 cm from the tip has been designed for recording intracavitary electrograms and monitoring pulmonary vascular pressures. The multipurpose flotation electrode catheter (MFEC) has been evaluated in 29 patients and the results demonstrate that: (1) The catheter can be passed easily at the bedside without fluoroscopy by monitoring either the intracavitary electrogram or the intracardiac pressure; (2) With the catheter tip stabilized in the pulmonary artery or its branches and measuring pulmonary artery pressure, the distal and proximal electrode pairs record simultaneously, right ventricular (RV) and right atrial (RA) bipolar electrograms, respectively. Such electrograms with appropriate filters (RV 15-300 Hz, RA 50-300 Hz), in contrast to surface electrocardiogram, do not show baseline shift, are virtually free of respiratory variation and artifacts due to patient movement and the signal to noise ratio is approximately 100:1; and (3) Reliable atrial pacing (threshold < 3 ma) was visible in the majority of patients. Ventricular pacing but at high threshold could be achieved in only a few patients. The catheter provides a simple means not only for monitoring intracardiac pressures but also for obtaining artifact free, clear, simultaneous RA and RV cavity electrograms for diagnosis of cardiac arrhythmias and suitable for online computer monitoring.

HEMODYNAMIC STUDIES OF SEQUENCED AND NON-SEQUENCED EXTERNAL COUNTERPULSATION

Lawrence S. Cohen, MD, FACC; Rene Langou, MD; Steven Wolfson, MD, FACC; Dean Porterfield, BS; Jere H. Mitchell, MD, FACC, Yale U. Sch. of Med., New Haven, Ct.

External counterpulsation, using sequential (S) inflation of pressurized leg cuffs (first distally and then proximally), was compared to simultaneous non-sequenced (NS), inflation of the cuffs. Six patients were studied during diagnostic cardiac catheterization, four with documented coronary artery disease, two with normal coronary vessels.

Central aortic (Ao) and left ventricular pressures (mm.Hg.), and cardiac output (CO) in L/min., were measured in the control (C), non-sequenced, another control and sequenced states. Non-sequenced and sequenced were each compared to their own control measurements.

	HR	Syst. Ao.	Diast. Ao.	Peak Diast.Ao.	Mean Ao.	CO
C	69±4	118±5	72±2	80±3	90±4	4.8±.6
NS	69±4	115±8	73±4	108±5*	94±5	5.0±.4
C	68±3	116±6	72±3	80±3	89±4	4.8±.4
S	67±3	113±7	73±4	111±5*	96±4	5.5±.5**

*p < 0.0005 **p < 0.005

The rise in CO with non-sequenced pulsation was not significant (p < 0.4). The rise in CO with sequenced pulsation was significant (p < 0.005). Peak diastolic augmentation and left ventricular end-diastolic pressure was equivalent in both modes of counterpulsation. Sequential counterpulsation leads to a greater increase in CO than does non-sequenced, presumably through more efficient augmentation of venous return.

EFFECT OF CLOFIBRATE ON PROGRESSION OF CORONARY DISEASE: A PROSPECTIVE, ANGIOGRAPHIC STUDY IN MAN

Keith Cohn, MD, FACC; Manly Langston, MD, Pacific Medical Center, San Francisco, California

Lowering blood lipids has been invoked as a means of controlling future coronary events. In this prospective study, the effect of a lipid-reducing agent clofibrate (CL, 2g daily) on extent of coronary artery (CA) disease was investigated. Forty pts, 31 having aortocoronary bypass, 7 having Vineberg operations, 2 having neither, were placed double-blind in placebo (PL, 24 pts) and CL (16 pts) groups, and restudied by selective coronary angiography one year later. An additional 24 pts dropped from the study, due to adverse drug reactions in 6. Each pt's right, left, anterior descending, and circumflex CAs (with their branches) were separately rated according to degree of obstruction. The CL group showed a significantly greater fall in triglyceride than PL group (-13.7% vs +2.3%; P=.45). In the CL group, 19 of 64 CAs (29.6%) showed progressive coronary narrowing, not significantly different from the PL group (24 of 96 CAs, 25%, narrowed; P=.26). No significant differences between drug groups emerged when the data were corrected for degree of fall of blood lipids, initial lipoprotein type, or effect in bypassed vs nonbypassed vessels (P always > .2). Regression of CA disease was not seen. We conclude that CL did not significantly influence the rate of progression of coronary artery disease in a one-year period.

CORONARY STEAL: ROLE IN DETRIMENTAL EFFECT OF ISOPROTERENOL FOLLOWING ACUTE CORONARY OCCLUSION.

Michael V. Cohen, MD; Edmund H. Sonnenblick, MD, FACC; Edward S. Kirk, PhD, Peter Bent Brigham Hospital, Boston, Mass.

Using epicardial electrograms others have established that Isoproterenol (Iso) infusion increases myocardial injury after acute coronary (cor) occlusion. To define the contribution of alterations in collateral blood flow to this increased ischemia, we have administered Iso to 10 dogs. After pretreatment with practolol in doses which successfully block inotropic but not vascular effects of β stimulants, intracoronary (IC) Iso continued to enhance the magnitude of S-T elevation in ischemic areas. Thus, vasodilation induced by Iso appears to divert flow from the ischemic area. To test this hypothesis IC adenosine (Ad) was given to cause cor vasodilation without enhancing inotropy. S-T elevation at ischemic and adjacent sites was significantly increased. Addition of IC Iso to the Ad infusion increased inotropy without further increasing cor flow, and was accompanied by evidence of greater myocardial ischemia. Neither agent had systemic effects, but each increased cor blood flow while concomitantly decreasing collateral flow as evidenced by a fall in cor pressure distal to the ligature and retrograde flow. In addition Ad significantly diminished the rate of ^{133}Xe clearance from the ischemic myocardium. Thus, Iso increases myocardial injury by two mechanisms. The observed increase is partly related to its positive inotropic effect. Moreover, cor steal itself also significantly aggravates ischemia by diminishing collateral blood flow to acutely ischemic myocardium. Intravenous Iso additionally diminishes collateral flow by decreasing cor perfusion pressure. It is postulated that any agent which causes either a primary or secondary cor vasodilation may cause a cor steal and subsequently enhance myocardial injury.

LOCALIZATION, DETECTION AND SIZING OF MYOCARDIAL INFARCTION WITH TECHNETIUM-99m-TETRACYCLINE AND ELECTROPHYSIOLOGIC TECHNIQUES

Guillermo A. Cook, MD; B. Leonard Holman, MD; Nelson Westmoreland, PhD; John V. Temte, MD, PhD; Franklin Zweiman, MD; Bernard Lown, MD, FACC, Harvard School of Public Health, Boston, Mass.

Electrophysiologic data were correlated with Technetium-99m-Tetracycline (^{99m}Tc-TC) concentration and histopathology. Suction electrode recordings of monophasic action potentials (MAP's) and epicardial electrocardiography (EE) were used to map the location and site of myocardial infarction (MI). MI was produced in 18 mongrel dogs by external occlusion (EO) (11 animals) or embolization (EB) (7 animals). ^{99m}Tc-TC was injected IV 24 hr (EO) and 40 hr (EB) post-occlusion and studied 24 hr (EO) and 8 hr (EB) later. In normal areas the EE showed Rs complexes with inverted T waves. The MAP's had a normal configuration with an amplitude of 52 ± 6 mA. In infarcted areas EE showed QS, Qr, or 2-3 mm ST segment elevation. MAP's showed either an isoelectric line, an electrogram, or decreased amplitude (11 mA ± 5) with increased ratio of phase 0 to phase 2 amplitudes and a "hump" or prolongation of phase 3 repolarization. There was excellent correlation between MAP, EE, and ^{99m}Tc-TC concentration for sizing and locating the MI in 17/18 dogs. In 1 dog the ^{99m}Tc-TC concentrated in a small area of myocardium (1%) while electrophysiological studies were normal. In tissue samples taken from an area that appeared from ^{99m}Tc-TC and electrophysiological mapping to be infarcted, the electron microscopic examination also revealed an infarct. Microscopic examination showed small cellular areas of damage in two hearts that appeared normal by electrophysiological and isotopic studies. MAP's, EE, and ^{99m}Tc-TC mapping accurately size and localize areas of MI.

ECHOCARDIOGRAPHIC EXAMINATION OF THE ANTERIOR LEFT VENTRICULAR WALL IN PATIENTS WITH CORONARY ARTERY DISEASE.

Betty C. Corya, MD; Harvey Feigenbaum, MD, FACC; Susan Rasmussen, RN; Mary Jo Black, BA; Krannert Institute of Cardiology, Indiana University School of Medicine, Indianapolis, Indiana.

Previous studies have demonstrated segmental changes in the echocardiographic motion of the interventricular septum (IVS) and posterior left ventricular wall in coronary artery disease (CAD). Moving the transducer laterally 2-3 inches from where the mitral valve, right (RV) and left ventricles (LV) are recorded, the IVS is crossed and the anterior RV wall becomes the anterior left ventricular wall (ALV). The ALV was recorded in 50 of 54 consecutive patients having coronary arteriography. Twelve patients were normal and 42 had CAD ($\geq$ 50% obstruction). Abnormal ALV motion (flat or anterior motion during systole) was noted in 21 patients. Twenty of these patients had CAD, with 18 patients having left anterior descending artery (LAD) lesions. One patient had an isolated right coronary artery (RCA) obstruction, and one had a RCA and left circumflex lesion. In 14% of the patients with CAD (6 of 42), the ALV was the only area of the LV echogram which demonstrated abnormal motion. This echocardiographic technique offers the examination of another area of the LV which is frequently affected by CAD and should be particularly useful in patients with LAD lesions.

SUSTAINED LOSS OF MYOCARDIAL NOREPHINEPHRINE AFTER RELIEF OF CONGESTIVE HEART FAILURE

Richard L. Coulson,Ph.D.; Shahriar Yazdanfar,MD; Alfred A. Bove,MD; James F. Spann,MD,FACC; Temple University, Philadelpia, Pa.

It is not known if the depletion of cardiac norepinephrine (NE) stores which accompanies pressure overload hypertrophy and congestive heart failure (CHF) is reversed following relief of CHF. Right (RV) and left (LV) ventricular NE stores were evaluated in 3 groups of cats:4 controls, (C); 5 with CHF due to 13 days of pulmonary constriction, (F); and 5 studied 32 days after relief of a 13 day period of CHF due to pulmonary constriction, (R).

	Control	CHF	Recovery
Heart rate, beats/min	234±13	196±16	234±13
Cardiac output/ml/min/Kg	68.9±.23	47.9±1.0	72.8±2.2
Systolic pressure mmHg	199±10	154±7	180±9
Diastolic pressure mmHg	150±7	115±7	139±7
RV systolic pressure mmHg	36.1±2.5	77.1±4	32±3.3
RV end diastolic pressure	3.25±2.5	14.9±1.4	2.58±57

RV wieght increased from C=0.52±4g/Kg to F=1.14±.08 ($p<0.01$) and following relief did not recover (R= 0.78±.08). LV weight remained relatively constant (C= 2.06±.15g/Kg,F=2.4±.08,R=2.56±21,p 0.1). NE was reduced from the control value of 1.42±29ug/g (RV) and 1.35±.33 (LV) to 0.08±.02 (RV) and 0.72±.08 (LV) in F, and remaind low in R,0.27±.09 (RV) and 0.63±.12 (LV) despite relief of CHF. Thus the cardiac adrenergic defect of congestive heart failure is not relieved by abolition of the pressure overload and resultant hemodynamic abnormalities. Further, it is suggested that, the persistence of NE depletion does not result from hypertrophic structural changes since reduced catecholamine levels continued in the left ventricle which did not hypertrophy.

HEMODYNAMICS AND MYOCARDIAL METABOLISM ABNORMALITIES IN FRIEDREICH'S ATAXIA

Michel Côté, M.D.; Ghanem Elias, M.D., Hôpital Maisonneuve-Rosemont, Montréal, Canada.

Nine patients (pts), 9 to 40 yrs old (average 22 yrs) suffering from Friedreich's Ataxia (F.A.) were studied during right and left heart catheterization and had left ventricular angiograms. Coronary sinus and arterial determinations of lactate were performed at rest in 7 pts and also during pacing in 6 pts. At rest, a left intraventricular systolic gradient (V.S.G.) was noted in 1 pt (78mmHg). 5 pts were also studied during isoproterenol infusion: a right V.S.G. appeared in all 5 pts (range 12-28mmHg) and a left V.S.G. in 2 pts (20 and 22mmHg). The end diastolic volume index was 48.9 ml/M^2 (range 28.8 - 75.5) and ejection fraction 77.7% (range 49-90%). L.V.E.D.P. was 15.1mmHg ±2.2 at rest, did not change significantly during pacing 13.2mmHg ±4.8 but was 20.5mmHg ±5.3 ($P<0.025$) after left ventricular angiography. Left ventricular stroke work index was 35.5Kgm/beat/M^2 ±8.2 at rest and 18.5 ±8.5 ($P<0.01$) during pacing. The mean rate of circumferential fiber shortening ranged from 0.6 to 3.1 circ./sec. The mean myocardial lactate extraction was 34.5% ±12 at rest (with less than 10% extraction in only one pt) and 16.8% ±14.1 ($P<0.025$) during pacing (with production in 4 of 6 pts). The mean O_2 extraction was 47% ±11 at rest and decreased to 30% ±13 ($P<0.01$) during pacing. The hemoglobin-O_2 dissociation curve was shifted to the left in 5 of 8 pts (P50 range 22.5 - 25 mmHg). The angiograms of all these pts demonstrated the hypertrophic nature of the cardiomyopathy in F.A. with or without significant outflow obstruction. 5 of 7 pts, either at rest or during pacing, had evidence of myocardial anaerobic metabolism associated with an increased hemoglobin affinity for O_2 and an abnormally low myocardial O_2 extraction.

COMPARATIVE EFFECTIVENESS OF EXERCISE TESTING AND HOLTER MONITORING FOR DETECTING ARRHYTHMIAS IN PATIENTS WITH PREVIOUS MYOCARDIAL INFARCTION

Michael Crawford, MD; Robert O'Rourke, MD, FACC; Nallan Ramakrishna, MD; Hartmut Henning, MD; John Ross, Jr., MD, FACC, University of California, San Diego, California

To detect arrhythmias requiring therapy, we studied 50 patients (pts) three to 44 months following myocardial infarction by both submaximal treadmill exercise testing (TE) and 10 hours of continuous ECG monitoring (HM) during normal activity. Fourteen pts (28%) had an enlarged left heart dimension on ECG-triggered x-ray ($>52mm/M^2$). In 23 pts (46%) significant arrhythmias were detected (ventricular tachycardia, atrial tachyarrhythmias, $>$ 2 PVCs/min on TE or $\geq$ 1 PVC/500 cycles on HM). Fourteen pts (28%) had frequent ectopic beats during or within 15 minutes after TE and 18 pts (36%) had significant arrhythmias during HM. In nine pts (18%) HM detected significant arrhythmias when TE did not, while in five instances (10%) frequent PVCs were present with TE but not during HM. In five of nine pts in whom both tests were positive, HM detected serious arrhythmias such as ventricular tachycardia when TE showed only isolated PVCs. Eight pts (16%) had one or more PVCs on resting ECG and all had significant arrhythmias detected by TE and/or HM; five pts were in NYHA Class III and all had significant arrhythmias. The presence of arrhythmias did not correlate with patient age, history of palpitation, left heart dimension, duration of follow-up, site of infarction by ECG, or development of angina or ST depression during TE. We conclude that both TE and HM are required for complete arrhythmia detection in post myocardial infarction pts and that HM often discloses different and more serious arrhythmias than TE.

DISSECTION OF THORACIC AORTA:MEDICAL OR SURGICAL THERAPY?

James E. Dalen, Joseph S. Alpert, Lawrence H. Cohn, Harrison Black and John J. Collins Jr., Peter Bent Brigham Hospital, Boston, MA

In a 10 year period, at the Peter Bent Brigham Hospital (1963-1973) dissection of the thoracic aorta was diagnosed by aortography, surgery, or postmortem examination in 45 patients (pts). Indications for surgical or medical therapy varied during this decade reflecting the shifting therapeutic concepts of this period. The pts were reviewed to assess the results of therapy (Rx) and to critically reassess the indications for surgery in this disease.

Dissection originated in the ascending aorta (DAA) in 31 pts. Twenty-one of these pts had primary surgical Rx; 16 (76%) survived; 12(57%) were alive and well (A/W) at follow-up. Of 10 pts with DAA who did not have surgical Rx, 3 (30%) survived and only 1(10%) was A/W at follow-up. Of 14 pts with dissection of the descending aorta (DDA), primary Rx was medical in all 14, and was successful in 6(43%) who were A/W at follow-up. In 8 pts DDA progressed despite medical Rx and surgery was required. Only 2(25%) of these pts survived.

Analysis of all cases revealed that at the time of admission 21(68%) of the 31 pts with DAA had one or more of the following absolute contraindications to medical Rx: hemopericardium (9), new AI with CHF (10), jeopardized carotid or coronary arteries (4) or systolic pressure<120 mm Hg with documented prior hypertension (4). However, no pt with DDA had a contraindication to medical Rx at the time of admission.

Thus, in a 10 year period at this hospital medical Rx was contraindicated in 21 of 31 pts with DAA, and was unsuccessful in 8 of 10 pts in whom medical Rx was even feasible. We conclude that the appropriate Rx for DAA is surgical. In pts with DDA, medical Rx is usually feasible and at times successful.

IDENTIFICATION OF CRITICAL CORONARY ARTERY LESIONS BY SUBMAXIMAL EXERCISE TESTING

James E. Davia, MD, Emile Barrow, MD, Carlos de Castro, MD, and Melvin D. Cheitlin, MD, FACC, Walter Reed Army Medical Center, Washington, D. C.

Increased mortality rates in patients with coronary artery disease (CAD) have been associated with both the magnitude of ST segment depression in post-exercise electrocardiograms and the presence of certain severe obstructive lesions, e.g. in the main left coronary artery (MLCA) or proximal left anterior descending (LAD) artery. In an attempt to identify the subgroup of CAD patients who have critical lesions, all patients who had 2 mm or more ischemic ST depression (ISD) on standard treadmill tests and who had coronary arteriography were evaluated. 37 patients met these criteria. 9/37(24.3%) patients had MLCA lesions 75% or more of the lumen diameter. Another 9/37(24.3%) had the equivalent of MLCA lesions, i.e. 75% or greater in both LAD and left circumflex (LCx) arteries proximal to any branches. Another 9/37(24.3%) patients had 75% or greater occlusion of the LAD proximal to the first major branch. Thus, of patients with 2 mm or more ISD on treadmill testing 18/37 (48.6%) had either critical MLCA or MLCA equivalent lesions and a total of 27/37(73%) had critical lesions. 22/27(81%) patients with critical lesions were considered operable on the basis of favorable anatomy. The magnitude of ST segment depression did not correlate with the severity of angina pectoris. Our data suggest that ISD 2 mm or greater indicates a high probability of critical coronary lesions. These patients should be considered for coronary arteriography in order to identify critical lesions that are potentially amenable to bypass surgery.

ANTIARRHYTHMIC EFFECTIVENESS OF 17,21-DI-MONOCHLORO-ACETYL-AJMALINE: HEMODYNAMIC AND METABOLIC STUDY

Marina Dalmastro, M.D.; Tzu-Wang Lang, M.D., FACC; Steven Rubins, M.D.; Costantino Costantini, M.D.; and Samuel Meerbaum, Ph.D., FACC

Cedars-Sinai Medical Center, Los Angeles, California

A study was designed to evaluate the antiarrhythmic effectiveness of 17,21-di-monochloroacetyl-ajmaline (DCAA).

Twenty dogs which received a digitoxic dose of 0.15 mg/Kg (I.V.) exhibited serious arrhythmias leading to a mortality of 60% (LD_{60}). Ten other dogs were treated with DCAA (1.74 mg/Kg) following digoxin LD_{60}. Serious digitalis-induced arrhythmias were abolished by DCAA in eight out of the ten dogs. Treatment decreased the mortality rate to 20%.

In another series of dogs, hemodynamic and metabolic function were measured prior to and following digitalis LD_{60}, and after administration of DCAA. Digitalis-induced tachyaarhythmias were accompanied by a reduction in systemic pressure, cardiac output and stroke work; abnormal myocardial lactate metabolism; and significant potassium loss. His bundle recordings revealed abnormal A-V conduction. Administration of DCAA usually converted the arrhythmias and normal A-V conduction usually was restored. Hemodynamic and metabolic studies revealed DCAA did not depress cardiac function. Coronary sinus flow increased after DCAA. Metabolic measurements revealed improved myocardial lactate balance and reduced oxygen extraction, but potassium balance remained unchanged. DCAA is an effective antiarrhythmic agent. It significantly reduced digitalis LD_{60} mortality rate and did not depress myocardial function.

COFFEE AND CORONARY HEART DISEASE

Thomas R. Dawber, MD; William B. Kannel, MD, FACC; Tavia Gordon, Boston University Medical Center, Boston, Ma.

A study was conducted utilizing the data from 18 years of follow-up in the Framingham Study to determine the relationship between coffee consumption and coronary heart disease (CHD). Coffee consumption was determined at the fourth biennial examination. A follow-up period of 12 years permitted a study of the relationship between coffee consumption (from none to 7+ cups per day) and the subsequent development of CHD. The association between coffee consumption and other risk factors, including cigarette smoking, was also investigated. Coffee consumption was studied in relation to: total CHD, angina pectoris, myocardial infarction, sudden death, other deaths from CHD, and death from all causes. No statistically significant relationship was found between coffee intake and these clinical categories except for "death from all causes" in which an increase in risk was observed with increasing coffee consumption. Further study showed that this relationship could be accounted for by the association between coffee consumption and cigarette smoking. It was concluded that coffee consumption, as engaged in by the general population, is not a factor in the development of CHD nor any of its manifestations.

CORONARY VENOUS INOSINE AS A METABOLIC INDICATOR OF MYOCARDIAL ISCHEMIA

Jan Willem de Jong, PhD, Sidney Goldstein, MD, FACC, Dept. Biochem. I and Thoraxcenter, Med. Faculty, Erasmus University Rotterdam, The Netherlands

During regional ischemia (Isch) changes in concentration of coronary vein inosine (I) and hypoxanthine (HY), catabolites of adenosine, and lactate (L) and potassium (K) were compared in 14 open-chest pigs. A fixed decrease in coronary blood flow from 46 ± 5 (SE) ml/min to 13 ± 2 ml/min was produced with a screw clamp and flow probe around the left anterior coronary artery. Regional venous blood was obtained from a local anterior coronary vein simultaneously with arterial samples. The mean of 3 serial 2-min values of I, HY, L and K during a control and Isch period were compared. During Isch, I increased from 10.9 ± 0.7 μM to 18.5 ± 1.8 μM ($P<0.001$); HY increased from 29.2 ± 1.5 μM to 33.0 ± 1.5 μM ($P<0.05$). Mean concentration of K and L and arterial concentration of all the substances did not change significantly. Within 2 min of Isch, however, K increased from 3.77 ± 0.10 mM to 4.16 ± 0.14 mM ($P<0.05$), but fell to control levels at 4 and 6 min. Percent L extraction changed from 42.6 ± 6.7% to -4.6 ± 12.5% ($P<0.005$) during Isch. These data indicate that I and HY concentration increases in the venous effluent of the Isch myocardium associated with changes in percent L extraction. Of the four compounds studied I is the most sensitive indicator of myocardial Isch.

THE SHORT-TERM PROGNOSTIC VALUE OF H-V INTERVAL IN PATIENTS WITH BIFASCICULAR BLOCK

Pablo Denes, MD; Ramesh C. Dhingra, MD; Ruben Chuquimia, MD; Delon Wu, MD; Fernando Amat, MD, Kenneth M. Rosen, MD, FACC, University of Illinois, Chicago, Ill.

Electrophysiological studies have been performed in 119 adults with chronic right bundle branch block and left axis deviation (-30° to -180°). H-V interval (normal 35-55 msec) was normal in 86 patients (NHV) and prolonged in 33 (PHV). PHV and NHV patients did not differ significantly in regard to age or sex. The following clinical variables were more frequent ($P<0.05$) in patients with PHV: Cardiac third sound (PHV vs NHV) 8/33 (24%) vs 5/86 (6%), holosystolic murmurs 12/33 (36%) vs 11/86 (13%), cardiomegaly on X-ray 24/33 (73%) vs 41/86 (49%), congestive heart failure 16/33 (48%) vs 19/86 (22%), and functional class (NYHA) III or IV 9/33 (27%) vs 3/86 (3%). All patients were prospectively followed in a conduction clinic at one to two monthly intervals after initial electrophysiological evaluation. Mean duration of follow-up was 279 ± 39 days in PHV patients and 316 ± 30 days in NHV patients. Documented second or third degree block distal to H developed in only 2 patients (1 PHV and 1 NHV). Mortality was analyzed using life table methods. One and two year cumulative survival in the PHV group was respectively 83.6% and 61.3% as compared to 85.8% and 81.3% in the NHV patients. The higher mortality ($P<.01$) at two years in the PHV patients primarily reflected progression of myocardial disease and not sudden death. In summary, prolonged H-V interval in patients with bifascicular block was often associated with serious myocardial dysfunction and a high mortality. The risk of progression of conduction disease was slight in bifascicular block patients with either PHV or NHV, during this relatively short follow-up period.

SURVIVAL IN LEFT MAIN CORONARY ARTERY DISEASE: THE ROLE OF CORONARY ANGIOGRAPHY, COEXISTING CORONARY ARTERY DISEASE, AND REVASCULARIZATION

Henry DeMots, M.D., Josef Rösch, M.D., Lawrence I. Bonchek, M.D., Richard P. Anderson, M.D., Albert Starr, M.D., FACC, and S.H. Rahimtoola, M.D., FACC.
University of Oregon Medical School Portland, Oregon

The assumption that left main coronary artery (LMCA) stenosis is the lethal factor in patients (pts) in whom it occurs has not been scrutinized. The role of direct revascularization (DR), the risk of coronary arteriography (CA) and the relative merits of different techniques of CA have been incompletely elucidated in these pts. Among 2100 pts studied by Judkins' technique (JT) there were 20 with 50 to 70% and 28 with 71 to 95% narrowing of LMCA luminal diameter. One death occurred 3 days after CA. No clinical parameter allowed reliable prediction of LMCA disease. Coexisting disease was found in 3 vessels in 21 pts, in 2 vessels in 16, in 1 vessel in 9, and in no other vessel in 2. Six of 10 pts judged inoperable by current criteria were dead within 16 months (mos). Of 16 patients judged operable, in retrospect, but treated without surgery, 8 were dead within 18 months (mos). The remaining 8 have survived 5 to 69 mos (mean 41 mos). There were one operative death and 2 late deaths among 16 pts treated with DR since 1970. While non-surgical survivors were functionally unchanged, each survivor in the DR group improved. Survival was not related to the severity of LMCA stenosis in any group.

We conclude that pts with LMCA disease cannot be identified before angiography but can be studied at low risk with JT. Prognosis in LMCA disease resembles that reported in 3 vessel disease alone. Analysis of angiographic data, including sequential angiograms in 15 pts, indicates that the major determinant of the poor prognosis in LMCA disease is the amount of coexisting disease. The extent of distal disease precludes surgery in 20% of pts but DR offers symptomatic benefit and may prolong life in the remainder.

FACTORS PREDISPOSING TO VENTRICULAR TACHYCARDIA IN ACUTE MYOCARDIAL INFARCTION

Neil deSoyza, MD; James Kane, MD; Joe Bissett, MD; Marvin Murphy, MD, FACC, James Doherty, MD, FACC, VA Hospital-Univ. of Ark., Little Rock, AR.

In experimental myocardial infarction (MI), factors predisposing to ventricular tachycardia (VT) include frequent premature ventricular contractions (PVC's) and the R on T phenomenon. The purpose of this study was to identify the features associated with VT in acute MI in man. Twenty-four hour Holter monitoring was performed within 24 hours of the acute MI in 35 consecutive patients with measurement of: (1) incidence of VT (3 or more PVC's at a rate > 100 beats per minute), (2) total number of PVC's per 1000 normal beats, (3) coupling interval (CI) of beats initiating VT versus CI of PVC's in patients without VT, (4) prematurity index (PI) (coupling interval divided by QT interval of sinus beat), and (5) incidence of slow VT (<100 beats per minute). Seventy-one episodes of VT were documented in 18 patients; 17 patients had no VT. There was no significant difference in the anti-arrhythmic therapy of the two groups. Results are shown below.

	Mean CI (SEC)		Mean PI		Slow VT ($P<0.01$)
VT	0.61 ± 0.16	NS	1.50 ± 0.31	NS	10/18 patients
No VT	0.55 ± 0.15		1.46 ± 0.30		2/15 patients

The median number of PVC's in the VT group (5.1 per 1000 normal beats) was significantly greater than that in the group without VT (0.8 per 1000 normal beats); $P<0.01$. Contrary to previous reports the results show that the R on T phenomenon as measured by the CI and PI does not predict the occurrence of VT in acute MI. An increased frequency of PVC's and slow ventricular rhythms are clearly associated with an increased incidence of VT. These results demonstrate significant differences between the occurrence of VT in human MI and previous data obtained from experimental animals.

TRICUSPID ATRESIA: THE CLINICAL COURSE IN 96 PATIENTS. Macdonald Dick, M.D., Donald C. Fyler, M.D., Alexander S. Nadas, M.D., Children's Hospital Medical Center, Boston, MA.

The charts, electrocardiograms, catheterizations and angiographic data were reviewed in 96 patients with tricuspid atresia(TA); 46% (45/96) were female; 54% (57/96) were male; 38%(37/96) died in the first year of life; 4% (4/96) survived into the third decade. TA segregates into two therapeutic groups. Group A: TA with decreased pulmonary blood flow(↓PBF), accounting for 80%(77/90) of all TA. Type I TA(normally related great arteries) comprised 76% (59/77) of this group; 83% (49/59) received arterial shunts; 32%(16/59) died; 11%(7/59) received Glenn (G) anastomoses; 4/7 died; 16%(8/49) of the arterial shunts developed either congestive heart failure(CHF)(5) or pulmonary vascular obstruction(PVO)(3). However 16%(10/59) were not operated and all died. Type II TA (d-transposition of the great arteries) contained 16%(13/77) of this group; 7/13 received either arterial or venous shunts; 3/7 died (arterial shunts); 6/13 were not operated and all died. Type III TA (l-transposition of the great arteries) made up 6%(5/77) of this group; 4 received arterial shunts with 1 survivor. Group B: TA with increased (↑) PBF accounted for 20%(19/96) of patients with TA. Type I TA contributed 31%(6/19) to this group; all but one are alive (age 9 months-29 years). Type II TA contributed 53%(10/19) of this group; 5/10 developed pulmonary artery hypertension (PAH), 3/10 developed PAH with PVO. Type III TA made up 16%(3/19) of this group; 3 died in late adolescence all in CHF. Atrial arrhythmias (AA) developed in 7%(9/96) of patients; the arrhythmias were related to 1. catheterization(1), 2. L-TGA(3), and long standing CHF(3). None were lethal. This experience with TA indicates that surgical intervention in Group A, though necessary, has a high initial mortality(37%) and that those successfully shunted have a pattern of complications similar to Group B (CHF, PAH, PVO, AA).

INCREASED LONGEVITY WITH LOW OUTPUT (PROGRAMMABLE) PACEMAKERS - Doris J. W. Escher, MD,FACC; Seymour Furman, MD,FACC; Philip Hurzeler, Ph.D.; Montefiore Hospital and Medical Center, Bronx, NY.

In 14 months 61 Cordis Omnicor pulse generators (PG), 17 asynchronous (VA), 1 atrial (AS), 11 ventricular synchronous(VS), 32 ventricular inhibited (VI), have been implanted; 27 with new continuous coil electrodes (CCE) (0.08cm^2tip) and 36 on old electrodes-6 CCE, 12 2mm (2ME) (0.12cm^2tip), 15 4mm (4ME) (0.28cm^2tip) and 3 myocardial. The PG are noninvasively programmable to nominal rates (R) of 60, 65, 70, 80, 90, and 100 bpm (VS and AS to 80 only) and currents of 9(high), 6(med), 4(low) and 2.3 (test) mA by coded electromagnetic signals. With CCE, 2ME and 4ME at acute thresholds at approximately 0.4, 0.6 and 1.2mA respectively and chronic thresholds at 1.0, 1.5 and 2.2mA at 1msec pulses, all but 5 patients paced at test, 3 with new CCE but recent myocardial infarctions and 2 with old 4ME. Patients undergoing PG changes can be programmed immediately on the basis of twice the chronic threshold. New implants can be carried at low, medium or high for 1 month, and then programmed to low or test depending on anticipated threshold and programming trials. So far, 100% of our patients appear capable of being paced at low and 90% could be carried at test with a twofold margin of safety. This low threshold system allows temporary current increases post-implantation or injury with low later current drain and anticipation of 3 to 5 years of longevity, particularly with the VI where chronic current drain is only 6μA during total inhibition. Slower rates allow emergence of conducted rhythm and higher rates aid suppression of intruded beats. There have been 4 premature failures under 1 year - cause yet unknown.

THE EVOLUTION OF SECOND DEGREE BLOCK IN THE CANINE PROXIMAL HIS-PURKINJE SYSTEM

Nabil El-Sherif, MD; Benjamin J. Scherlag, PhD; Ralph Lazzara, MD; Philip Samet, MD, FACC, Mount Sinai Medical Center, Miami Beach, Florida

Second degree block (2^o) was studied in 36 anesthetized dogs with acute ischemia of the proximal His-Purkinje system (HPS) due to ligation of the anterior septal artery. Using recordings from the His bundle (Hb) and both bundle branches (BB), the block was localized in the Hb in 26 and in the proximal BB in 10. An increase of the H-V time from 30±5 to 46±4 msec occurred before 2^o block developed. The first stage of 2^o block was a Mobitz type II (Mob II) block in which beats preceding and following the blocked impulse showed a "constant" H-V interval (within the measurement error). In 28 dogs stage 1 merged into stage 2 of 2^o block with gradual increment of the H-V interval before block (Wenckebach arrangement-WA). The increment can gradually increase from a few msec up to 180 msec. In 20 dogs this stage advanced to complete (3^o) A-V block. In 10 dogs the heart was excised and the portion of the septum containing the Hb and BB were superfused and probed with intra- and extracellular electrodes. Purkinje cells in the Hb and very proximal BB displayed a time-dependent block on pacing with progressive conduction delay before failure of impulse transmission. The Hb-BB conduction time before and after the blocked impulse varied from 5 to 120 msec. Characteristic changes in action potentials with slow foot potentials and hump-like prolongation of the plateau were observed according to the state of transmission and site of maximum conduction delay. We conclude: 1) ischemic HPS conducts decrementally and reflects mainly time-dependent kinetics in contrast to the voltage-dependent kinetics of normal HPS; 2) Mobitz type II and WA are different stages of the same electrophysiological disturbance with Mob II representing the initial stages of decrement of conduction.

ECHOCARDIOGRAPHIC FEATURES OF ENDOCARDIAL CUSHION DEFECT

Eshagh Eshaghpour, MD; Howard B. Turnoff, MD; Benedict Kingsley, ScD; Joseph W. Linhart, MD, FACC, Hahnemann Medical College and Hospital, Philadelphia, Pa.

Five patients with endocardial cushion defect (ECD) were studied by echocardiography to establish the precise characteristics of their ultrasonic waveforms. Diagnosis was confirmed at surgery and/or by angiocardiography in 4 patients. Clinical, ECG, and X-ray findings were compatible with ECD in the other patient. The reproducible echo waveforms for each patient demonstrate the following features of ECD:

1. Multiple echo deformities in late diastole and early systole and a "break" in upstroke of mitral valve echo represent the cleft of the anterior leaflet of the mitral valve.
2. Rapid slope and large excursion of the mitral valve echo and large "v" waves of the posterior left atrial wall denote mitral insufficiency.
3. Paradoxical motion of the interventricular septum (IVS) with late systolic anterior motion of mitral echo indicate right ventricular diastolic overloading.

The study was repeated in one pt. postoperatively. All abnormal features of the echo waveforms were normalized except the paradoxical motion of the IVS. One pt. was studied six years after surgical closure of a primum ASD and suture of a cleft mitral valve. Echo deformities suggesting a cleft mitral valve and valvular insufficiency were present. Severe mitral regurgitation and a cleft mitral valve were found on selective left ventriculography confirming the postoperative breakdown of his mitral valvular repair as indicated by echo.

This study identifies the echocardiographic features of ECD and their value as an adjunct in clinical diagnosis and postoperative assessment.

THE VALUE OF HOLTER MONITORING IN ASSESSMENT OF CARDIAC ARRHYTHMIAS IN SYMPTOMATIC PATIENTS

Jaime Espinoza,MD, Larry Cohen,MD,Michael Motro,MD,Janet Lipski,MD,Ephraim Donoso,MD,FACC, and Simon Dack,MD,FACC. Mount Sinai School of Medicine of the City University of New York, New York.

Thirty consecutive patients(pts) with dizziness, palpitations, syncope and multiple ECG's non-diagnostic for arrhythmias were monitored for 24 hours. There were 13 males and 17 females. Ages ranged from 27-83 years (mean 62). Pts were divided into 2 groups. Group I- In 14 pts (47%) no dysrhythmias were recorded. The etiology of cardiac disease was: ASHD (myocardial infarction or angina pectoris) in 8; RHD in 2; no known cardiac disease in 2; congenital heart disease in 1; and cor pulmonale in 1. Group II- 16 pts (53%) had abnormal recordings. Etiology of cardiac disease was: ASHD in 8; RHD in 2; no known cardiac disease in 5; myocardiopathy in 1. Holter monitoring revealed sinus bradycardia(SB)(34-54 beats/min) in 8 pts (50%). Sinus arrest (2.5,1.6,3.0, and 4.0 sec.) with junctional escape beats were present in 4 pts (25%). One patient in this group with sinus arrest of 3 sec. had SB at a rate of 36 beats/min and one episode of Wenckebach phenomenon. Three pts had a bradycardia-tachycardia syndrome. Two had chronic atrial fibrillation with a rapid ventricular response of 140 and 160 beats/min changing to 33 and 40 beats/min respectively. The third pt had paroxysmal atrial flutter (150 beats/min) alternating with SB at a rate of 40 beats/min. The remaining pt had a permanent demand pacemaker implanted for complete heart block who was hospitalized for syncope with no evidence of pacemaker malfunction; monitoring disclosed pacemaker failure with 4 sec. periods of cardiac arrest.

Sick sinus node was present in 15 of 16 pts with abnormal recordings. Twenty-four hour Holter monitoring is a very useful diagnostic tool in evaluation of symptomatic pts with paroxysmal dysrhythmias, however, a longer monitoring interval may be needed in those with non-diagnostic recordings.

FABRIC DEGENERATION IN STARR-EDWARDS CLOTH-COVERED HEART VALVE PROSTHESES

Theodore L. Folkerth, M.D., Robert D. Wuerflein, M.D. and William W. Angell, M.D., Veterans Administration Hospital, Palo Alto, Calif., and Santa Clara Valley Medical Center, San Jose, Calif.

Over the past three years, a series of 166 patients underwent either aortic or mitral, or a combination of aortic and mitral valve replacement, using the cloth-covered 2320 model aortic valve prosthesis and the 6320 model mitral valve prosthesis. Over the past 6 months there has been a very significant complication rate directly associated with degeneration of the fabric on these valves. Five patients were reoperated and their prostheses replaced with tissue valves. All 5 were noted to have significant fabric wear at the struts and also at the base of the sewing ring. Wear in general was extensive, with examples of total strut cloth dehiscence and severe deterioration at the composite seat. The sixth patient, a double valve replacement, had multiple myocardial infarctions which were eventually fatal. At postmortem they proved to be secondary to platelet fibrin aggregates originating from the frayed fabric on these valves. The total operative mortality was 9%. The mean 18 month mortality was 16% for aortic, 20% for mitral, and 47% for double valve replacement. A series of 50 homograft valve replacements over this same time interval had a 4% mortality rate. The 18 month mortality for a series of 369 patients using non-cloth-covered Starr-Edwards valves was 18%. The total 18 month embolic rate for the cloth-covered valves was 6% without long-term anticoagulation. Because of the high incidence of failure, we have discontinued the use of the cloth-covered valves. Patients with these valves should be continued on anticoagulation. Multiple embolic episodes should be treated by replacement with non-cloth-covered mechanical valves or with tissue valves.

STUDIES ON VENTRICULAR DEFIBRILLATION

John C. Fischer, MD; Douglas P. Zipes, MD, FACC; Robert M. King, MD; Walter W. Jolly, MD; Ann deB Nicoll, RN; The Krannert Institute of Cardiology, Department of Medicine, Indiana University School of Medicine, Indianapolis, Ind.

The role of a critical myocardial mass required to maintain ventricular fibrillation (VF) initiated by rapid ventricular pacing was studied by 2 methods in dogs placed on total cardiopulmonary bypass. Electrograms were recorded from atrium and from multiple sites on left (LV) and right (RV) ventricles. In the first method, the left circumflex (LC), left anterior descending (LAD) and right coronary (RC) arteries were cannulated with small polyethylene tubing which did not occlude blood flow. Injection of 1.0 to 1.5 mEq KCl simultaneously into LC and LAD abolished electrical activity over nearly the entire LV. VF in RV then regularized, spontaneously ceased and could not be reinitiated as long as LV was inexcitable. Injection of the same amount of KCl into RC failed to abolish VF in LV. Thus, when KCl depolarized LV, VF in RV could not be sustained but depolarizing RV did not terminate VF in LV. In the second method, pairs of circular electrodes (area=3.14cm^2) were sewn on RV and LV 4cm apart, parallel to the septum. We evaluated the amount of current necessary to terminate VF when passed in the form of a trapezoidal wave (24 msec duration) between the 2 RV electrodes, between the 2 LV electrodes, and between one RV and one LV electrode. The shock delivered between electrodes at opposite poles across both ventricles required the least current to terminate VF, while the shock delivered between 2 RV electrodes required the most. We conclude that successful defibrillation results when a critical myocardial mass becomes depolarized by either KCl or electrical discharge; depolarization of every cell in both ventricles is not necessary to terminate VF in the entire heart.

THE ACCURACY OF THE CONTINUOUS ECHOCARDIOGRAPHIC RECORDING METHOD FOR ASSESSING AORTIC ROOT SIZE

Gary S. Francis, LCDR, MC, USN; Arthur D. Hagan, CDR, MC, USN; Robert A. O'Rourke, MD, FACC; U.S. Naval Hospital, San Diego and University of Calif at San Diego

To evaluate the normal range and accuracy of echocardiographic measurements of the aortic root diameter, we studied 109 patients without aortic valve disease or hypertension utilizing the continuous recording technique. The aortic root internal diameter was measured at end diastole in all patients. An additional 22 patients who underwent aortic valve replacement were also studied and the echo results were compared with the aortic annulus size measured at operation. The 109 normal patients consisted of 59 females and 50 males with an age range of 18 to 74 years (average 38 years). In these patients the echo root diameters ranged from 17 to 33 mm (mean 24 mm) with a mean diameter in females of 22.9 $\pm$ 3.6 mm compared to a mean diameter in males of 25.4 $\pm$ 3.3 mm which is a significant difference ($p < .0003$). This difference between males and females is not explained by body surface area. In the 22 operated patients the internal aortic root diameter measured by ultrasound averaged 26.7 $\pm$ 3.0 mm and the aortic annulus diameter at operation averaged 25.8 $\pm$ 1.5 mm. 16 of the 22 patients (73%) had root measurements by echo within 2 mm of the corresponding annulus size at surgery. The results in the 109 unoperated patients indicate a lower normal range of aortic root diameters than those previously reported in normal patients using the Polaroid film technique. Moreover, the measurements obtained in the 22 operated patients confirm the accuracy of the continuous echocardiographic recording method for assessing aortic root size.

LATE RESULTS OF THE BAFFLE REPAIR FOR TRANSPOSITION OF THE GREAT ARTERIES

Beat Friedli, MD, MSc; Michael J. Godman, MB; B.S. Langford Kidd, MD, FACC; Andre Pasternac, MD; George A. Trusler, MD; William T. Mustard, MD, FACC, Hospital for Sick Children, Toronto, Ontario, Canada.

Fourteen unselected patients have been assessed hemodynamically 4 to 10 years (mean 5.5 years) after the Mustard operation for transposition of the great arteries (TGA). Investigations were directed principally at, i) detection of baffle obstruction by pressure measurements in the pulmonary veins (PV) and venae cavae and by recording simultaneously right ventricular (RV) and pulmonary wedge (PCW) pressures; ii) detection of baffle leaks by dye curves and by selective angiography; iii) assessment of RV and LV function by calculating peak VCE (dp/dt/28 p) from high fidelity recordings in 11 patients. Severe baffle obstruction to the PV return was found in 1 patient. The others had no or minimal gradients between the RV end-diastolic and PCW pressures (mean 1.3 $\pm$ 0.69 mm Hg). After Isuprel infusion cardiac output rose from 4.1 $\pm$ .22 to 7.1 $\pm$ .62 l/min/m^2 (+73%), but the gradient between RV end-diastolic and PCW pressures remained insignificant (2.2 $\pm$ 1.13 mm Hg). There was no caval obstruction. Baffle leaks were found in 5 patients with mild bi-directional shunting. Mild tricuspid regurgitation was demonstrated in 2 patients by RV angiography and was absent in 12 others. The contractility index peak VCE averaged 1.87 $\pm$ .122 sec^{-1} for the RV and was significantly lower for the LV (1.53 $\pm$ .135 sec^{-1}, $P < 0.01$). Only 1 patient presented significantly decreased contractility with a peak VCE of 1.07 sec^{-1} and poor contractility on the RV angiogram. These data indicate that the longterm outlook after the Mustard operation should be optimistic in most patients and that the RV is able to function at the level of contractility of a normal LV.

PLATELET AGGREGATION IN ANGINA PECTORIS: EFFECT OF EXERCISE INDUCED STRESS

William Frishman, MD; James Christodoulou, MD; Babette Weksler, MD; Charles Smithen, MD; Simon Horwitz, MD; Thomas Killip, MD, FACC, The New York Hospital-Cornell Medical Center, New York, N.Y.

Several observers have suggested that platelet dysfunction may be important in the pathogenesis of symptomatic coronary artery disease. Platelet aggregates have been demonstrated in the coronary microvasculature of animal models following catecholamine infusions or the production of severe stress. To test the hypothesis that stress may lead to altered platelet function in man, exercise tolerance tests (ETT) were performed on 10 patients (pts) with angina pectoris and 10 age matched normals (nls) using a bicycle ergometer. Six angina pts had repeat ETT while receiving 80mg/day of oral propranolol (P). Exercise endpoint was either chest pain, severe fatigue or a heart rate of 160/min. Platelet aggregation (agg) studies were obtained at rest and immediately after exercise. Biphasic agg threshold in response to ADP and epinephrine was measured in fresh platelet rich plasma. At rest, minimum concentration of ADP for full agg response was 2.7± 0.6 uM in pts and 6.0±1.4 in nls ($p < .05$); with epinephrine, 8.6±3.1 uM in pts and 20±4.6 uM in nls ($p < .05$). However, following exercise with significant increase in heart rate and blood pressure, no change in agg threshold was found in either the nl or pt groups. At rest, P treated pts required an increased concentration of ADP to induce agg, 4.5±0.5 uM ($p < .01$); after exercise, this effect was maintained or further increased concomitant with improvement in work performance. Thus, exercise induced stress does not acutely alter resting platelet agg in nls or pts with angina pectoris. Angina pts show increased platelet agg at rest which is restored towards normal by P, an effect which persists despite submaximal exercise.

NON-INVASIVE ASSESSMENT OF CLINICAL RESPONSE TO ORAL PROPRANOLOL

William Frishman, MD; Charles Smithen, MD; Thomas Killip, MD, FACC, The New York Hospital-Cornell Medical Center, New York, N.Y.

Nineteen patients (pts) with severe angina pectoris entered a double blind controlled study to evaluate the effect of oral propranolol (P) on exercise tolerance measured with a bicycle ergometer, and left ventricular (LV) function measured by echocardiography and systolic time intervals. In the P treated group dosage was increased from 80 to 320mg/day. Studies , which included blood P levels, were obtained before treatment and at each P dose. On P 80mg/day total work increased by 128% from 765±125 to 1,785±285 kpm when compared to pre-treatment performance ($p < .01$). At dose levels of P $\geq$ 160mg total work performance decreased, but remained higher than at control levels. In the P treated group LV function decreased progressively with increasing drug dose. As measured from the echocardiogram, maximum endocardial posterior wall velocity fell 35% from 62±19 to 40±11 mm/sec, ejection fraction fell by 12% from .68±.05 to .60±.04, and end diastolic volume increased from 90±23 to 111±28 ml/m^2, (all $p < .05$). PEP/LVET significantly increased with each dose increment and correlated with the decrease in ejection fraction measured from the echocardiogram, ($r = .75$, $p < .01$). There was no correlation between blood level of P and improved work performance. Thus exercise tolerance was maximally improved with dosages of 80mg/daily. At higher dose levels LV function deteriorated and exercise work fell. Non-invasive assessment of LV function proved more valuable than drug levels in management of patients with angina pectoris and provides a guide to optimal adjustment of dosage.

ANODAL INFLUENCE ON VENTRICULAR FIBRILLATION

Seymour Furman, M.D., FACC Rahul Mehra, B.S., Montefiore Hospital and Medical Center, Bronx, New York

The difference between cathodal, anodal and bipolar fibrillation threshold was investigated in open chest anesthetized dogs with SA nodal destruction and ventricular pacing at 150/min. Constant current 2 msec duration rectangular cathodal, anodal or bipolar pulse trains of 100 Hz were applied via the pacing electrode(s) for 500 msec to the left ventricular apex with the onset of the R wave during interruption of ventricular pacing. The current required to fibrillate using cathodal trains was 2.5 times larger than that required for anodal or bipolar trains, both of which had equal fibrillation thresholds. Electrograms indicated shorter refractory periods with more rapid ventricular responses for anodal or bipolar trains than for cathodal. Fibrillation threshold was also determined after two consecutive premature ventricular contractions by a 2 msec pulse. Starting from total refractory, a time range of vulnerability was determined in which anodal fibrillation threshold was less than cathodal. It is hypothesized that lower anodal or bipolar fibrillation threshold is due to their shorter refractory period and lower threshold in relative refractory. These data support the observed greater relative frequency of ventricular fibrillation in the presence of bipolar cardiac stimulation than unipolar, and suggest that unipolar cathodal stimulation is intrisically safer than bipolar, especially when fibrillation threshold is reduced as with myocardial ischemia.

ANGIOGRAPHIC PATTERNS EARLY IN THE ONSET OF THE CORONARY SYNDROMES

Valentin Fuster, MD; Daniel C. Connolly, MD,FACC; Robert L. Frye, MD,FACC; Margaret A. Danielson; Lila R. Elveback, PhD; Leonard T. Kurland, MD. Mayo Clinic and Mayo Foundation, Rochester, Minnesota.

Little information is available regarding angiographic patterns soon after the onset of different coronary syndromes. Coronary angiography was performed in 300 patients (pts) within one year of onset of symptoms of coronary artery disease. 164 pts had angina pectoris alone (AP), 63 subendocardial myocardial infarction (SMI), and 73 transmural myocardial infarction (TMI). In the three groups there was an equal distribution of one, two, or three vessel disease (50% or more obstruction). The distribution of obstruction was also similar in the three groups--left anterior descending 81%, right coronary 60%, circumflex 49%, left main coronary 7%. Of the vessels not totally occluded, the degree of stenosis was also similar in the three groups. However, the percentage of vessels with total occlusion was much higher in TMI (53%) than in the SMI (30%) or AP (24%) groups. Of the total number of diseased vessels with associated collaterals (30%), 84% were completely occluded and only 16% were not. The association of collaterals with occlusion was greater in AP (85%) and SMI (85%) than in TMI (61%) pts. The presence of collaterals was not apparently related to duration of symptoms. Ventriculography was performed in 297 pts. Localized or diffuse reduction of contractility was present in 75% of TMI and only in 29% of SMI and 26% of AP pts. The degree and distribution of coronary lesions could not be correlated with hypertension, cigarette smoking or elevated serum lipids in any of the three groups.

In conclusion, within one year of onset of AP, SMI or TMI, angiography showed strikingly similar patterns in all three groups, apart from the high incidence of vessel occlusion and abnormal ventriculography in TMI. Coronary angiographic patterns were unrelated to risk factors in this selective group of patients.

CORONARY PATHOLOGY AND LEFT VENTRICULAR FUNCTION IN PATIENTS WITH CORONARY HEART DISEASE

Martin P. Gander, MD; Bruce Ham; Melvin P. Judkins, MD. FACC. Loma Linda University, Loma Linda, CA 92354

Detailed clinical and laboratory observations have shown that a great disparity may exist between the severity of coronary lesions and heart muscle damage in patients with coronary heart disease (CHD), a disparity which depends on the heart's ability to protect jeopardized muscle through collateral circulation. In 300 CHD patients undergoing coronary arteriography, coronary morphology was correlated with ventriculographically-observed left ventricular contractions and left ventricular dynamics measured by post-contrast injection end-diastolic pressure (EDP) and ejection fraction (EF). Single-vessel involvement did not significantly alter ventricular dynamics, except in lesions proximal to the origin of the first septal artery (SA); here the EDP was increased to 21± 7 mm Hg. The incidence of left ventricular asynergy and proximal lesion aneurysm was markedly higher (43%) than in lesions involving other vessels. Patients with triple-vessel disease showed decreased left ventricular function: lesions proximal to the first SA - EF 44± 13.2%, EDP 28± 8.2 mm Hg and lesions distal to the first SA - EF 48± 14.3%, EDP 22± 7.3 mm Hg. In this patient group, the occurrence of left ventricular aneurysms was identical to that in lesions proximal and distal to the first SA (39%).

These findings clearly confirm the very important role that collateral blood flow through the septum, via either the first SA or the posterior descending system, plays in preserving myocardium.

CLINICAL USE OF AN ISOTOPIC CARDIAC PACEMAKER.

Andrew A. Gage, M.D., William M. Chardack, M.D. and Anthony J. Federico, M.D. Veterans Administration Hospital, Buffalo, New York

Long-lived radioisotope pacemakers were first used by Laurens and Piwnica in April of 1970. The Medtronic-Alcatel pacemaker is of the demand type. The fuel capsule contains about 150 mg of Plutonium-238. Heat is converted into electricity by a bismuth telluride thermocouple. Radiation level at the surface is 3 mrem/hr and is expected to reach 5 mrem/hour after 5 years, well within safety limits. The design life of the pacemaker is 10 years. It has been extensively tested and found to be safe under all conditions of credible accident.

The first clinical use in the United States was made by us in July of 1972 and since then we have treated 18 patients. Primary installations (5) were made with myocardial electrodes to avoid potential dislodgement, occasionally seen with endocardiac electrodes. Replacements (13) were made with myocardial or endocardiac electrodes which had been shown to be stable.

All patients have made an uneventful recovery and all pacemakers have functioned satisfactorily. At the present time, about 400 such units have been used, mostly in Europe, and at the time of this writing, pacemaker malfunction has not been observed.

EFFECT OF RESTORATION OF NORMAL LEVELS OF MEMBRANE POTENTIAL ON OUABAIN TOXICITY IN CARDIAC PURKINJE FIBERS.

Jeremiah M. Gelles, MD; Ronald S. Aronson, MD; Brian F. Hoffman, MD, Columbia University College of Physicians and Surgeons, New York, N.Y.

A principal manifestation of ouabain (O) toxicity in Purkinje fibers (PF) is transmembrane depolarization presumably due to inhibition of the Na-K pump. To determine whether other manifestations of O toxicity derive from this principal effect, we restored the transmembrane potential (TMP) to control levels during O exposure and studied the effect of this maneuver on action potential (AP) parameters. A two-microelectrode technique was used. One electrode passed current while the other measured TMP. A third electrode was used for extracellular stimulation (cycle lengths 630-1300 msec). Shortened sheep cardiac PF (previously described) were superfused in vitro with Tyrode sol. (K=4.0mM; T,36°C). During O ($2x10^{-7}$M) superfusion, polarizing current was passed intermittently to restore the TMP to control levels. The rate of rise and overshoot of the AP returned towards control levels. Spontaneous activity that had developed during O toxicity was suppressed. O-induced enhanced phase 4 depolarization (P4D) was decreased. In PF that had become inexcitable, restoration of the TMP to control levels restored excitability. Repetitive stimulation at this time resulted in a gradual increase in P4D, escape from the stimulus, and depolarization of the fiber. These results indicate that restoring TMP to control levels can substantially ameliorate the toxic effects of O on the AP. In conjunction with voltage clamp experiments (previously described) these results further support the hypothesis that O exerts its effects on PF by disrupting the integrity of the Na-K pump.

PRELOAD DEPENDENCE OF EJECTION FRACTION

R.D. Gentzler, M.D., A.S. Hunter, M.D., and J.H. Gault, M.D., Penn State University College of Medicine, Hershey, Pa.

The effects of varying preload on left ventricular (LV) contraction were examined by means of beat-to-beat measurements of LV volume, derived from biplane cineangiograms, over a sequence of 5-8 cardiac cycles in six patients with atrial fibrillation. The level of myocardial inotropic state was determined simultaneously from the rate of isometric LV pressure rise, recorded by means of a catheter-tip micromanometer, at a common developed (dev) isometric pressure (P) of 40 mmHg (dp/dt/Pdev 40). Variations in LV end-diastolic volume (EDV), ejection fraction (EF), and dp/dt/Pdev 40 were expressed as percent changes over values observed at the smallest level of EDV in each patient. Substantial variations in preload, or EDV, (avg. +22.7 ± 2.9%) were accompanied by comparable and directionally similar changes in EF (avg. +18.1 ± 3.9%). However, dp/dt/Pdev 40 exhibited no variation with increments in preload (avg. change +1.3 ± 2.6%), indicating that changes in myocardial inotropic state were not responsible for beat-to-beat changes in EF. When measurements of EF were "corrected" i.e. normalized by dividing by EDV (NEF), preload-induced variations in EF were no longer evident (avg. change -2.7 ± 1.9%). Thus, because EF varies substantially with changes in preload alone, the value of this commonly-employed parameter as a comparative indicator of LV performance is limited. Normalization of EF (NEF) for corresponding EDV may provide a more accurate estimate of LV myocardial function.

BENEFICIAL EFFECTS OF PROSTAGLANDIN F2α IN EXPERIMENTAL MYOCARDIAL INFARCTION.

Roy D. Goldfarb, Ph.D. and Thomas M. Glenn, Ph.D. Department of Pharmacology, University of South Alabama, Mobile, Alabama.

The ability of prostaglandin F2α (PGF2α) infusion to modify the hemodynamic and biochemical alterations resulting from myocardial infarction (MI) was investigated. PGF2α (30µg/kg,i.v.) or saline was infused in cats subjected to ligation of the left anterior descending coronary. Post-infarction survival times of PGF2α-treated cats was 353% ($p<0.01$) greater than saline treated animals. Plasma activity of myocardial depressant factor (MDF), a peptide involved in the development of lethal shock, was 347% higher in saline treated infarcted cats than in cats receiving PGF2α. Cardiac output (CO) of saline treated infarcted cats fell to 53% of control at 60 min. and to 38%, 180 min. postinfarction. Whereas, CO of PGF2α treated cats fell to 69% of control at 60 min. and only to 62%, 180 min. postinfarction. Following infarction the increases in total peripheral resistance, plasma lysosomal enzyme activity, plasma MDF activity, and splanchnic lysosome fragility seen in saline treated cats was significantly attenuated by PGF2α infusion. The protective action of PGF2α appears to be related to its ability to maintain lysosome integrity of ischemic tissues and subsequently, prevent the formation of the cardiotoxic peptide-MDF.

DERANGEMENTS OF MYOCARDIAL METABOLISM DURING ISCHEMIC ARRHYTHMIAS.

Herbert Gold, M.D., FACC; Steven Rubins, M.D.; Samuel Meerbaum, Ph.D., FACC; Tzu-Wang Lang, M.D., FACC; Costantino Costantini, M.D.; and Eliot Corday, M.D., FACC. Cedars-Sinai Medical Center, Los Angeles, California.

Metabolic effects of arrhythmias in ischemic and non-ischemic myocardium were determined in 17 dogs. Following LAD intracoronary balloon occlusion, myocardial oxygen extraction [O_2(A-V)], lactate (LB) and potassium (KB) balances were measured separately from both occluded (O) and nonoccluded (NO) perfusion zones of the myocardium. Results were compared during preocclusion control (POC), after occlusion but before arrhythmias (Pre-A), when ischemic ventricular arrhythmias supervened (A), and during ventricular fibrillation (VF) (*$p < 0.05$ relative to POC):

		POC	Pre-A	A	VF
O_2 (A-V) (%)	NO	58.0	64.1 *	61.8 *	39.6 *
	O	55.7	62.8 *	62.5 *	42.7 *
LB (A-V)/A (%)	NO	31.1	23.3	18.1 *	-26.8 *
	O	33.3	14.9 *	3.7 *	-66.9 *
KB (A-V) (mEq/L)	NO	0.01	- 0.06	- 0.16*	- 0.25*
	O	0.01	- 0.21*	- 0.33*	- 0.45*

Following occlusion (Pre-A), oxygen extraction increased in both O and NO; significant K^+ loss and abnormal lactate metabolism occurred in the occluded segment.

When arrhythmias supervened, further deterioration of abnormal lactate metabolism and increased K^+ loss occurred in NO as well as in O segments, demonstrating onset of "global" myocardial metabolic dysfunction. VF exhibited severe lactate production and increased K^+ loss in both NO and O zones. Oxygen extraction dropped drastically in both zones during VF.

Arrhythmias and VF after coronary occlusion cause significant metabolic derangements in both NO and O regions.

EFFECT OF SURVEILLANCE ON PACER LONGEVITY AND PATIENT RISK

Bernard S. Goldman, MD, FACC; James G. Heller, Ph.D.; H. Dominic Covvey, M.Sc.; Edward J. Noble, MD.; John D. Morrow, MD. Toronto General Hospital, Toronto, Canada.

Evaluation of pacemaker follow-up is necessary to ensure maximal pacer longevity and minimal patient risk at reasonable cost to the health economy. To assess our program, we reviewed 633 pulse-generator replacements performed over the past 5 2/3 years. The mean duration of all units, removed for all reasons, was 20.7 mos; 169 elective replacements (26.9%) averaged 24.9 mos; and 310 units replaced for failure (50.3%) averaged 21.6 mos. (90.1% manufacturers' corroboration in 128/142 units). In the period prior to establishing a Pacemaker Clinic, mean pacer life was 22 mos; with a follow-up Clinic using an elective replacement schedule, mean pacer life was 21 mos. In the latest period, with a computer-based Pacemaker Centre, co-operating network of peripheral clinics and trans-telephone evaluation, pacer life averaged 23 mos; however 24 units, monitored only by telephone, lasted 26.6 mos. Of 104 patients currently followed by telephone analysis, mean duration of functioning implants is 30.5 mos for asynchronous (range 18.0-44.5 mos) and 24.7 mos for demand units (range 18.0-40.0 mos). Emergency replacements fell from 55% (1968) to 10% (1973); return of symptoms occurred in 66% initially and 27% recently. A Pacemaker Clinic alone may not increase pacer longevity but does reduce risk and morbidity. Telephone surveillance permits extended longevity but with considerable time, personnel and cost implications, and possibly patient anxiety. The average duration of implants in the present sample of patients on telephone evaluation approximates the industry recommendation for removal. Is an elective replacement schedule a reasonable, effective and less expensive alternative?

CORONARY COLLATERAL FUNCTION IN PATIENTS WITHOUT OCCLUSIVE CORONARY ARTERY DISEASE.

Robert E. Goldstein, MD; Lawrence L. Michaelis, MD; Andrew G. Morrow, MD; and Stephen E. Epstein, MD, NHLI, Bethesda, Md.

Little is known of the functional capacity of coronary collaterals in humans without occlusive coronary artery (CA) disease. We therefore measured peripheral coronary pressure (PCP) and retrograde flow (RF) from CA at aortic valve replacement in 7 patients without occlusive CA disease. Using a t-connection interposed in left (L) and right (R) coronary perfusion lines, data were obtained during brief proximal occlusion of each line. PCP was expressed as a fraction of perfusion pressure (PP) and collateral resistance (CR) was calculated as PP/RF. Mean values were as follows:

Occluded perfuser	RF (ml/min)	CR (mm/Hg/ml/min)	PCP (mm Hg)	PCP/PP
LCA	1.8	46	13	0.19
RCA	1.2	62	16	0.24

In contrast, previous studies of well-collateralized distal segments of diseased CA revealed mean RF 15.7, CR 5.1, and PCP/PP 0.50. Under the conditions of study, all vessels interconnecting the non-diseased RCA and LCA delivered flow and pressure less readily than collaterals to a single distal segment of a diseased CA. Thus, collaterals in patients without diseased CA have an extremely limited capacity to transmit either flow or pressure. The absolute values of RF were small relative to the muscle mass perfused by each CA, suggesting that perfusion of only one CA in man during operation may not provide substantial perfusion for large portions of myocardium. Comparison of performance of collaterals supplying diseased and non-diseased CA indicates that proximal occlusion may be an important factor stimulating enhancement of collateral function.

DUAL ISOTOPE MYOCARDIAL IMAGING: ASSESSMENT OF CORONARY FLOW RESERVE FROM CHANGES IN REGIONAL PERFUSION DURING CORONARY HYPEREMIA IN ANIMALS AND MAN

Lance Gould, MD, Glen Hamilton, MD, Kirk Lipscomb, MD, Ward Kennedy, MD, VA Hospital and University of Washington School of Medicine, Seattle, Washington.

Resting coronary flow and regional distribution are normal despite up to 85% diameter coronary stenosis. Accordingly, regional perfusion was evaluated during hyperemia in order to quantify maldistribution occurring at high flow rates but not at rest. In 8 open chest dogs quantitative regional distribution of left coronary flow was determined by electromagnetic flowmeters on the anterior descending and circumflex arteries and simultaneously by double radionuclide studies. Coronary flow was varied from basal to maximum by intracoronary injections of Hypaque-M, 75%, previously shown to be a potent, repeatable stimulus for maximal hyperemia. Malperfusion due to coronary stenoses quantified with the gamma camera correlated closely with results by electromagnetic flowmeters (r=0.96). In the presence of balanced lesions on the circumflex and anterior descending arteries, hyperemic responses were reduced and regional perfusion was normal. To demonstrate the applicability of this approach in man, 12 patients were studied by intracoronary injection of ^{113m}Indium macroaggregated albumin (MAA) in the resting state and ^{99m}Tc MAA during the hyperemia following the injection of intracoronary contrast media. Scintiphotographs from patients with moderate to severe angiographic coronary lesions demonstrated normal regional distribution at rest but maldistribution during hyperemia. The results in patients also demonstrated that collaterals failed to maintain normal distribution during hyperemia despite normal perfusion at rest.

TRICUSPID LEAFLET PROLAPSE AS A COMPONENT OF THE SYSTOLIC MURMUR-CLICK SYNDROME

Alden S. Gooch, MD; Vladir Maranhao, MD; Sing San Yang, MD; D. R. Sena, MD; Harry Goldberg, MD; Deborah Heart and Lung Center, Browns Mills, New Jersey

Patients with systolic murmur and/or clicks are often proven to have prolapse of the mitral leaflets. In order to assess the tricuspid valve in such cases, right ventriculography was performed in 61 patients. There were 51 females and 10 males. Systolic murmurs were present in 47 cases and 32 had clicks. Thirty-seven had nonanginal chest pains and 23 complained of palpitations. Left ventriculography revealed definite prolapse of the mitral valve in 52 cases and ventricular asynergy was seen in 43. Right ventriculography was performed in the right anterior oblique projection. Late systolic prolapse of the tricuspid valve was seen in 32 patients (52.4%); including all leaflets in 15 cases and limited to the inferior leaflet in 17. Deformities of the right ventricular musculature, tricuspid ring and/or leaflets were seen in an additional thirteen cases. In 17 cases (27.9%) the degree of tricuspid prolapse was greater than that of the mitral leaflets. This study demonstrates that the systolic murmur-click syndrome may be associated with prolapse of either or both of the atrio-ventricular valves.

ELECTROPHYSIOLOGIC ALTERATIONS IN CARDIAC DYSRHYTHMIAS: ANTIARRHYTHMIC EFFECTS OF APRINDINE.

Kalman Greenspan, Ph.D., FACC; Mitchell Steinberg, Ph.D.; Donald Holland, M.S.; Alan R. Freeman, Ph.D., Indiana University School of Medicine, Indianapolis, Indiana.

Studies on isolated cardiac tissue superfused with low concentrations of Aprindine [N-phenyl-N(3-diethylamino propyl)-2-indanylamine HCl] were initiated in order to determine the effects of this agent upon normal tissue and in tissues made dysrhythmic under conditions simulating infarction. Membrane potential, rate of rise of phase 0, action potential amplitude, duration, and impulse conduction were assessed utilizing intracellular electrodes. In normal non-automatic Purkinje fibers, Aprindine depressed the rate of rise of phase 0 with a concomitant reduction in action potential amplitude, duration and at times in membrane potential. With prolonged superfusion, conduction became altered with varying degrees of block, and exhibited the clinical counterpart of the Wenkebach structure. In Purkinje fibers rendered automatic by stretch, hypoxia, digitalis or catecholamines, the slope of phase 4 depolarization was reduced and eventually abolished with Aprindine. The onset of automaticity, by the above interventions, was prevented by prior administration of Aprindine. Conduction depression, (and block at high doses), also occurred in muscle with this agent, but was less sensitive than Purkinje tissue. The alteration in conduction in association with abolition of automaticity, could thus abolish a tachycardia. The effects occurred with low doses and persisted for a long time. This, with the reported long biological half-life, would minimize the requirement for repeated administration for the prevention and treatment of cardiac dysrhythmias.

MORPHOLOGY OF THE CORONARY ARTERY-BYPASS GRAFT ANASTOMOSIS

Lawrence S. C. Griffith, M.D., Robert K. Brawley, M.D. and Grover M. Hutchins, M.D., Departments of Medicine, Surgery and Pathology, The Johns Hopkins University School of Medicine and Hospital, Baltimore, Maryland

Sixty bypass graft anastomoses in 34 patients dying in the immediate operative period (25 patients) or up to 5 months (9 patients) after direct coronary revascularization were studied at autopsy by angiography and serial histologic sectioning of the graft to artery anastomosis. Graft patency was 90% (54/60). Most patent grafts including their proximal connection showed no significant narrowing. Comparison of the preoperative and postmortem angiograms and histology showed that 23 anastomoses and the corresponding coronary artery were widely patent, 16 coronary arteries had a significant (> 70%) new narrowing and 21 arteries had a new total occlusion. New coronary occlusions and narrowings occurred adjacent to either the proximal or distal ends of the anastomosis and were due to compression or loss of circumference of the arterial lumen (68%), thrombus formation (16%) or mural dissection of the coronary wall (16%) and appear related to suture placement or surgical endarterectomy. A local atheroma and/or small coronary lumen were significant factors predisposing to these occlusive changes. Fewer changes were identified in those instances where the distal end of the arteriotomy terminates at the apex of a branch point rather than continuing down one of the two branches.

The findings emphasize the importance of careful artery selection for bypass, the need to avoid local vascular disease and the difficulties encountered in the presence of local atheromata or a small coronary lumen.

RELATIVE EFFECTS OF LEFT VENTRICULAR MASS AND WALL THICKNESS ON DIASTOLIC STIFFNESS

William Grossman, M.D., Lambert McLaurin, M.D., Miltiadis Stefadouros, M.D.
University of North Carolina, Chapel Hill, N.C. 27514

The influence of left ventricular (LV) mass and posterior wall thickness at end diastole (h_p) on LV diastolic stiffness has been examined in 24 patients with various forms of heart disease by use of a combined ultrasonic and hemodynamic technique. The slope of late diastolic LV pressure-diameter relations ($\Delta P/\Delta D$) was calculated and used as a measure of effective diastolic stiffness (S) late in diastole. S was normalized for average LV pressure during the interval of measurement ($\bar{P}$) as $S/\bar{P}$, called S_N. Ultrasonically determined LV mass index (LVMI) and h_p were measured in each patient simultaneous with the determination of S and S_N.

The range of h_p was 5.6 to 18.6 mm; it was highest in aortic stenosis, and lowest in mitral stenosis. Linear regression of h_p against S and S_N showed significant correlation with r=.85 and .75, respectively ($p < .001$ for each). LVMI ranged from 42 to 387 gm/M^2 and 11 of the 24 patients had increased LVMI (>124 gm/M^2). In this group of 11 patients, h_p varied widely (increased in 6, normal in 5), depending on the nature of the underlying disorder (increased h_p in amyloidosis and concentric hypertrophy, normal h_p in dilated, failing LV). Within this group of 11 patients, h_p was an excellent predictor of S (r=.86, $p < .001$) while LVMI itself was a poor predictor (r=.50, NS), suggesting that increased LV mass is a determinant of diastolic stiffness only in so far as it is associated with increased h_p.

In conclusion, these observations indicate that h_p is a major determinant of LV diastolic stiffness, independent of total LV mass.

TOTAL BODY ANGIOGRAPHY IN PATIENTS WITH DIFFUSE ATHEROSCLEROSIS

Liliana R. Grinfeld, MD, Luis M. de la Fuente, MD, FACC, Kazumitzu Shinji, MD, Ezio Zufferdi, MD, René G. Favaloro, MD, FACC.

It is a well known fact that atherosclerosis affects frequently more than one area of the cardiovascular system. Using the brachial approach, with local anesthesia, and in one session we were able to study angiographically the coronary arteries, supra aortic vessels, abdominal branches of the aorta and/or the peripheral circulation, which were registered in a 35 mm. film with a 9 inch image intensifier and overframing. Out of a total of 180 cases, we evaluated the first 100 patients in whom multiple angiographic studies were performed. The primary cause of the angiography was A.S.H.D. in 47 patients and A.S.O. (atherosclerosis obliterans) in 44 patients which constitutes 91% of the cases. As a secondary study we did 20 coronary arteriographies, 55 selective renal arteriographies, 31 carotid vertebral opacifications and 17 peripheral arteries visualizations. Five aortic aneurysms were diagnosed. In this report we discuss the technic, indications and findings of these multiple studies.

CARDIOMYOPATHIC FEATURES IN THE SYNDROME OF SYSTOLIC CLICK, MURMUR AND MITRAL VALVE PROLAPSE.

Stephen Gulotta, MD, Louis Gulco, MD, Thomas Maley, MD, John Morrison, MD, Vellore Padmanabhan, MD, North Shore University Hospital-Cornell University Medical College, Manhasset, New York

Twenty-six patients with systolic clicks, murmurs, and prolapsed mitral valve leaflets were studied because of distressing anginal symptoms or troublesome arrhythmias. Cardiac catheterization revealed normal coronary arteries and a high incidence of left ventricular (LV) dysfunction. The patients, 20 of whom were women, averaged 41 years of age. Thirteen of the 22 patients with angina experienced pain of sufficient severity to warrant hospital admission for suspected acute myocardial infarction. Twenty of 26 had abnormal ECG's which included sinus bradycardia, 1^o, 2^o and 3^o block, atrial and ventricular arrhythmias and abnormal ST-T wave vectors. Three had patterns of healed transmural infarctions and 5 of 16 had positive exercise tests. LV dysfunction was hemodynamically documented in 20 patients by either elevated LV end diastolic pressure, low resting cardiac index, or inappropriate rise in cardiac index during exercise. In the remaining 6, impaired LV dynamics were demonstrated angiographically. Left ventriculography revealed mitral valve prolapse in all patients, mitral regurgitation in 20, and mild to moderate LV hypertrophy in 14 patients. Contractility, as judged angiographically, was significantly impaired in 13 patients. They had marked hypokinesis of the anterolateral wall of the LV resulting in the appearance of an unusual prominent convexity in this portion of the ventricle in end systole and early diastole. Seven others had similar impairment of LV contractility, but less severe. These results indicate that the syndrome of prolapsed mitral valve leaflet has a significant component of LV dysfunction which has not been previously emphasized.

ULTRASOUND EVALUATION OF SYSTOLIC ANTERIOR SEPTAL MOTION IN PATIENTS WITH AND WITHOUT RIGHT VENTRICULAR VOLUME OVERLOAD

Arthur Hagan, MD; Gary Francis, MD; David Sahn, MD; Joel Karliner, MD, FACC; William Friedman, MD, FACC; and Robert O'Rourke, MD, FACC, U. S. Naval Hospital and University of California, San Diego, California

Systolic anterior septal motion (SASM) has been proposed as a reliable indicator of right ventricular volume overload (RVVO). Accordingly, we studied 244 patients (pts) without clinical or catheterization evidence of RVVO employing the ultrasound continuous recording technique. At the level of the mitral valve SASM was present in 111 pts; in 39 pts the septum did not move during systole while in 74 pts, septal motion was variably anterior and posterior during the same recording. However, at the level of the chordae tendinae, 225 of the 244 pts (92%) had normal posterior septal motion. The other 19 pts had severely impaired left ventricular function. In 30 pts with RVVO, 16 had abnormal septal motion at the level of the chordae tendinae (13 with SASM and 3 with no movement). To evaluate septal motion further, 100 normal subjects were studied using a phased multicrystal ultrasound system (by Bom) which provides a saggital plane image of the cardiac structures. In all 100 subjects the superior septum moved anteriorly in systole with the aortic root, whereas the midportion of the septum acted as a "hinge" for the inferior portion, which moved posteriorly. In 8 of 20 pts with RVVO, the entire septum moved anteriorly during systole; variable patterns occurred in 5 pts, while normal septal motion was present in 7 pts. We conclude: 1) that SASM is usually present when septal motion is recorded at the mitral valve level in pts with and without RVVO, and 2) that abnormal septal motion is not a constant echocardiographic finding in pts with RVVO even when recordings are performed at the level of the chordae tendinae.

DIAGNOSIS VALUE OF THE ELECTROCARDIOGRAM IN RECURRENT MYOCARDIAL INFARCTION : AN AUTOPSY STUDY.

Robert Haïat, MD, Associate Fellow ACC; Christine Halphen, MD; Claude Seban, MD; Paul Chiche, MD FACC; Hôpital Tenon, Paris, France.

Of 294 consecutive autopsies data of patients (pts) dying of myocardial infarction (MI), 45 with recurrent MI, were selected and correlated to the electrocardiogram (ECG). ECGs were first interpreted without knowledge of pathological findings. Accuracy of the ECG diagnosis was then evaluated. Results were classified into 3 categories : (1) in 14 pts (31,1%) diagnosis was correct as both old and recent MIs were recognized; (2) in 26 pts (57,7%) diagnosis was incomplete due to the lack of ECG signs of either the old (8 pts) or recent (18 pts) MI; (3) in 5 pts (11,2%) MI could not be detected on the ECG. Many factors contribute to obscure the diagnosis : lack of serial tracings especially when ECG have become normal after the previous MI; presence of intraventricular conduction disturbances, left bundle branch block mainly; recurrent MI occurring in the subendocardial region or in an already infarcted area (31 of 45 pts); atypical ECG patterns, the absence of early ST-T changes being quite remarkable.

It is concluded that, ECG is inaccurate in recognizing recurrent MI as correct diagnosis was possible in only 14 of 45 pts (31,1%), the recent MI being twice more often unrecognized than the old one.

ANTI-ARRHYTHMIC EFFICACY OF APRINDINE IN ACUTE MYOCARDIAL INFARCTION.

Frans Hagemeijer, MD; Paul G.Hugenholtz, MD, FACC, Thoraxcenter, Erasmus University Rotterdam, Netherlands.

Aprindine (A) is a new, long-acting, orally effective anti-arrhythmic drug, with electrophysiologic properties akin to those of Lidocaine (L). In 40 consecutive patients (pts) admitted to the CCU with a diagnosis of acute myocardial infarction (MI) and evidence for ventricular irritability, a double-blind randomized study was undertaken comparing the effectiveness of oral A (200 mg, then 100 mg q 12 h for 60 h) and intravenous L (2 mg/min for 60 h) in preventing ventricular arrhythmias. These were detected by on-line computer monitoring of the ECG, standard monitoring, recording of a 60 sec rhythm strip every two hours, and observation by nurses and doctors. 5 pts (1A, 4L) proved not to have MI. Treatment was considered excellent if no ventricular arrhythmias were observed; good if no serious arrhythmia occurred; a failure if VF, VT, doublets, or early VPB's appeared despite therapy :

	Excellent	Good	Failure
A	13	2	4
L	5	2	9

Gas chromatographic analysis of serum levels of A gave the following values (mg/l) : 0.6-1.1 12 h after first dose; 1.7-2.8 60 h after first dose; 0.9-2.0 48 h after last dose. The only possible symptoms of drug toxicity involved the central venous system : nightmares, hallucinations, restlessness. 2 A pts and 3 L pts were so affected.

1 A pt and 2 L pts died during the first 7 days after admission. Oral Aprindine compares favourably with intravenous Lidocaine in preventing ventricular arrhythmias after acute MI.

DETERMINANTS OF REVERSIBILITY OF LEFT VENTRICULAR FUNCTION AFTER AORTOCORONARY BYPASS SURGERY

Robert I. Hamby, MD, FACC; Agop Aintablian, MD; Farouk Tabrah, MD; Marvin L. Hartstein, MD; B. George Wisoff, MD, Long Island Jewish-Hillside Medical Center, New Hyde Park, New York.

Left ventricular (LV) hemodynamics and contractile patterns were evaluated in 104 patients (pts) before and after aortocoronary bypass surgery. All pts had patent grafts (171). Group I consisted of 44 pts with single grafts. Mean LV end-diastolic pressure (LVedp), volume and ejection fraction (EF) did not change. Twenty-four pts who had asynergy preop revealed 16 with a normal contractile pattern postop. Group II consisted of 47 pts with double vein grafts. Significant decrease in LVedp ($p < 0.005$) and increase in EF ($p < 0.001$) postop. Asynergy in 29 pts preop revealed postop 15 synergy, 3 improved, 9 no change and 2 became worse. Group III consisted of 10 pts with triple vein grafts. EF significantly increased postop ($p < 0.01$). All but 2 of the 8 pts with asynergy preop showed synergy postop. Synergy in 43 pts preop, with one exception, persisted postop. Asyneresis in 41 instances preop revealed postop 38 (93%) had normal wall movement. In 29 instances of preop akinesia of a wall, only 8 (28%) showed a return to normal wall movement. Unstable angina pectoris alone did not influence reversibility of abnormal contractile patterns. Unstable angina pectoris with absence of abnormal Q waves in the EKG was noted in 23 pts with asynergy. All but 1 pt had synergy postop. Pts with infarction pattern on the EKG, when accompanied by asynergy, were unlikely to have a normal contractile pattern postop (4/23). Reversibility of LV function after surgery is common, not related to number of grafts, but is related to type of LV wall abnormality, EKG and clinical state of pt.

THE EJECTION FRACTION AS A PREDICTOR OF SURVIVAL IN PATIENTS WITH CARDIOVASCULAR DISEASE

K. E. Hammermeister, MD, Richard Lewis, BA, J. Ward Kennedy, MD, H. T. Dodge, MD, VA Hospital and University of Washington, Seattle, Washington.

To ascertain the predictive value of the left ventricular ejection fraction (EF) regarding survival, the records were reviewed and follow-up obtained on all patients undergoing cardiac catheterization and who had adequate left ventricular volume measurement by quantitative angiography at the VA Hospital from 1960 to 1970. Actuarial survival curves were constructed for 193 adult patients (age range 20 to 73, mean age 48) and with cardiovascular diagnosis predominantly valvular (59%) and coronary (15%) heart disease. The survival curves for those with borderline EF (45-54%) was the same as that for the group with normal EF ($\geq$ 55%) for the first six years following catheterization (5-year survival 58-60%, 50% dead 6.0-6.8 years), but at ten years the group with normal EF had a 38% survival while the group with borderline EF had a 25% survival. Those with moderate depression of EF (30-44%) had a 5-year survival of 37%, and 50% were dead by 2.8 years. Those with severe depression of EF ($\leq$ 29%) had 5-year survival of 28% with 50% dead by 1.8 years. The 59 cardiac surgical patients with EF $\geq$ 50% had better survival (5-year = 60%, 50% dead at 9 years) than the 51 medical patients with EF $\geq$ 50% (5-year = 43%, 50% dead at 4.2 years). The 31 surgical patients with EF $\leq$ 49% had 5-year survival of 52% with 50% dead at 5.4 years, while the 54 medical patients with EF $\leq$ 49% had 5-year survival of 24% with 50% dead at 1.4 years. EF is an important determinant of survival following catheterization with minimal reduction in EF being associated with decreased late survival. More severe impairment of EF is associated with shorter survival in both medical and surgical groups. Medical patients had shorter survival than surgical patients with comparable EF.

THE DIFFERENTIAL DIAGNOSIS OF ANOMALIES OF THE GREAT VESSELS BY REAL-TIME, TWO-DIMENSIONAL ECHOCARDIOGRAPHY

Walter L. Henry, MD; Barry J. Maron, MD; James M. Griffith; and Stephen E. Epstein, MD, NHLI, Bethesda, Md.

The recent development of a sector-scanner that produces real-time, two-dimensional echocardiograms has made possible cross-sectional imaging of the heart. In this scanner system, a transducer is angled rapidly through a 30 or 45 degree sector and generates 30 high resolution images per second, each one containing 100 individual ultrasound data lines. To determine if this system is useful in the differential diagnosis of congenital anomalies of the great vessels, we studied 23 pts (age 2 to 33 yrs) with cyanotic congenital heart disease previously diagnosed by cardiac catheterization. Images were generated perpendicular to the long axis of the heart at the level of the origin of the great vessels. Satisfactory great vessel visualization was obtained in 20 of 23 pts. Vessels in cross-section appeared as circles; those sectioned longitudinally appeared sausage-shaped. Three patterns were seen: A) a large single circle, seen in 2 pts with truncus arteriosus and 3 with pulmonary atresia; B) 2 adjacent circles, seen in 11 pts with transposition of great vessels including one pt with Taussig-Bing and 2 with double outlet right ventricle; and C) a circle with an anterior sausage-shaped structure curving laterally and inferiorly from right to left, seen in 4 pts with tetralogy of Fallot. This latter pattern, also seen in 11 normal subjects and 20 pts with acquired heart disease, is characteristic of normally related great vessels. In addition to anatomic relationships, absolute measurements of vessel diameter were made. We conclude that two-dimensional echocardiography is a quick, non-invasive and extremely powerful technique for diagnosing congenital anomalies of the great vessels.

CHANGES IN THE SUBUNIT COMPOSITION OF MYOSIN FROM HEARTS UNDERGOING HYPERTROPHY

Philip D. Henry, MD, and Burton E. Sobel, MD, FACC, Dept. of Medicine, Washington University, St. Louis, Missouri.

Experimentally induced changes in the contractility of skeletal muscle appear to be associated with structural and enzymic alterations in myosin. To determine whether the altered contractility of hypertrophied myocardium is associated with analogous changes in myosin from heart muscle we produced right ventricular hypertrophy in 20 rabbits by constriction of the pulmonary artery for one week, evaluated papillary muscle mechanics, analyzed the subunit composition of purified myosin from the same hearts by SDS gel electrophoresis, and assayed myosin ATPase activity. As anticipated from previous reports, the force-velocity relation was significantly depressed in papillary muscles from hypertrophied hearts ($n = 8$) compared to those from normal hearts ($n = 8$) matched for cross sectional area. Myosin from sham operated animals exhibited only two low molecular weight (MW) components (MW = 20,000 and 27,000, $n = 5$ preparations). In contrast, myosin from hypertrophied hearts exhibited a third low molecular weight component (MW = 16,000) and exhibited an electrophoretic pattern similar to that shown by white skeletal muscle. EDTA-activated ATPase activity was significantly depressed in myosin from hypertrophied hearts ($n = 5$) compared to controls ($n = 5$) averaging 240 ± 10 and 281 ± 8 nmoles/mg protein/min respectively ($p < .05$). These results indicate that myosin from myocardium undergoing hypertrophy exhibits alterations which may be related to changes in contractility in the intact muscle.

IDIOPATHIC PAROXYSMAL VENTRICULAR TACHYCARDIA IN CHILDHOOD

Antonio Hernandez, MD; Arnold Strauss, MD; Alexis F. Hartmann, Jr., MD, FACC; David Goldring, MD, FACC, Washington University School of Medicine, St. Louis, Mo.

This is a report on 6 children 3-10 years of age with idiopathic paroxysmal ventricular tachycardia (IPVT) who have been observed in the last two years. The evaluation included clinical, electrocardiographic (ECG), and roentenographic examinations, exercise tolerance with ECG monitoring, 24 hour urinary vanilmandelic acid and catecholamine excretion, serum T_4, electrolytes, blood gases, and electroencephalogram. Therapeutic evaluation included acute response to lidocaine (LI) and procainamide (PA) and chronic therapy with PA and/or propranolol. Holter monitoring for 24 hour periods before and after changes in therapy was used to evaluate the frequency, duration, and time of occurrence of attacks. No cause of IPVT was found in five patients; one patient had clinical evidence of tuberous sclerosis and angiographic evidence suggestive of an intracardiac tumor. LI was the most effective drug for treating two of the patients with acute syncopal and hypotensive attacks. PA was reliable in preventing attacks, and serum PA levels of 7-15 µg/ml were necessary to abolish or decrease the frequency of the arrhythmia as shown in 24 hour ECG recordings. In two patients the firm diagnosis of IPVT could only be made by analysis of the Holter recordings. These cases emphasize that (1) the initial presentation and frequency of attacks varies greatly among patients, (2) LI is most effective for acute symptomatic attacks, (3) relatively high serum levels of PA are necessary to control the arrhythmia on a prophylactic basis, (4) Holter monitoring was found invaluable in establishing the initial diagnosis and assessment of therapeutic results.

SICK SINUS SYNDROME IN CHRONIC CHAGAS' HEART DISEASE.
Otto Hernández-Pieretti, MD, FACC; José R. Lozano-Wilson, MD; Adalberto Urbina-Quintana, MD; Guillermo Villoria, MD; Maria I. de Hernández, MD; Enrique Gómez-Amundarain, MD. "Hospital y Escuela de Medicina Vargas" and "Hospital Central de las Fuerzas Armadas" Caracas. Venezuela.

Sick Sinus Syndrome (SSS) had not been reported as such in Chronic Chagas' Heart Disease (CCHD). The following study was conducted to evaluate the incidence and clinical picture of SSS in CCHD. The clinical records of 300 pts. with CCHD were reviewed. The mean age, the absence of angina and the other clinical features did not suggest coronary artery disease. The ECG of 15 pts. were consistent with SSS and divided into two groups. Group I (5 pts.) did not reveal associated A-V conduction disturbances; the mean age was 38.6 yrs. and there was no evidence of congestive heart failure (CHF). Group II included 10 pts. in whom SSS was associated to A-V conduction disturbances; the mean age was 45.9 yrs. CHF was present in 30 %. Dizziness and Stokes Adams Syndrome (SAS) were observed in both groups: 40% in group I and 20% in group II. Permanent pacemakers could be implanted in only 33% of pts. The analysis revealed that SSS is not a common isolated finding in CCHD. However, this disorder was associated with severe symptoms, including SAS. The ECG abnormalities associated to SSS further indicate severe damage to atrial, junctional and ventricular tissue (P wave abnormalities, intermittent slow junctional and ventricular rhythms, A-V block, BBB, hemiblocks, PACs, PVCs, etc.) with involvement of pacemakers and conducting system. Relatively long periods of atrial and ventricular asystole were recorded by Dynamic ECG, indicating severe depression of sinus node and subsidiary pacemakers.

PRODROMA OF VENTRICULAR FIBRILLATION IN ACUTE ISCHEMIA: EFFECT OF HEART RATE AND ANTI-ARRHYTHMIC DRUGS
Ronald R. Hope, MB, MRACP: Benjamin J. Scherlag, PhD; Philip Samet, MD, FACC, Mount Sinai Medical Center, Miami Beach, Florida

The efficacy of antiarrhythmic drugs in the prehospitalization phase of acute myocardial infarction has not been established. In 25 open chest dogs with the anterior descending coronary artery (ADCA) temporarily occluded (2-6 min), ischemic zone subepicardial electrograms (IZE) were recorded. Ventricular arrhythmias (including premature contractions, tachycardia and fibrillation) occurred in all and followed increasing delay in IZE onset up to 320 msec whereas the average QT interval was 280 msec. The effect of heart rate (HR), lidocaine and propranolol on IZE delay was examined. With atrial pacing (AP), an average increase in HR of 32% in 6 normal and 3 denervated dogs during ADCA occlusion resulted in severe IZE delays and ventricular arrhythmias whose average onset was 1.4 min earlier than at control HR (2.8 min with AP; 4.2 min control HR). The effect of lidocaine (10-15 mg/kg) during 14 temporary occlusions of the ADCA in 10 dogs was compared with 19 occlusions without lidocaine in the same dogs. At the same period of ischemia there was no difference in IZE delay with or without lidocaine (70±20 msec and 69±20 msec, respectively. Propranolol slowed the average HR from 140/min to 109/min. Average IZE delay at the same period of ADCA occlusion was 42±8 and 49±6 msec with and without propranolol, respectively. ADCA occlusion for the same period with AP at 170-200/min resulted in IZE delays of 66±5 msec without, and 76±2 msec with propranolol. IZE delay and ventricular arrhythmias after ADCA occlusion occurred earlier if HR was increased. Propranolol inhibited the onset of IZE delay by slowing HR. Lidocaine had no effect on HR and did not influence IZE delay or the onset of early ventricular arrhythmias.

EVALUATION OF ACUTE MYOCARDIAL INFARCTION WITH TECHNETIUM-99m-TETRACYCLINE INFARCT IMAGING
B. Leonard Holman, MD; Michael Lesch, MD, FACC; Franklin Zweiman, MD; John Temte, MD, PhD; Mrinal K. Dewangee, PhD; Bernard Lown, MD, FACC; Richard Gorlin, MD, FACC, Peter Bent Brigham Hospital, Boston, Mass.

Tetracycline binds to necrotic tissue; its fluorescence has been used to identify experimental acute myocardial infarction (AMI). When Tetracycline is labeled with Technetium-99m (^{99m}Tc-TC), its concentration in the infarcted tissue can be imaged by noninvasive external means, permitting detection, localization and sizing of the lesion. The thorax was imaged in anterior, LAO and RAO projections in 13 CCU and 8 control patients 4, 8 and 24 hours after injection of 20mCi of ^{99m}Tc-TC. Abnormal activity was localized with a radionuclide angiocardiogram ($^{99m}TCO_4^-$) performed immediately after ^{99m}Tc-TC imaging. All controls had negative scans. By clinical criteria, 9 CCU patients sustained AMI, (7 transmural, 2 nontransmural), in 3 the diagnosis was equivocal and in 1 AMI was ruled out. The scan was positive in 9/9, 1/3 and 0/1 patients, respectively. Positive scans returned to normal within 1-2 weeks in 8/9 patients. A negative scan became positive in 1 patient who developed AMI in-hospital. The technique differs from K^+ analogue scanning for infarct detection because: a) ^{99m}Tc-TC produces a positive image which can be analyzed for intensity and size, b) ^{99m}Tc-TC binds to acutely necrotic tissue and therefore does not image areas of old infarction or fibrosis, and c) sequential daily imaging permits temporal analysis of the infarct. In conclusion, ^{99m}Tc-TC permits localization and accurate detection of acutely infarcted myocardium.

HEMODYNAMIC ASSESSMENT OF TOTAL ANOMALOUS PULMONARY VENOUS CONNECTION (TAPVC) FOLLOWING CORRECTION DURING INFANCY
Allan J. Hordof, M.D., Constance J. Hayes, M.D., Frederick O. Bowman, Jr., M.D., James R. Malm, M.D., Welton M. Gersony, M.D., Columbia University College of Physicians & Surgeons, New York, N.Y.

Nine patients with TAPVC and pulmonary artery hypertension (PAH) who survived open heart correction prior to 6 months of age, have been followed for one to 6 years after surgery. Five of the infants had supracardiac TAPVC; 3 had drainage into the coronary sinus and one had a mixed type of venous connection. Postoperatively, all of the children were asymptomatic and displayed normal growth and development. Chest x-rays revealed normal heart size and pulmonary vascular pattern in 8 patients, whereas mild cardiomegaly was noted in one instance. Electrocardiograms showed frontal QRS axes ranging from 80° to 105° with mild right ventricular conduction delays. Regression of preoperative right ventricular hypertrophy was apparent in each case. Ectopic atrial pacemakers with heart rates in the range of 85 to 120 were present in 2 patients.

Seven patients underwent post-operative cardiac catheterization 10 months to 5 years (mean =3 years) after surgery. Pulmonary artery pressures ranged from 16/8 to 32/12 (mean=23/10, $\overline{16}$). One patient had an elevated pulmonary artery wedge pressure (14 mm Hg). Two infants had small L→R shunts (1.3/1; 1.4/1), in the area of the coronary sinus, and one had a catheter patent interatrial communication. None had R→L shunts. In each patient, angiography revealed the site of the common pulmonary vein-left atrial (CPV-LA) junction to be widely patent with a normal sized left atrium and left ventricle. This study indicates that successful corrective surgery for TAPVC with PAH by open CPV-LA anastomosis performed in infancy, results in an excellent long term prognosis.

ACTIVITY OF A MYOCARDIAL DEPRESSANT FACTOR AND ASSOCIATED LYSOSOME ABNORMALITIES IN EXPERIMENTAL CARDIOGENIC SHOCK

Kiyoshi Hosono, MD, FACC; Minoru Okuda,MD; Toshihiko Yamada,MD, Keio University School of Medicine, Tokyo

It has been reported that a myocardial depressant factor (MDF) accumulates in plasma during various forms of circulatory shock. The present study was undertaken to clarify the properties and significance of this factor in cardiogenic shock. The experimental shock model was produced in dogs by embolization of left coronary artery with metallic mercury. MDF was isolated from the plasma ultrafiltrates on gel-filtration column chromatography, and determined under controlled assay condition. MDF recovered in the chromatographic fraction of molecular weight range between 800 to 1000, gave a positive ninhydrin test and appeared to be small peptide(s). MDF activities increased concurrently with progression of the shock states, reaching to 30 ± 3.2 units and 61 ± 5.9 units at three and five hours after coronary embolization , respectively (mean value ± SE, n = 12, $P < 0.001$). The pre-embolization control samples processed in the same manner yielded no or little MDF which was virtually devoid of myocardial depressant activity (0 ± 1 units, n = 6). Correlative electron microscopic, cytochemical examinations of the visceral organs revealed striking lysosome abnormalities accompanied with severe ischemic cellular injuries particularly in the pancreas, consistent with the lysosomal involvement in MDF production. The data presented indicate that MDF accumulation in the systemic circulation during cardiogenic shock may contribute to the operating pump failure and lethality of shock.

PROPHYLACTIC AND THERAPEUTIC USE OF TRANSVENOUS PACEMAKERS IN INFANTS AND CHILDREN

Roger A. Hurwitz, MD, FACC; Donald A. Girod, MD, FACC, Indiana University, Indianapolis, Ind.

Treatment for symptomatic atrio-ventricular heart block (AVB) often consists of a pacemaker. Though transvenous pacemakers (TP) are commonly used in adults with AVB, their use in pediatric patients is seldom described. This paper presents experience with TP in 18 infants and children. In 4, TP were used more than once. Half the patients had congenital AVB, and the others had acquired AVB. Transvenous pacemaking was employed for short term (1-4 hour) prophylaxis on 9 occasions during catheterization or induction of anesthesia prior to cardiac surgery. On 13 occasions TP were utilized therapeutically for treatment of symptoms related to AVB. Transvenous pacing was accomplished in an infant 3 days of age and in 8 patients less than one year old. TP were introduced into leg veins 17 times, 11 percutaneously. Successful pacing was accomplished in all patients. Long-term pacing was carried out for up to 28 days; the pacemaker was used for more than 48 hours on 10 occasions. Stokes-Adams attacks were eliminated in the 4 patients presenting with syncopal spells. In the 9 patients with congestive failure, the clinical condition was improved in 8. Complications were: 1) one catheter required repositioning after one day; 2) there was one perforation of the right ventricle with no apparent hemodynamic side effects; 3) mild leg edema and superficial wound infection occurred twice. Transvenous pacemaking in infants and children has proven relatively easy to perform and is relatively safe. It should be considered for prophylactic and temporary therapeutic management in patients with AVB.

DISTORTION OF LEFT VENTRICULAR (LV) CHAMBER ANATOMY BY RIGHT VENTRICULAR (RV) VOLUME OVERLOAD (VO).

A.S. Hunter, R.D. Gentzler, J.H. Gault, W.R. Vincent. Penn. State Univ., College of Medicine, Hershey, Pa.

In previous studies in our laboratory diastolic LV chamber geometry and symmetry of contraction have been examined quantitatively by means of comparative measurements of volume derived independently from frontal (AP) and lateral (LAT) films of biplane cineangiograms (V_{true}=1.03 Vcalc.$_{AP}$ - 7.7 ml; V true = 0.85 V calc $_{LAT}$ + 5.9 ml). This technique was employed in the present study to characterize LV anatomy in 15 patients with RVVO (13 interatrial shunts, Qp/Qs > 2.0/1, 2 pulmonary valve incompetence), and in 12 patients with congenital cardiac defects not associated with RVVO. In the latter group, normal LV chamber geometry was evidenced by close correspondence of measurements of EDV in AP and LAT films (EDV_{AP} 99.9 ± 14.2 ml; EDV_{LAT} 92.9 ± 13.4 ml, r = 0.96); levels of ejection fraction (EF) in the respective views were also similar (EF_{AP} .65 ± .04, EF_{LAT} .55 ± .04, N.S.), demonstrating that LV contraction was symmetrical. In contrast, in patients with RVVO, EDVs differed consistently in AP and LAT films (EDV_{AP} 158.5 ± 25.6 ml, EDV_{LAT} 81.6 ± 13.7 ml, p<.001), indicating substantial distortion of diastolic LV cavity posture and/or shape. Further, measurements of EF also differed significantly (EF_{AP}.66 ± .02, EF_{LAT} .43 ± .03, p<.001), consistent with asymmetric LV contraction. Of interest, at end-systole, at completion of RV emptying, LVV measurements were similar in the two views (ESV_{AP} 57.9 ± 13.3 ml, ESV_{LAT} 45.5 ± 7.8 ml, N. S.). These observations indicate that sustantial alterations in LV diastolic cavity geometry and in symmetry of contraction occur with RVVO, and may result in significant errors in estimation of LV performance based on single plane measurements of volume or dimensional changes.

INFLUENCE OF HYPERTONIC MANNITOL ON REGIONAL MYOCARDIAL BLOOD FLOW DURING MYOCARDIAL ISCHEMIA IN AWAKE, UNSEDATED, AND IN ANESTHETIZED DOGS

Ian Hutton, MD; John T. Watson, PhD; Gordon H. Templeton, PhD; David E. Fixler, MD; W. L. Sugg, MD; James T. Willerson, MD, U. Tex. Southwestern Med. Sch. at Dallas, Dallas, Texas.

The influence of mannitol (M) on regional myocardial blood flow (RMBF) was assessed in awake, closed-chest, unsedated (A) and in anesthetized (AN) dogs on right heart bypass (RHBP) during acute myocardial ischemia (AMI). AMI was provided by proximal LAD reversible occlusion. Heart rate was kept constant. RMBF was measured using radioactive microspheres (8 μ). M (25%) was given intravenously either as pretreatment (Pr) or following LAD occlusion (Pt). Serum osmolality increased 23 ± 5 (SE) mOsm with M. Hct, LVEDP, mean arterial pressure did not change significantly (NS) after M in AN dogs but mean arterial pressure increased significantly in A ones ($p < 0.05$). Max LV dp/dt increased with M 189 ± 89 mm Hg/sec ($p = 0.05$) in Pr studies, 125 ± 76 mm Hg/sec (NS) in the Pt RHBP ones, and 214 ± 67 mm Hg/sec ($p < 0.025$) in A ones; dp/dt/p also increased significantly in A ones. Pr with M resulted in significant increases in collateral coronary blood flow (CCBF) to the ischemic area (IA) of the LV of 33 ± 12% ($p < 0.025$), to the ventricular septum (VS) of 50 ± 9% ($p < 0.001$), to the nonischemic portion (NI) of the LV of 46 ± 8% ($p < 0.001$), and of 34 ± 13% ($p < 0.025$) to the RV in AN dogs. Pt M produced increases in CCBF of 30 ± 9.6% ($p < 0.02$), to the VS of 19.3 ± 5.2% ($p < 0.02$), to NI portion of LV of 13 ± 4% ($p < 0.01$), and 24.6 ± 10.6% ($p = 0.05$) to RV in AN dogs. M in A dogs with AMI increased regional coronary flow to the VS 32 ± 10% ($p < 0.05$), to the NI portion of LV 30 ± 9% ($p < 0.02$), and to the total LV 23 ± 8.5% ($p < 0.05$). CCBF increased in IA in 4 of 6 studies (15 ± 9%) but the change was NS. These data suggest that M given Pr and Pt LAD occlusion increases RMBF and improves ventricular function during AMI in both awake, unsedated and anesthetized dogs.

LONG-TERM DURABILITY OF PATENT SAPHENOUS VEIN AORTO-CORONARY BYPASS GRAFTS. Samuel B. Itscoitz, MD; David R. Redwood, MD; Leonard E. Grauer, MD; Robert L. Reis, MD; Edward B. Stinson, MD; and Stephen E. Epstein, MD, NHLI, Bethesda, Md.

The ultimate role of saphenous vein bypass operation (SVBO) in the treatment of coronary artery disease (CAD) depends largely on whether grafts tend to occlude with time. To answer this question we restudied 17 patients (aged 36 to 62 years; avg, 49) who underwent SVBO for chronic severe angina pectoris. Patients were selected if they had patent grafts demonstrated at early postoperative study (3 to 9 mos postoperatively). One additional patient (25 years of age) was studied who had SVBO 6 years previously for anomalous origin of the left coronary artery. The 17 CAD patients had a total of 26 grafts patent at early postoperative study: 18 grafts were widely patent with good distal run-off, 5 were widely patent with slow distal run-off, 2 had stenoses at the coronary anastomosis (one mild, one severe with poor run-off), and one had minor luminal irregularities. Late postoperative study was performed 15 to 36 mos (avg 21 mos) following SVBO for CAD. Twenty-four of the 26 grafts were unchanged. One patent graft with good run-off developed minor luminal irregularities; the graft with severe stenosis at the coronary anastomosis had occluded. In the patient with anomalous left coronary artery, a widely patent graft with good run-off was found 4 months postoperatively. Restudy 4.5 years later revealed no change in the appearance of the graft. These results suggest that vein grafts, which within 3 to 9 months following SVBO are widely patent and have good run-off, are anatomically and functionally stable during the ensuing one to 4 years. Their history subsequent to this awaits further definition.

DETECTION OF MITRAL REGURGITATION BY DOPPLER ECHOCARDIOGRAPHY
Steve L. Johnson, MD; Donald W. Baker, BSEE; Robert A. Lute, BS; John A. Murray, MD, FACC, University of Washington, Seattle, Wash.

A range-gated pulsed Doppler flowmeter, with a 2x4 mm teardrop-shaped sample volume, was used to detect the presence or absence of mitral regurgitation (MR) in 58 sequential patients that underwent left heart catheterization and angiocardiography. Using the A-Mode display, the sample volume was positioned within the left atrium (LA), and at least 3 separate flow readings were obtained before MR was excluded. In MR there is a harsh systolic jet that sounds like steam escaping from a high-pressure pipe. Two of the 58 patients were excluded due to very poor ultrasound penetration, and 4 were excluded due to uncertainty concerning their catheterization results. In the remaining 52 patients, there was a negative Doppler study in 24, which consisted of 20 with no MR at catheterization and 4 false negatives, 3 of whom had minimal to mild MR and one with moderate MR. The other 28 patients had a positive Doppler test, and at catheterization 26 had clearcut MR and 2 had MR only with premature ventricular contractions. These latter 2 patients may be either false positives or may indicate that the Doppler test is very sensitive. This technique provides an indirect method for localizing the origin of cardiac murmurs, and in some patients makes further diagnostic studies unnecessary.

CORONARY HEMODYNAMICS, AND MYOCARDIAL PERFUSION AFTER REESTABLISHING CORONARY FLOW IN EXPERIMENTAL MYOCARDIAL INFARCTION
Jay M.M. Jarmakani, M.D., Jimmy L. Cox, M.D., Thomas C. Graham, D.V.M., and Donald B. Hackel, M.D., Duke University Medical Center, N.Carolina, UCLA Medical Center, Ca.

To determine the effect of varying periods of ischemia on coronary hemodynamics and regional myocardial flow, both phasic left circumflex coronary artery (LCCA) flow and regional myocardial flow using the radioactive microsphere (8-10μ) method were utilized in 3 groups of chronically prepared awake dogs: I, 60 minutes occlusion of the LCCA (n=6); II, 3 hours occlusion of LCCA (n=13); and III, 24 hours occlusion of LCCA (n=5). The aortic pressure, phasic LCCA flow and the electrocardiogram were monitored continuously before, during and after LCCA occlusion. Inner and outer regional myocardial flow were determined before (control) and during occlusion, 15 minutes after reestablishing LCCA flow, and 26 hours after occlusion. LCCA flow after releasing the snare was significantly increased in all dogs. Both coronary flow and hyperemic response to 20 second LCCA snare returned to normal in 30-60 minutes. During occlusion, the flow in the infarcted region was higher ($p<.001$) in the epicardial region (33$\pm$3% of control) than in the endocardial region (9$\pm$2%). 15 minutes after reestablishing flow, the infarcted region flow was significantly ($p<.01$) higher than control in groups I, II, but was significantly ($p<.001$) reduced in group III (22$\pm$15%). In group II the endocardial flow after releasing the snare decreased significantly ($p<.01$) from 137$\pm$6% to 37$\pm$8% 23 hours later and was not different from endocardial flow in group III. These data indicate that the histological changes produced by 3 hours of myocardial ischemia severely limits future myocardial perfusion, even if flow is reestablished after the initial ischemic period.

DOES RESTORATION OF BLOOD FLOW PRESERVE ACUTELY ISCHEMIC MYOCARDIUM? James Kane, MD; Marvin Murphy, MD, FACC; Joe Bissett, MD; James Doherty, MD, FACC; Karl Straub, MD. VA Hospital & Univ of Ark Med Center, Little Rock, AR.

Surgical intervention with bypass grafts has been advocated as treatment for acutely ischemic myocardium. The purpose of this study was to determine the length of time myocardium remains viable as measured by mitochondrial function after acute coronary occlusion and whether restoration of blood flow would salvage ischemic muscle. The left anterior descending coronary artery was occluded at its midportion in 27 pigs and then released at intervals varying from 15 minutes to 3 hours. One group of animals had a permanent ligation. The ischemic zone and blood flow were estimated by gross inspection, epicardial ECGs, vital dye stain, distribution of ^{3}H digoxin, and flow probe studies. Two hours after ligature release the beating heart was removed and a mitochondrial pellet prepared from ischemic and non-ischemic LV. Oxygen consumption, respiratory control ratio (RCR), and ADP/O were measured with malate and glutamate substrates. Results for ischemic tissue are expressed as a percentage of the control (glutamate):

LIGATION TIME-min	O_2 CONSUMPTION	RCR	ADP/O
15-30	68.4±11.6	97.9± 7.9	95.5± 3.0
60	29.4±19.6	62.6±16.8	92.2±13.0
120	25.6± 8.4	47.8±11.8	96.2± 9.6
180	9.6± 4.1	43.8±30.5	94.2±22.3
180-no release	19.4± 2.0	17.3± 4.2	72.3± 5.3

The results show marked impairment of mitochondrial function in the ischemic zone. The defect appears to be a block in electron transport (state 3 respiration) rather than uncoupling of oxidative phosphorylation and was not reversed by restoration of blood flow. The results suggest that irreversible myocardial damage occurs during the first 1-3 hours of coronary occlusion.

THE GENESIS AND NATURAL HISTORY OF THE SYSTOLIC MURMUR OF SAPHENOUS VEIN AORTO-CORONARY BYPASS TO THE LEFT ANTERIOR DESCENDING CORONARY ARTERY

Leonard Karpman, MD; William Kerth, MD, FACC, Pacific Medical Center, San Francisco, California

The systolic murmur (M) of saphenous vein aorto-coronary bypass (ACB) to left anterior descending coronary artery (LAD) was studied with an experimental, Hewlett-Packard recorder that synchronously averaged demodulated cardiac sound. M was recorded from the surface of an ACB in both surgery and the animal laboratory. M was obliterated by momentary distal graft occlusion. No M was detected from the surface of the aorta. Fifty-two pts with no preoperative M were recorded serially 3 to 15 months postoperatively. In 11 pts with ACBs to coronary arteries other than LADs, no M appeared. Twenty-four of 41 pts with ACB to LAD developed M. There was progressive diminution or disappearance of M with time. Of 10 pts with M followed for a year, M disappeared in 8 and diminished in 2. All pts with M at the time of ACB revisualization had patent grafts, as did the majority of those without M. We conclude that M is produced by systolic flow through ACB, persistence of M predicts graft patency, and absence of M has no predictive value. M diminution with time may reflect a change from turbulent to laminar flow.

LONG TERM FOLLOW UP WITH INTERNAL MAMMARY ARTERY BYPASS

Earle B.Kay,MD,FACC; H.Naraghipour,MD,FACC; M.DeManey,MD, FACC; A.Tambe,MD,FACC; H.A.Zimmerman,MD,FACC; St.Vincent Charity Hospital, Cleveland, Ohio.

Between January 1969 and August 1973, 529 internal mammary coronary artery bypasses were performed in 355 patients including single and double bypasses. In 137 patients requiring triple bypass the third bypass was a saphenous vein. Operative mortality during the past 3 years has been 1.7%. Seventy nine internal mammary (IMA) bypasses and 21 saphenous vein grafts (SVG) were studied in 52 patients 12 to 36 months after surgery for a patency rate of 97% for IMA and 81% for SVG. Blood flow was measured in 40 patients with 62 IMA bypasses and 10 SVG. The flow in IMA bypasses ranged between 20 to 135 cc per minute, an average of 61 cc per minute. The blood flow in 10 SVG ranged between 32 to 145 cc per minute, an average of 91 cc per minute. The average velocity flow in 62 IMA bypasses was 20 cm per second and for 10 SVG, 14 cm per second. Average velocity flow was also determined in the normal right coronary artery of patients without coronary artery disease. This was found to be 27 cm per second. Velocity is believed to be an important hemodynamic factor in relating blood flow to thrombus. Maximum flow velocity occurs through the graft when its diameter is equal to or only slightly larger than the artery to which it is anastomosed, assuming the absence of significant distal disease and obstruction. This can best be achieved by using the IMA rather than a SVG in the distal coronary anastomosis. The lower velocity in vein grafts tends to cause sluggishness of flow with a higher incidence of late thrombosis. Reactive hyperplasia also has not been seen with IMA bypasses.

LIMITATION OF CORONARY ANGIOGRAPHY AS A CRITERIA TO BYPASS SURGERY

Earle B.Kay.MD,FACC; H.Naraghipour,MD,FACC; R.A.Beg,MD; M. DeManey,MD,FACC; A.Tambe,MD,FACC; H.A.Zimmerman,MD, FACC: St.Vincent Charity Hospital, Cleveland, Ohio.

Coronary angiography, ventriculography and ventricular function studies are essential in cardiac evaluation of a patient with coronary artery disease being considered for bypass surgery. These studies have certain limitations. A non-visualized artery does not necessarily mean that a suitable vessel is not present to which a bypass anastomosis may be performed. Nor does a highly obstructed vessel proximally with only faint visualization of a narrow distal coronary artery mean distal disease rather than a poorly perfused artery. Nor does an acontractile or even a paradoxical area of the myocardium necessarily indicate that such an area is destroyed. Such responses may be the result of ischemia alone, particularly if the patient complains of angina. This study presents a broup of 50, out of 305 patients operated in the past 2 years, in whom distal coronary arteries were not visualized or so poorly visualized by either antegrade or retrograde flow that by previously accepted standards they would have been denied myocardial revascularization by bypass technics. These patients at the time of surgery had entirely satisfactory distal vessels to which adequate anastomoses were performed. Functional bypasses were corroborated by postop angiograms. Postop flow studies (over one year) were obtained in the majority of the group. Acontractile or paradoxical areas of myocardium as noted by ventriculography were inspected by cardiotomy. In approximately 50%, failure of contraction was due to ischemia which improved following restoration of the coronary circulation.

AN INTRACARDIAC GANGLIONIC DEPRESSOR REFLEX

Michael P. Kaye, MD; Gilbert R. Hageman, AB; and Walter C. Randall, PhD.
Loyola University Medical Center, Maywood, Ill. 60153

Many reflexes arising from the heart have been described. All such reflexes are apparently mediated through central connections of the autonomic nervous system. It is the purpose of this presentation to describe a negative inotropic reflex that is strictly intracardiac in nature. Acute experiments were performed on 13 anesthetized open chest dogs. Strain gauge arches were sutured onto both atria and both ventricles. Arterial blood pressure and lead II ECG were recorded. One to twenty micrograms of acetylcholine injected into a pulmonary vein induced marked decrease in left and simultaneously right atrial contractile force within 2 seconds without change in heart rate. Injection of acetylcholine into the superior vena cava induced a decrease in right atrial force only. To eliminate circulatory effects and possible central nervous system modulation, the vagus nerves and stellate ganglia were sectioned and the animal placed on total cardiopulmonary bypass. Acetylcholine injected into a pulmonary vein still induced a decrease in left atrial and simultaneously right atrial contractile force. Acetylcholine into a pulmonary vein of a dog which had undergone total preganglionic cardiac denervation induced similar changes indicating that this reflex is mediated by an intact parasympathetic postganglionic mechanism. Intravenous injection of the ganglionic blocking drug hexamethonium blocked the acetylcholine induced atrial depressions. Therefore it is concluded that acetylcholine stimulation of ganglionic cell bodies in the left atrium causes inotropic depression of both left and right atria thru a neural mechanism and acts as a negative intracardiac feedback mechanism in both the innervated and denervated hearts.

FAILURE OF SUCCESSFUL MYOCARDIAL REVASCULARIZATION TO ALTER LEFT VENTRICULAR FUNCTION

J. Ward Kennedy, MD; Karl E. Hammermeister, MD; Glen W. Hamilton, MD; Kenneth L. Gould, MD, University of Washington, Seattle, Wa.

55 consecutive patients with chronic angina pectoris were evaluated with biplane angiocardiography for determination of left ventricular volumes, ejection fraction (EF) and contraction pattern before and a median of 4 months following saphenous vein by-pass surgery. The total group was divided into subgroups based on graft patency and adequacy of revascularization as follows: At least one patent graft, 51 pts. All patent grafts, 40 pts, revascularization of all significant coronary lesions, 24 pts. Functional class improved in 82% of pts. Max treadmill performance showed significant improvement in 42 pts tested ($p < 0.001$). Ischemic ST response reverted to normal in 22/29 (76%) and remained negative in 8 others. End-diastolic volume was unchanged in the entire group, preop 84.7 ml/M^2, postop 81.4 ml/M^2, but was reduced significantly in the 24 pts with total revascularization, preop 80.8 ml/M^2 postop 70.9 ml/M^2 ($p < .01$). End-systolic volume, stroke volume and end-diastolic pressure, did not change following surgery. The mean EF was 50.5% preop and 49.5% postop in the entire group and did not change in any subgroup. Heart rate increased from 76 to 85.7/beats/min. ($p < .001$) in the whole and all subgroups. Cardiac index was normal preop and increased significantly in those pts with total revascularization, 3.19 to 3.30 L/min ($p < .01$). Analysis of contraction patterns revealed 35 unchanged, 10 improved and 10 worse following surgery. No subgroup showed consistent improvement. We conclude that partial or total myocardial revascularization fails to improve LV function in patients with chronic angina pectoris.

THE DISSOCIATION OF THE INOTROPIC EFFECT OF DIGITALIS FROM ITS EFFECT ON ATRIOVENTRICULAR CONDUCTION(AVC).

Young I. Kim,MD, R. Joe Noble,MD,FACC, Douglas P. Zipes,MD FACC and Charles Fisch,MD,FACC. Dept. Med., Indiana Univ. School of Medicine, Indianapolis, Indiana.

Sequential changes in left ventricular(LV)contractility and AVC were assessed in open chest dogs(with constant*atrial pacing)during administration of acetylstrophanthidin (AS)IV at 5 minute intervals(.005mg/Kg)until toxic arrhythmias developed. At each interval, a His electrogram, high fidelity LV pressure and its electronic derivative (dp/dt)were simultaneously recorded, and AV refractory period(AVRP)determined by graded trains of single stimuli. Three groups of 5 dogs each were studied:I.autonomic nervous system(ANS)intact(morphine anesthesia)II.ANS blocked (atropine and propranolol)and III.parasympathetic NS blocked(atropine). The linear regression analysis of the results calculated at control and after 25%,50%,75% and 100% of subtoxic dose of AS showed:

Group	max dp/dt	dp/dt 40 mmHg	SH*	AVRP
I	r=0.65	r=0.55	r=0.23	r=0.55
	P<.001	P<.005	NS	P<.005
II	r=0.75	r=0.78	r=-.80	r=0.15
	P<.001	P<.001	NS	NS
III	r=0.56	r=0.73	r=0.10	r=0.69
	P<.005	P<.001	NS	P<.001

Thus, the data indicated 1)dissociation of linearly related effects of AS on LV contractility from its effects on AV conduction(SH)and 2)dependency of AS induced changes in AVRP upon autonomic tone of AV node. Clinically, the data implicate that the dosage and serum level of digitalis required for heart failure may differ from that required for control of supraventricular arrhythmias,the therapeutic response of the latter largely dependent on ANS tone. *Atrial stimulus to His spike interval.

EFFECT OF ARTERIAL PRESSURE MANIPULATIONS ON SEGMENTAL WALL MOTION ABNORMALITIES IN ACUTE MYOCARDIAL ISCHEMIA.

Richard E Kerber, MD, Francois M Abboud, MD, FACC, University of Iowa Hospitals, Iowa City, Iowa.

The effect of alterations in blood pressure (BP) on segmental dyskinesis induced by acute coronary ligation was evaluated in open-chest anaesthetized dogs. Wall motion was recorded by ultrasound reflected directly off the ischemic muscle. Acute ischemia produced characteristic dyskinesis: aneurysmal bulging during isometric contraction and markedly reduced wall velocity (WV) during ventricular ejection. During ischemia the dogs received either methoxamine (M) to elevate BP 25-50% or nitroprusside (NP) to lower BP 25-50%. A control group (C) received no drug during ischemia. NP infusion resulted in improvement in WV (12.7±SEM 1.5 to 18.0±1.9 mm/sec, $p < 0.05$) while M caused WV to decline markedly (13.9±1.9 to 5.8±0.8 mm/sec, $p<0.01$). NP caused little change in aneurysmal bulging during isometric contraction of the ischemic area (3.4±0.2 to 3.2±0.2 mm, p=NS), but M reduced it as the entire ventricle dilated (4.3±0.5 to 2.7±0.7 mm, $p<0.05$). After 1 hour of ischemia the drug infusions were ended, the coronary ligation was released and the ischemic area reperfused. Dogs which had received NP showed more return of wall motion toward the control pre-ischemia state than did the dogs receiving M, but NP was not significantly better than C in this regard.

We conclude that the deleterious effects of increased afterload and/or cardiac depression with M outweighed the beneficial effects of increased coronary perfusion and resulted in more dyskinesis during ischemia and a poorer response to subsequent reperfusion. Decreasing afterload with NP improved wall motion during the period of acute ischemia, but the later improvement with reperfusion was not enhanced.

SUPPRESSION OF OUABAIN-INDUCED VENTRICULAR ECTOPY WITH VERAPAMIL AND REVERSAL WITH CALCIUM

Robert M. King, MD; Douglas P. Zipes, MD, FACC; Ann deB Nicoll, RN; James Linderman, The Krannert Institute of Cardiology, Department of Medicine, Indiana University School of Medicine, Indianapolis, Indiana.

Verapamil has been shown in vitro to block a slow ionic current carried by calcium and/or sodium, but not block the rapid current carried by sodium. We evaluated the efficacy of verapamil to suppress ouabain-induced ventricular ectopy in open-chested dogs. Lead II and bipolar epicardial electrograms were recorded from atria and ventricles. Right atrium and right ventricle were paced simultaneously at regular intervals for 10 beats, after which a premature ventricular stimulus was delivered or pacing suddenly terminated. Ouabain was administered IV in divided doses (total 40-60µg/kg) until a repetitive ventricular response (RVR) regularly followed a single premature ventricular stimulus, and an accelerated ventricular escape (AVE) regularly followed termination of ventricular pacing. Verapamil was then infused IV (10-30µg/kg/min) until RVR and AVE disappeared or their escape intervals were lengthened by approximately 50%. At this point, calcium gluconate or chloride (100mg/min) was infused IV. In 6 control dogs not given verapamil, RVR and AVE escape intervals remained fairly constant at least 3 hours following ouabain administration. In 14/16 dogs, verapamil completely suppressed RVR and AVE or lengthened the escape intervals by approximately 50%. Calcium antagonized the effects of verapamil by restoring RVR and AVE or by shortening their escape intervals in 8/8 dogs. We conclude that verapamil suppresses ouabain-induced RVR and AVE, and that calcium reverses the inhibiting effect of verapamil. Ouabain-induced ventricular ectopy, possibly analagous to transient depolarizations in vitro, may be due to transmembrane calcium flow of the slow current.

VENTRICULAR TACHYCARDIA AND VENTRICULAR EXTRASYSTOLES DURING THE LATE RECOVERY PHASE OF MYOCARDIAL INFARCTION

Robert E. Kleiger, MD; Thomas F. Martin, MD; J. Philip Miller, AB; G. Charles Oliver, MD, FACC, Washington University School of Medicine, St. Louis, Missouri

In order to determine the relationship between early premature ventricular contractions (PVCs) and ventricular tachycardia in patients recovering from myocardial infarction, we evaluated 141 patients serially with 10 and 24 hour Holter recordings obtained at monthly intervals. Patients were studied 2 weeks to 18 months after myocardial infarction. Tapes were scanned manually to detect: 1) PVCs, 2) early PVCs on the T wave of a preceding normal complex, and 3) complex ventricular dysrhythmias. Each tape was categorized as follows: 0, no PVCs; 1, < 10 PVCs/hr; 2, ≥ 10 PVCs/hr; 3, multiform PVCs; 4, couplets; 5, ventricular tachycardia. The distribution of classification was 0, 37%; 1, 19%; 2, 9%; 3, 26%; 4, 8%; and 5, 2%. Ninety-one % of the patients exhibited VPCs on one or more tapes. Sequential monthly tapes from the same patient yielded the same classification or differed by only 1 class in 75% of pairs analyzed (486/644). Thus, patients exhibited relatively constant types of ventricular dysrhythmias. Seven percent (56/845) of tapes and 27% (38/141) of patients exhibited at least one early PVC. The frequency of early PVCs was independent of both time after infarction and Lown classification. Ventricular tachycardia was observed 19 times in 14 patients. It was initiated by an early PVC only once. These results indicate 1) that ventricular tachycardia occurring during the late recovery period after myocardial infarction is only rarely initiated by early PVCs, 2) VPC patterns are generally stable over time and 3) almost all patients exhibit ectopic ventricular activity late after infarction.

PATHOGENESIS OF THE POST-ISCHEMIC T WAVE ABNORMALITIES

Chien-Suu Kuo, MD; Daniel F. Butler; Chia-Mao Chen, MD; Borys Surawicz, MD, FACC; University of Kentucky, College of Medicine, Lexington, Kentucky.

In myocardial infarction the stage of acute ischemia with ST segment deviation is usually followed by a post-ischemic stage with inverted T wave, prolonged QT interval and prolonged refractory period in the infarcted area. The cause of post-ischemic T wave changes is unknown but unlike other types of T wave abnormality, they persist after isoproterenol (ISP) infusion.

We studied ventricular monophasic action potentials (MAP) obtained by suction electrodes in open-chested dogs 3-10 days after applying an ameroid constrictor to the left coronary artery. At the time of study the ECG showed typical post-ischemic T wave changes with lengthening of the QT interval by 31±9 msec. but no significant change in QRS duration. After recording MAP's from the noninfarcted area (NI) and the vicinity of the infarcted area (I), ISP (2-5 μg) was injected i.v. to observe its effect on the T wave and MAP's. The hearts were then removed and transmembrane action potentials (TAP) were recorded by microelectrodes from I and NI tissues. In 19 experiments MAP duration in I exceeded that in NI by 32±16 msec. This was due to lengthening of phase 3 although phase 2 was shortened. TAP's showed similar phases 2 and 3 changes and decreased overshoot, but no change in resting membrane potential. After ISP infusion, MAP in NI shortened by 15±8 msec. and in I by 17±12 msec. (difference between the shortenings in NI and I MAP, N.S.) and the T wave abnormalities persisted.

We concluded that: 1) post-ischemic T wave abnormalities are caused by lengthening of phase 3 of ventricular AP in the vicinity of infarction, and 2) ISP does not abolish the difference between the ventricular AP durations in NI and I areas, and therefore does not reverse post-ischemic T wave abnormalities.

COMPARISON OF SURGICAL AND MEDICAL TREATMENT FOR OCCLUSIVE DISEASE CONFINED TO THE ANTERIOR DESCENDING CORONARY ARTERY

Nicholas T. Kouchoukos, MD, Albert Oberman, MD, Richard O. Russell, Jr., MD, FACC, W. B. Jones, MD, FACC, University of Alabama, Birmingham, Ala.

This study assesses the long-term course of 53 patients (pts) with angina pectoris, high-grade occlusive disease confined to the proximal anterior descending coronary artery (LAD), and absence of significant left ventricular dysfunction. Twenty-nine pts had saphenous vein bypass grafts to the LAD and 24 were managed medically following coronary arteriography. Two of the surgical pts (SP) sustained a myocardial infarction (MI) postoperatively and one late postoperatively (10%). There was one late death in the followup period (mean 20 mos). Twelve (41%) of the SP are free of angina and 11 (38%) have less angina. Nineteen pts had coronary arteriography postoperatively (mean 9 mos) and patent grafts (PG) were present in 13 (68%). Seven of 13 pts (54%) with PG and 3 of 6 (50%) with occluded grafts were free of angina. Of the 24 pts managed medically, there have been no deaths and one MI (4%) in the followup period (mean 32 mos). Five of the pts (21%) are free of angina and 12 (50%) have less angina. Bypass grafting in pts with isolated LAD disease is more effective than medical therapy in producing complete relief of angina. Isolated LAD disease in the absence of significant left ventricular dysfunction has a favorable prognosis with regard to death and incidence of myocardial infarction. The prognosis is not enhanced by bypass grafting.

LATE RESULTS OF SURGICAL TREATMENT FOR PREINFARCTION ANGINA.

Hillel Laks, MD; Lawrence Cohn, MD, FACC; Richard Gorlin, MD, FACC; Michael Herman, MD, FACC; John J. Collins, Jr., MD, FACC, Peter Bent Brigham Hospital, Boston, Massachusetts

Although medical therapy provides effective and safe treatment for most acute episodes of preinfarction angina (PIA), the course of patients followed for one or more years has shown a high incidence of myocardial infarction (MI) and death. Comparison of late surgical results is useful. Of 309 patients undergoing coronary revascularization at the Peter Bent Brigham Hospital from January 1971 to August 1973, 32 (10%) met the criteria for PIA. Of these, 23 had the intermediate coronary syndrome, while 9 had crescendo angina. Twelve patients had previous MI. Eleven patients had significant stenoses (>80%) of the main left coronary artery. Three patients had triple vein grafts, 18 double vein grafts, 9 single vein grafts, and 2 had internal mammary artery grafts to the left anterior descending coronary artery (LAD). In 10 patients, endarterectomy of the right coronary artery (RCA) was performed, and in 2, endarterectomy of the LAD. There were no surgical deaths. Three patients sustained in-hospital MI. A mean followup of 15 months was available for 28 patients 6 to 32 months after operation. There were no late deaths. Only one late MI has occurred. Twenty (71%) have excellent results (insignificant angina without medication and return to full occupation); three have good results (mild occasional angina), and 2 have returned to work. Three patients have fair results, and only 2 have persistent severe angina. Eight patients have had repeat angiography with excellent correlation between graft patency and functional status. These data suggest significantly less mortality and morbidity after surgery for PIA.

REGIONAL PATHOPHYSIOLOGIC EFFECTS OF MYOCARDIAL REVASCULARIZATION AFTER ACUTE CORONARY OCCLUSION

Tzu-Wang Lang, M.D., FACC; Samuel Meerbaum, Ph.D., FACC; Jules Osher, B.A.; Costantino Costantini, M.D.; Steven Rubins, M.D.; and Eliot Corday, M.D., FACC.
Cedars-Sinai Medical Center, Los Angeles, California.

The effects of coronary reperfusion (R) after 3 hours of LAD occlusion were determined in 7 closed chest dogs. Global and regional myocardial metabolism (M) and hemodynamics (H) were measured during intracoronary balloon occlusion of the LAD and after R. M in both the occluded (O) and nonoccluded (NO) zones were measured simultaneously with H. Significance ($p < 0.05$) is relative to pre-O control (*) and to 3 hours occlusion (†):

		Control	3 Hr O	5 Hr R
Systolic pressure (SP)(mmHg)		136	133	107*
LVEDP (mmHg)		6	11*	6
LV dP/dt (mmHg/sec)		2740	1840*	2270
Cardiac output (CO)(L/min)		3.3	2.3*	2.1*
SV resistance (d.s. cm^{-5})		2720	4365	3640*†
Stroke work (SW)(g·m)		47	34*	17*†
Lactate (A-V)/A	NO	41.0	28.1	22.2*
% extraction	O	38.7	20.9*	-2.9*†
Potassium (A-V) balance	NO	-0.07	-0.14	-0.21*
	O	-0.08	-0.16	-0.22*

Five hours of R caused significant further reduction in SP, CO, SW and SV resistance, as well as marked deterioration of M in O and NO segments in all 7 dogs. Two dogs developed shock. Following R, heart rate increased up to 57%. Arrhythmias developed in 6 dogs. The appearance of Q waves in the ECG and CPK elevations indicated further myocardial damage during R. Histopathologic studies demonstrated hemorrhages, reactive hyperemia, microthrombi and often accelerated necrosis.

These studies suggest that R after 3 hours of occlusion may adversely affect cardiac function and myocardial viability.

THE PROTECTIVE ZONE FOLLOWING ACUTE CORONARY OCCLUSION

Joseph Lanigan, MD; Guillermo A. Cook, MD; John V. Temte, MD, PhD; Bernard Lown, MD, FACC, Harvard School of Public Health, Boston, Mass.

Studies in this laboratory have shown that a second stimulus (S2) delivered during a critical interval following a fibrillatory stimulus (S1) protects an animal against ventricular fibrillation (VF). This critical interval has been called the protective zone (PZ). This study was designed to evaluate the PZ following coronary occlusion. Ten mongrel dogs were anesthetized with alpha-chloralose and a balloon catheter was placed around the left anterior descending coronary artery (LAD). Epicardial electrodes (4 dogs) and right ventricular endocardial electrodes (6 dogs) were positioned and heart rate maintained constant at 220 beats/min. The vulnerable period (VP) and PZ were mapped with unipolar cathodal square wave pulses by variably coupling to pacemaker spikes. The PZ was determined by delivering S1 in the midpoint of the VP with stimuli 20 mA above VF threshold. S2 was variably coupled to S1 and the PZ boundaries mapped. The LAD was occluded and the PZ was determined at 0-3 min, 3-6 min, 6-10 min, and upon release. Narrowing of the PZ occurred after occlusion of the LAD whether determined endocardially ($P < 0.001$) or epicardially ($P < 0.05$). Upon release the PZ returned toward control values. Five additional dogs were studied using a 3-stage LAD occlusion and epicardial electrodes. The VP and PZ were determined at 30-60 min and 120-150 min. A significant constriction of the PZ ($P < 0.01$) and lengthening of the VP ($P < 0.05$) occurred at 30-60 min. At 120-150 min both the VP and PZ had returned to control values. The lengthening of the VP duration and coincident abbreviation of the PZ may be factors contributing to the emergence of VF following coronary occlusion.

CONCEALED INTRAVENTRICULAR CONDUCTION (CIVC) IN THE HUMAN HEART.

Richard Langendorf, MD, FACC; Alfred Pick, MD, FACC, Cardiovascular Institute, Michael Reese Hospital and Medical Center, Chicago, Illinois.

Partway (concealed) penetration of supraventricular or ventricular impulses into the intraventricular conduction system has been demonstrated in animal experiments and also occurs in the human heart. However, its numerous manifestations in clinical electrocardiography as deduced from its aftereffects, in a manner analogous to concealed A-V conduction, have not as yet been systematically evaluated. The following classification of CIVC is proposed, based on the direction and timing of the impulse and the presence of unidirectional bundle branch block (BBB): (A) Transseptal retrograde CIVC, responsible for 1) perpetuation of functional BBB and aberrant ventricular conduction (AVC), 2) alternation of AVC in supraventricular bigeminy, 3) normalization of intraventricular conduction with acceleration of rate in bradycardia-dependent BBB, and 4) prevention of the manifestation of Wenckebach periods in a bundle branch or fascicle. (B) Antegrade CIVC, responsible for 1) prevention of expected AVC when a short cycle follows a long one, and 2) exceptions to the "rule of bigeminy." (C) Retrograde CIVC of a ventricular escape in association with unidirectional bundle branch or fascicular block, responsible for 1) resumption of A-V conduction in "paroxysmal A-V block" with BBB, and 2) facilitation (supernormality) of A-V conduction in type II A-V block due to bilateral BBB. (D) CIVC of a premature ventricular impulse, responsible for 1) initiation or termination of a reentrant ventricular tachycardia, 2) resetting of an idioventricular pacemaker, and 3) pseudo-intraventricular or pseudo-A-V block. Representative examples in clinical electrocardiography will be demonstrated.

TRANSMEMBRANE POTENTIALS IN THE HIS BUNDLE AFTER CORONARY OCCLUSION

Ralph Lazzara, MD; Benjamin J. Scherlag, PhD; Nabil El-Sherif, MD, Mount Sinai Medical Center, Miami Beach and Veterans Administration Hospital, Miami, Florida

In the first four hours after occlusion of the anterior septal coronary artery, 9 dogs developed bundle branch block and/or heart block. The hearts were excised and preparations dissected to include the His bundle (Hb) and bundle branches. Eight uninfarcted dogs were similarly prepared for comparison. In the Hb and most proximal bundle branches resting potentials (RP) were reduced and diminutive action potentials (AP) had slow upstrokes often with notches or steps. AP sometimes showed distinct rapid and slow components. In more severely affected cells refractoriness had a time-dependent component which outlasted the AP resulting in a departure from voltage-dependent behavior. Encroachment upon this time-dependent refractory period resulted in further diminution of upstroke velocity and amplitude of the AP and progressive prolongation of foot potentials in a Wenckebach periodicity (WP). AP recorded proximal to the site of delay showed late humps during WP. Rapid stimulation could produce repetitive decremented AP and repetitive block (paroxysmal block). Mobitz II block was rarely observed. Automaticity in the Hb was not enhanced and pacemaker function was disturbed. The threshold potential was not constant during phase-4 and pacemaker potentials sometimes were intermittently diminutive resulting in intermittent failure to propagate ("generator dysfunction")- the electrophysiological correlate of concealed escape. There was functional dissociation of nearby cells so that electrotonic interaction might occur while propagation was blocked. Electrotonic interactions could influence pacemaker firing by summation. In summary, ischemia resulted in disturbance in conduction, automaticity, and cell interaction in the Hb.

THE ANATOMIC BASE OF LEFT BUNDLE BRANCH BLOCK

Maurice Lev, MD, FACC; Paul N. Unger, MD, FACC; Kenneth M. Rosen, MD, FACC; Saroja Bharati, MD, Hektoen Institute for Medical Research, Chicago, Ill.

The anatomic base of left bundle branch block (LBBB) is at present disputed. Accordingly the entire conduction systems of 8 hearts diagnosed electrocardiographically as having LBBB were studied histologically by serial section.

In all cases total or subtotal destruction of the connection between the left main bundle and the bundle of His was found. Pathologic change in the left bundle branch (LBB) more distally was also present. There was no difference in histologic findings between cases with and without left axis deviation. Pathologic change in other parts of the conduction system was not constant.

Five cases had severe atherosclerotic narrowing of 3 main coronary arteries, 1 of 2, and 1 of 1 coronary artery. All 7 of these cases had old and 5 had recent infarction, both anteroseptal and posteroseptal. Two were associated with hypertension in addition. The eighth case had rheumatic heart disease.

This study therefore shows that (1) there is an anatomic base in the conduction system in most if not all cases of LBBB, (2) the lesions found are in the main left bundle or predivisional and (3) the lesions are pathogenetically both ischemic and mechanical. The mechanical factor is related to the vulnerability of the beginning of the LBB to mechanical stresses at the summit of the ventricular septum, exacerbated by hypertension, sclerosis of the left side of the cardiac skeleton, and by infarction of the septum.

DIFFERING EFFECTS OF PROPRANOLOL, DIGOXIN AND COMBINED THERAPY IN PATIENTS WITH ANGINA PECTORIS

Martin LeWinter, MD; Michael Crawford, MD; Joel Karliner, MD, FACC; John Ross, Jr., MD, FACC; Robert O'Rourke, MD, FACC
University of California, San Diego, California

Using a single blind protocol, we treated 15 stable angina pectoris (AP) patients (pts) for 2 weeks with propranolol (P, 160 mg/day), digoxin (D, 0.5 mg/day) and P plus D. This sequence was preceded and followed by 2 weeks of placebo therapy. The radiographic left heart dimension (LHD), treadmill exercise response, and mean AP attack rate/week (AP/wk) were followed serially. Serum D levels were consistently in therapeutic range (0.5 to 2.0 mg/ml). During P alone, average resting heart rate (HR) decreased from 64 to 54 beats/min ($p<.001$), HR-systolic blood pressure (BP) product at the end of treadmill exercise decreased from 21.0 to 14.7×10^3 ($p<.001$), and LHD increased from 46.7 to 47.9 mm/M^2 ($p<.01$). Thirteen of the 15 pts (5 of whom had impaired left ventricular (LV) function) improved on P, AP/wk decreasing from 17 to 6 ($p<.03$); 3 pts no longer had chest pain with treadmill exercise and no pts developed X-ray evidence of pulmonary venous congestion. With P plus D, resting HR, HR-BP product, and AP/wk were the same as with P alone, but LHD decreased in 9 of 15 pts, despite the persistence of resting bradycardia. D alone decreased LHD and HR-BP product from control values ($p<.05$) but AP/wk increased in 7 of 15 pts (47%) from 5 to 15. In 3 pts with impaired LV function, D decreased AP/wk and in the 5 remaining pts AP/wk was unchanged. We conclude that P produces objective and subjective improvement in unselected AP pts without inducing cardiac failure, despite an increase in LHD. The addition of D often reduces the LHD without diminishing the effectiveness of P in these pts, but when used alone, D can aggravate AP.

NOREPINEPHRINE INFUSION FOLLOWING CORONARY OCCLUSION: ISCHEMIC INJURY LIMITED BY ENHANCED COLLATERAL FLOW

Jay A. Levine, MD; Michael V. Cohen, MD; Edward S. Kirk, PhD, Peter Bent Brigham Hospital, Boston, Mass.

Norepinephrine (NE) has been used widely for the treatment of cardiogenic shock. However, NE, by raising blood pressure and myocardial contractility, increases myocardial oxygen demand. Unless oxygen supply increased correspondingly, ischemic injury following coronary artery occlusion would be augmented. To evaluate the effect of NE on the balance of supply and demand in ischemic myocardium, measurements were made shortly after coronary artery occlusions in anesthetized, open-chest dogs. Collateral blood flow was measured in 10 dogs by the clearance of ^{133}Xe from 0.01 ml depots of saline injected into the ischemic area; and myocardial injury was indicated by the sum of the S-T segment elevations in epicardial electrograms recorded from multiple sites in 6 dogs. Intravenous doses of NE (20-50 µg/min) which increased contractile force and left ventricular dP/dt 2 to 3 fold, and increased mean aortic pressure by 10%, caused only minor increases in myocardial injury. The local energy balance appeared to be maintained in the ischemic area. Accordingly, NE significantly enhanced collateral flow: the half-time for ^{133}Xe clearance decreased from a control of 2.7 min to 1.6 min ($P<0.05$). In contrast, doses of isoproterenol having similar inotropic effects greatly increased ischemia and decreased clearance. We conclude that the ability of NE to enhance collateral flow counters its effect on myocardial metabolism. The clinical usefulness of NE may depend on the balance of these opposing effects.

BENEFICIAL EFFECT OF INTRAVENOUS ATROPINE IN THE PREHOSPITAL PHASE OF ACUTE MYOCARDIAL INFARCTION

Richard P. Lewis, M.D., FACC and James V. Warren, M.D., FACC, The Ohio State University College of Medicine, Columbus, Ohio.

Recent animal studies of experimental myocardial infarction (MI) have suggested that atropine (A) may be undesirable in the presence of acute ischemia. The development of a mobile coronary care system has allowed clinical evaluation of A in the earliest stage of acute MI. Seventy patients (pts) with bradyarrhythmia (BA) defined as any rhythm with HR < 60 were studied. Fifty-six percent were seen within 1 hour of onset of symptoms. The pts were divided according to systolic blood pressure (SBP) and treatment (Rx). Six pts received isoproterenol (I) as well as A. The average dose of A was 0.86 mg (0.4-2.0 mg).

SBP	Rx	n	Mean HR	Mortality
NL	A	23	50 ± 8 (SD)	13%
NL	none	21	53 ± 7	14%
<100 mmHg	A	16	47 ± 10	25%
<100 mmHg	A & I	6	33 ± 9	33%
<100 mmHg	none	4	51 ± 5	75%

In the 16 hypotensive pts treated only with A, 9 were restored to nl BP and HR. The mortality for these pts was only 11%. A HR response >100 occurred in only one treated pt. There were two unexpected episodes of ventricular fibrillation (VF) in the untreated normotensive pts and only 1 in the treated normotensive group. Only 12% of untreated pts had a spontaneous remission of BA. After hospitalization BA recurred in 80% of pts who had initially been restored to normal by A. Thus the tendency for BA in the early phase of MI is persistent. In conclusion, atropine did not affect mortality when BP was normal but may have reduced the incidence of VF. Atropine clearly reduces mortality when hypotension is present.

FACTORS DETERMINING MORTALITY IN THE PRE-HOSPITAL PHASE OF ACUTE MYOCARDIAL INFARCTION

Richard P. Lewis, M.D., FACC and James V. Warren, M.D., FACC, The Ohio State University College of Medicine, Columbus, Ohio.

Two hundred seventy-four patients with acute myocardial infarction (AMI) seen by a mobile coronary care system were analyzed to determine the major variables influencing mortality. Forty-eight percent were seen within one hour of onset of symptoms. Fifteen had ventricular fibrillation on arrival and of these 53% were long-term survivors. In the remaining 259 the initial systolic blood pressure (SBP) was the most important determinant of mortality.

Mortality According to Initial BP and HR

	HR < 60	HR 61-100	HR >100	TOTAL
SBP < 100 (n = 46)	36%	67%	83%	61%
Normal SBP (n = 123)	15%	11%	26%	18%
SBP >160 (n = 90)	0%	16%	8%	10%
TOTAL	24%	17%	27%	

Chi-squared 2 x 3 contingency analysis showed that the progressively decreasing mortality with increasing BP was highly significant ($p < 0.0005$). Of interest, the presence of ectopic rhythms or heart block (67% of which were treated) did not influence mortality within each subgroup. When the hypotensive group was excluded from analysis, patients seen < 1 hr. after onset of symptoms had a lower mortality (8.6%) than those seen >1 hr. (19.6%, $p = 0.04$). Patients (pts) under age 65 had a lower mortality than older pts (9.5% vs 21%, $p = 0.026$). The group with ↓ BP had a higher incidence of subendocardial MI (40% for ↓ BP, 25% for normal BP, 9% for ↑ BP) ($p < 0.005$) and of peak SGOT values < 100 unit (48% for ↓ BP, 25% for normal BP, and 25% for ↑ BP) ($p < 0.001$). Thus pts with initial ↓ BP have a better prognosis which appears to be related to smaller sized MI.

MECHANISM AND SIGNIFICANCE OF WIDENED QRS COMPLEXES DURING COMPLETE AV BLOCK IN ACUTE INFERIOR MYOCARDIAL INFARCTION.

K. I. Lie, M. D., H. J. Wellens, M. D., FACC, R. M. Schuilenburg, M. D., and D. Durrer, M. D., FACC. Dept of Cardiology and Clinical Physiology, Wilhelmina Gasthuis, Amsterdam, The Netherlands.

35 out of 225 consecutive patients (pts) with acute inferior myocardial infarction (IMI) developed complete AV block. 12 of these had widened QRS complexes (WQRS) in escape beats (EB). 4 pts showed left bundle branch block (LBBB) configuration, 5 right bundle branch block (RBBB) configuration and 3 both LBBB and RBBB in EB. 3 of 7 pts with LBBB in EB showed during second degree AV block also LBBB in conducted beats, after critical lengthening of RR interval. His bundle (H) recordings, made in 5 of 7 pts with LBBB, all showed a H potential preceding the LBBB shaped EB at HV intervals of 45 - 60 msec. These intervals were equal to those measured later after resumption of 1 : 1 AV conduction. Bradycardia dependency of LBBB in EB was demonstrated in 2 pts by H pacing. Ischaemic phase 4 block could have been responsible for LBBB. LBBB occurred exclusively during AV block and not during sinusbradycardia even at slower ventricular rates. In contrast to LBBB, H recordings made in 6 of 8 pts with RBBB, showed in none a H potential preceding the RBBB shaped EB, whereas the RBBB shaped escape rhythm (ER) occurred together with or even dominated the AVJ ER. Our observations revealed that in pts with WQRS during complete AV block in IMI, the site of AV block was always located in the AVJ. WQRS could either be due to an AVJ ER with phase 4 LBBB or to a ventricular ER alternating with the AVJ ER. 2 of 12 pts with WQRS died. There were no significant differences in immediate, 6 months mortality and mean peak SGOT between pts with narrow and with WQRS, suggesting that WQRS during complete AV block in IMI has no prognostic significance.

INCREASED MYOCARDIAL ISCHEMIC INJURY DURING INSULIN INDUCED HYPOGLYCEMIA.

Peter Libby, MD; Peter R. Maroko, MD, and Eugene Braunwald, MD, FACC, Dept Med, Harvard Med Sch and Peter Bent Brigham Hosp, Boston, MA.

Increased glucose supply reduces myocardial ischemic damage following coronary occlusion, but the effect of hypoglycemia is unknown. Accordingly, in 6 open chest dogs 2 serial 20 min occlusions of the left anterior descending coronary artery were performed. The first occlusion served as control (CON) and the second was carried out 15 min after regular insulin (INS) administration (2.5-3u/kg i.v.). The extent and severity of myocardial ischemic injury were determined by epicardial electrocardiography 15 min after each occlusion at 12-16 sites on the left ventricle. While blood glucose fell from 76±8(SEM) (CON) to 37±4mg%(INS) ($p<.01$), the average ST segment elevation rose from 3.8±0.9(CON) to 6.3±1.2mV(INS) ($p<.05$) and the number of sites with ST segment elevation>2mV rose from 8±1(CON) to 11±1(INS) ($p<.05$). Heart rate and mean arterial pressure did not change significantly (from 146±11 to 135±5beats/min and from 113±10 to 93±5mmHg, respectively). In 15 dogs with permanent occlusions, ST segment elevation 15 min after occlusion was compared to myocardial creatine phosphokinase activity (CPK) at the same site 24 hrs later. With occlusion alone, logCPK=-0.095ST +1.57(N=95specimens, r=-.8), showing that ST segment elevation reliably predicts subsequent local CPK. In dogs receiving INS starting 30 min after occlusion, CPK was lower than expected in the area which had acute ST segment elevation and CPK depletion extended to 50% (10/20) of specimens predicted by EKG to be normal. Hypoglycemia increases myocardial damage following coronary occlusion, supporting the importance of glucose availability to cellular survival and suggesting the potential dangers of hypoglycemia in diabetic patients with ischemic heart disease.

EIGHT TO TWELVE YEAR FOLLOW-UP OF 100 PATIENTS WITH FIXED-RATE PACEMAKERS.

Janet Lipski,MD;Mark Stern;Robert Litwak, MD,FACC;Simon Dack,MD,FACC;Ephraim Donoso,MD,FACC.Mt.Sinai School of Medicine of the City University of New York,N.Y.

This is an 8 to 12 yr follow-up of 100 consecutive patients(pts) with fixed rate pacemakers(P) implanted from 1961-65 for complete heart block(CHB)and Stokes-Adams syndrome(SA). Ages ranged from 6-91 yrs. with 91% of pts.> 58 yrs. Myocardial infarction(MI) or angina pectoris was present in 45, hypertension in 13, valvular disease in 6, congenital disease in 4, unknown cause in 28, miscellaneous in 4. Post P 10 of 49 (20.4%) died of non-cardiac disease (NCD). Av. ages of 27 survivors is 80.2 yrs. There was 1 P insertion in 1961, pt lost to follow-up(LTF) after 4 yrs. In 1962: 3 P were implanted. Death was 3,5, and 8-1/2 yrs respectively post P; sudden death (SD) occurred in 2, acute pulmonary edema(APE) in 1. Av. age of death was 76 yrs. In 1963: 32 P implanted. Nineteen pts died-5 pts lived<1 yr, 8 pts 1-5 yrs, 1 pt 5-7 yrs, 5 pts 7-9 yrs; hospital death(HD) in 2, SD in 8, APE in 3, acute MI(AMI) in 3, runaway P in 1, NCD in 2. Av. age of death was 76 yrs. Five pts were LTF, 2 after discharge (D), 2 after 1 yr and 1 after 3 yrs. Eight of 32(25%) are alive-2>9 yrs and 6>10 yrs. In 1964: 28 P implanted. Eleven died-4 lived<1 yr, 5 pts 1-5 yrs, 1 pt 5-7 yrs, 1 pt 7-9 yrs; HD in 1,SD in 5, AMI in 1, runaway P in 1, NCD in 3. Av. age of death was 73 yrs. Ten were LTF-5 after D, 2 after 1 yr, 1 after 2 yrs, 1 after 4 yrs, 1 after 6 yrs. Seven of 28(25%) are alive> 9 yrs. In 1965: 36 P inserted. Sixteen pts died-six lived<1 yr, 6 pts 2-5 yrs, 2 pts 5-7 yrs, 2 pts 7-9 yrs; SD occurred in 7, HD in 1, AMI in 3, NCD in 5. Av. age of death was 69.5 yrs. Eight pts were LTF-3 after D, 1 after> 1 yr, 1 after 3 yrs, 3 after 4 yrs. Twelve of 36 pts (33%) are alive> 8 yrs. In summary, long term follow-up of pts with CHB and SA indicated that P implantation significantly improves hospital mortality and longevity as compared to a previous report of a similar series in this institution prior to P era.

ACUTE EFFECTS OF EXTERNAL COUNTERPULSATION ON THE RELATIONSHIP BETWEEN MYOCARDIAL OXYGEN DELIVERY AND REQUIREMENT IN PATIENTS WITH CORONARY ARTERY DISEASE

Henry S. Loeb, M.D., FACC; Mushtaq Khan, M.D.; William Towne, M.D.,; Rolf M. Gunnar, M.D., FACC, Veterans Administration Hospital, Hines, Ill. and Loyola University Stritch School of Medicine, Maywood, Ill.

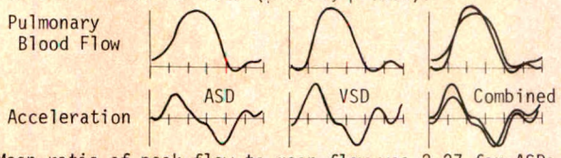
Hemodynamic studies were performed in 22 patients (pts) with stable coronary artery disease (CAD) prior to and during external counterpulsation (ECP). During ECP peak and mean arterial diastolic pressure (ADP) were significantly increased ($p < .01$) by 28 ± 3mmHg and 8 ± 2mmHg (mean ± SEM) respectively. Coronary sinus flow (CSF) measured by continuous thermal dilution in 17 pts averaged 119 ± 16cc/min prior to ECP and 113 ± 13cc/min during ECP. Parameters measured which relate to myocardial oxygen requirement were: left ventricular stroke work index (LVSWI) which increased 4 ± 3%, the product of peak arterial systolic pressure and heart rate (double product) which increased 1 ± 3% and pulmonary capillary wedge pressure (PCWP) (10 pts) which fell 1.6 ± 0.8mmHg. None of these changes were significant ($p > .05$). Arterial and coronary sinus lactate was measured in 13 pts. Four of seven pts who had abnormal (<10%) lactate extraction (L-Ext) before ECP changed to normal L-Ext during ECP, however two of six pts with normal L-Ext before ECP developed abnormal L-Ext during ECP. These changes in L-Ext during ECP were not correlated with simultaneous changes in CSF, LVSWI or double product.

Conclusion: In pts with stable CAD, ECP increases peak and mean ADP but does not augment CSF, fails to reduce the indices of myocardial oxygen requirement and does not consistently improve myocardial lactate metabolism. Based upon these findings the ability of ECP to acutely reverse ischemia in pts with unstable angina or to limit the size of infarction in pts with acute myocardial infarction remains in doubt.

CONTRASTING PULMONARY BLOOD FLOW PROFILES IN CHILDREN WITH ATRIAL AND VENTRICULAR SEPTAL DEFECTS

Carol L. Lucas, PhD; Benson R. Wilcox, MD; Norman A. Coulter, MD, Univ. of North Carolina, Chapel Hill, N.C.

To better understand the difference in pulmonary vascular response to left to right shunts, instantaneous pulmonary artery (PA) flow profiles were studied in 9 children with atrial and 9 with ventricular septal defects (ASD & VSD) at time of defect closure. Groups were comparable in age (4-9 yrs), BSA, and mean PA pressure, flow, and resistance. Parameters related to blood flow and acceleration rate profiles were studied in the time domain; Fourier analysis was used to examine the waveforms in the frequency domain. Average systolic time was essentially the same, ASDs=.34 sec, VSDs=.33 sec. Peak acceleration and flow rates were reached at .07 sec and .17 sec respectively for ASDs and .04 and .13 sec for VSDs ($p=.024$; $p=.036$).



Mean ratio of peak flow to mean flow was 2.27 for ASDs vs. 2.58 for VSDs ($p=.024$); mean ratio of peak acceleration to mean flow was 29.8 for ASDs and 38.2 for VSDs ($p=.06$). Mean normalized flow moduli (modulus/mean flow) of the 3 harmonics were higher for the VSDs. Average difference in phase angle between the 1st and 2nd harmonic was -2.22 radians for ASDs and -1.60r for VSDs ($p=.004$). These differences in profiles of instantaneous PA blood flow in ASDs and VSDs, in spite of comparable mean pressure and flow values, may be a key to understanding the difference in pulmonary vascular response to these two defects.

THE RELATIONSHIP BETWEEN CORONARY PERFUSION PRESSURE, FLOW, AND RESISTANCE IN STENOSED HUMAN CORONARY ARTERIES: THE CRITICAL IMPORTANCE OF SMALL CHANGES IN % STENOSIS.

Samuel E. Logan, PhD; John V. Tyberg, MD, PhD, William W. Parmley, MD, FACC; H.J.C. Swan, MD, PhD, FACC. Cedars-Sinai Medical Center, Los Angeles, California 90029.

Nineteen proximal coronary arteries with varying focal stenoses (2%-98%) were dissected from fresh post mortem adult hearts and perfused with isotonic glycerol saline (n=2.7 centipoise) at constant pressures of 30, 50, 75, 100, 150 and 200 mmHg, while varying the distal bed resistance (r_b) over the range 0.1 to 5 mmHg/ml/min. Flow rate (Q) and arterial segment pressure drop (ΔP) were measured at each perfusion pressure and r_b, and a permanent cast of silicone rubber was made under 100 mmHg pressure following perfusion. Hydraulic resistance ($R=\Delta P/Q$) was proportional to a Poiseuillian scaling ($R_o \alpha 1/r4$) at lowest flow rates (10-30 ml/min), with resistance increasing to 2 or 3 times R_o at higher flow rates (30-100+ ml/min). Curves of flow rates vs. % stenosis showed that flow rate was relatively constant with stenoses less than 70-80%. With a small further increase in stenosis, however, flow rate decreased dramatically. Furthermore, significant reductions in flow rate occurred at lower % stenoses for greater demands (lower r_b). Elastic effects were important in arteries with an eccentric lesion, in that an 80% eccentric stenosis had an additional flow loss of 5% (as compared to a concentric stenosis) when the perfusion pressure was lowered from 100 to 70 mmHg. In conclusion, small changes in % stenosis, perfusing pressure, or increased "demand" (decreased r_b) had dramatic effects on the pressure-flow relationship across focal lesions in human coronary arteries. These results have important implications relative to the quantitation of lesions on coronary angiograms, the alteration of perfusing pressure or changes in myocardial O_2 demand.

IMPROVEMENT IN LEFT VENTRICULAR WALL MOTION ABNORMALITIES AFTER NITROGLYCERIN.

John H.McAnulty,MD, Mark T.Hattenhauer,MD,Josef Rösch,MD,Frank E.Kloster,MD, S.H.Rahimtoola,M.D.,FAAC,University of Oregon Medical School,Portland,Oregon.

The effects of nitroglycerin (NTG) on left ventricular (LV) wall motion abnormalities (WMA) were evaluated in 18 patients. Twelve had coronary artery disease (CAD) (70% stenosis of at least one coronary artery) and 10 of these had asynergy while 2 had normal wall motion. Of 6 with normal coronary arteries, 5 had normal wall motion and one had diffuse hypokinesis from a cardiomyopathy. LV cineangiography was performed prior to and 6 minutes after 0.4 mg. of NTG given sublingually. Heart rate increased in all patients (mean 14.5 beats/min) and arterial pressure fell (mean 22 mmHg.).

Asynergy was shown on the initial LV angiogram in 10 of the 12 CAD patients and in 6 of these (5 with hypokinesis and 1 with akinesis) the WMA improved after NTG. In these 6 the ejection fraction (EF) rose (mean 0.15) as did the mean circumferential fiber shortening rate (MCFSR), a mean of 6.0 cm/sec. In the 4 who showed no improvement, the increase in EF and MCFSR were less, averaging 0.05 and 1.6 cm/sec respectively.

One patient with generalized hypokinesis from a cardiomyopathy and no CAD showed no improvement in wall motion, EF, or MCFSR following NTG.

The 7 patients with normal LV wall motion (2 with CAD) showed no change with NTG. Small increases in EF (mean 0.04) and MCFSR (mean 3.8 cm/sec) occurred after its use.

NTG has potential value diagnostically in identifying areas of WMA that may be reversible. It may have value therapeutically in improving LV function.

MAXIMAL CARDIAC OUTPUT BEFORE AND AFTER CORONARY ARTERY SURGERY IN PATIENTS WITH ANGINA

John R. McDonough, M.D., F.A.C.C., Ruth Ann Danielson, B.A., and Richard K. Foster, M.D., U.S. Public Health Service Hospital and University of Washington School of Medicine, Seattle, Washington.

Oxygen intake ($\dot{V}O_2$), oxygen content of arterial and mixed venous blood ($\bar{A}$-$\bar{V}O_2$), cardiac output ($\dot{Q}$), heart rate (HR), stroke volume (SV), and systemic and pulmonary arterial pressures were measured in 10 angina patients aged 48-63 years, at one minute intervals during multistage exercise to the point of exhaustion. Fifty-seven control (C) measurements of exercise $\dot{Q}$ were made before surgery, and 65 exercise $\dot{Q}$ measurements were made 6 months after surgery (S). All patients experienced relief of angina and subjective improvement in exercise tolerance following surgery. Maximal values (mean and S.D.) were as follows:

Duration (sec) C = 581 ± 112, S = 673 ± 118, P< .01
$\dot{V}O_2$ (L/min) C = 1.534 ± 0.38, S = 1.713 ± 0.56, P< .01
$\dot{Q}$ (L/min) C = 12.84 ± 3.19, S = 13.62 ± 3.60, P< .01
$\bar{A}$-$\bar{V}O_2$ (ml/L) C = 120 ± 13.9, S = 124 ± 19.9, P> .3
HR (b/min) C = 133 ± 12.4, S = 160 ± 16.2, P< .001
SV (ml) C = 97 ± 25.6, S = 85 ± 19.1, P< .001

The data indicate significant improvement in exercise capacity, maximal $\dot{V}O_2$, and maximal $\dot{Q}$ following coronary artery surgery. The marked change in maximal HR may reflect improved coronary blood flow following surgery, while the unexpected but significant decrease in SV might indicate an adverse surgical effect on the myocardium.

CLINICAL SIGNIFICANCE OF TREADMILL EXERCISE INDUCED VENTRICULAR ARRHYTHMIAS

Paul L. McHenry, MD, FACC; Stephen N. Morris, MD; Morton Kavalier, MD, Indiana University School of Medicine, Indianapolis, Indiana

The incidence of treadmill exercise induced ventricular arrhythmias (EIVA) was studied in 360 patients (pts.) undergoing left heart catheterization and coronary arteriograms (CA) for known or suspected coronary heart disease (CHD). Clinically all pts. had exertional angina or had experienced episodes of chest pain. Only pts. with normal sinus rhythm and no ventricular premature complexes (VPC) at rest were included in the study. All were exercised until the onset of chest pain of their usual day to day intensity or until they reached at least 90% of their predicted maximal heart rate. A dual lead ECG was recorded on magnetic tape and the incidence, frequency and classification of EIVA was determined. The CA were normal in 149 pts. and all were free of evidence of other types of heart disease. The remaining 211 pts. had greater than 50% stenosis of one or more coronary arteries. EIVA were observed in 37 non-CHD pts. (25%) and 80 CHD pts. (38%). Of the 117 pts. with EIVA, 32% were non-CHD pts., 68% CHD pts. Frequent VPC (> 10/min.) were observed in 2% of non-CHD pts., 4% of CHD pts. Exercise suppression of EIVA at progressive workloads and heart rates occurred in 41% of non-CHD pts., 42% of CHD pts. The EIVA were paired or from 2 foci in 30% of non-CHD pts. and 34% of CHD pts. Ventricular tachycardia (VT) and multiple, multifocal VPC were observed almost exclusively in CHD pts. but the overall incidence was only 8% (17 of 211). These data suggest that EIVA do not differentiate between chest pain pts. with CHD and non-CHD except when VT or multiple, multifocal VPC are observed.

RUBIDIUM-81, A NEW AGENT FOR MYOCARDIAL PERFUSION SCANS AT REST AND EXERCISE, AND COMPARISON WITH POTASSIUM-43.

Ronald L. McGowan, M.D., Neil D. Martin, M.D., Barry L. Zaret, M.D., Harry P. Wells, and M.D. Flamm, M.D., FACC. David Grant USAF Medical Center, Travis AFB, CA 94535

Although myocardial imaging with potassium-43 (^{43}K) has been established as an effective method for noninvasive evaluation of regional myocardial perfusion both at rest and at exercise, undesirable production characteristics of ^{43}K, limiting its availability, warrant a search for an effective substitute radionuclide. Rubidium-81 (^{81}Rb) is more easily produced than ^{43}K, therefore cheaper and more readily available. This report details our preliminary experience with ^{81}Rb for myocardial perfusion imaging. Rubidium-81 myocardial scanning was performed in 14 patients with coronary artery disease and 1 normal subject at rest, exercise, or both. Rest scans were obtained in anterior and LAO positions after an intravenous injection of 4 mCi of ^{81}Rb; exercise scans were obtained in an identical manner after angina or fatigue had been induced on a treadmill. All patients scanned with ^{81}Rb had myocardial images of diagnostic quality. The myocardial image of the normal subject after exercise was normally homogeneous. Eleven patients had previous myocardial infarction (MI), and all were seen as perfusion defects on rest scans. Seven of these also had exercise scans; four had angina pectoris (AP) and scans showed larger perfusion defects than at rest, three without AP had scans unchanged from rest. Two of three AP patients without MI had normal rest scans and demonstrated perfusion defects after exercise; the third had an equivocal study. Ten patients had ^{43}K scans and in every case the ^{81}Rb image was comparable. It appears that ^{81}Rb, which has significant production advantages over ^{43}K, is an effective substitute for ^{43}K in myocardial imaging.

SUBSELECTIVE PULMONARY ARTERIOGRAPHY WITH BALLOON-OCCLUSION FOR THE DETECTION OF PULMONARY EMBOLISM.

K.M. McIntyre, M.D. and G.V.R.K. Sharma, M.D. VA Hospital, West Roxbury and the Dept. of Medicine, Harvard Medical School, Boston, Massachusetts.

Subselective pulmonary arteriography employing occlusive arrest of local blood flow by a balloon-tip catheter was evaluated in 18 mongrel dogs. Conventional (main and selective pulmonary) angiograms were obtained in each dog using a Schonander rapid film changer, and a #7 Eppindorf catheter. A second catheter (#5 French end-hole with a 5 cc volume balloon 2 cm from the tip) was introduced and, after balloon occlusion, 5 cc of dye was injected manually through it under fluoroscopy and control pulmonary angiograms obtained. Pulmonary embolism (PE) was produced by injection of thrombin-clots made in vivo. Conventional pulmonary angiograms were repeated; cut-offs (C) and filling defects (D) were identified. Evidence of embolization was then sought by the balloon occlusion technique.

Following dye-injection in the balloon occluded vessel, no wash-out was seen until balloon deflation. C and D seen on conventional pulmonary angiograms were clearly seen at fluoroscopy. Additional C and D were often noted. A single chest roentgenogram was then obtained to document evidence of PE seen at fluoroscopy.

Location of PE was verified at autopsy. No evidence of balloon-trauma or dye-toxicity was observed.

Comparison of conventional pulmonary angiography with the balloon-occlusion technique in this model indicates: (1) diagnosis of PE can be made at fluoroscopy; (2) dye-injection can be reduced by 90%; (3) diagnosis of PE can be documented by a single chest roentgenogram, thus minimizing radiation and (4) there is a better definition of pulmonary vasculature.

THE "RANDOM" NATURE OF TREATMENT SELECTION IN CORONARY ARTERY DISEASE

J. Frederick McNeer, M.D.; C. Frank Starmer, Ph.D.; Alan G. Bartel, M.D.; Victor S. Behar, M.D.; Yihong Kong, M.D.; Robert H. Peter, M.D.; Robert A. Rosati, M.D., Duke University Medical Center, Durham, N.C.

This report presents our experience with the medical and surgical management of 700 consecutive patients (PTS) with coronary heart disease. Three hundred forty-eight were treated medically and 352 were treated with aorto-coronary bypass surgery. Two-year survival was the same in the medically treated (83%) and surgically treated (84%) PTS. The comparison of courses of these PTS is valid because treatment selection (TS) tended to be random. The medically treated and surgically treated PTS were compared with respect to 89 baseline characteristics (BC). There were only four statistically significant inequalities in the distribution of BC. These four characteristics did not affect two-year survival. Arteriovenous oxygen difference, the number of coronary vessels with greater than 70% occlusion, and left ventricular contraction were found to be discriminators of survival regardless of TS. These characteristics were used to define subgroups in which surgically treated PTS had a higher two-year survival, in which medically treated PTS had a higher two-year survival, and in which TS did not appear to affect two-year survival. The construction of a clinical information system and the ability to compare cohorts in similar subgroups can thus extend the doctor's ability to manage PTS by allowing him to focus on distant goals.

DISTRIBUTION OF CORONARY ARTERY LESIONS FOUND AT AUTOPSY IN PATIENTS WITH PRE-INFARCTION ANGINA

James D. Maloney, MD, Barry D. Rutherford, MD, Robert L. Frye, MD, FACC, Jack Titus, MD, Ph.D., Mayo Clinic, Rochester, Minnesota

Autopsy evaluation of the coronary arteries and left ventricle was undertaken in 21 patients (pts) dying within six months of presenting with pre-infarction angina (PA). Feasibility of premortem saphenous vein grafting SVG was determined.

Evaluating only high grade lesions (>75%), the total distribution of lesions was: 18 in left anterior descending (LAD), 17 in right coronary artery (RCA), 13 in marginal branch of circumflex (M), 7 in proximal circumflex (Cx), 6 in atrioventricular groove vessel, 4 in diagonal of LAD and 2 in the left main coronary (LMC) for a total of 67 lesions.

Criteria for a graftable vessel (G) were taken to be, distal vessel free of severe disease, at least 1.0 mm in diameter and supplying viable myocardium. Results indicated for LAD 12 of 18 vessels G (67%), RCA 13 of 17 G (67%), M 8 of 13 G (61%), Cx 6 of 7 G (86%) and 1 of the LMC vessels was G.

Of the 21 pts only 2 had single vessel disease, both in the LAD and both G. Three pts had only 2 vessel disease, all had at least 1 G vessel. Of 18 pts with 2 or more vessels involved, only 3 had no G vessels.

Therefore, in this group of pts dying following PA, SVG seems feasible in the majority.

CLINICAL LOCALIZATION OF CORONARY OBSTRUCTION BASED ON THE CHARACTERISTICS OF CARDIAC PAIN.

Radi Macruz, MD, FACC; Norma Toriano, MD; Valéria Bezerra de Carvalho, MD; Siguemituzo Arie, MD; João Paulo Marrara, MD; João Tranchesi, MD, FACC; Fulvio Pileggi, MD, FACC; Luiz V. Décourt, MD, FACC.

University of São Paulo, Brasil.

Analyses of the cardiac pain characteristics in 151 patients, later studied by cinecoronariography, permitted the following conclusions: (1) Localization of the pain in the majority of cases was central (retrosternal) or left sided (precordial or in the nipple area). (2) Pain due to obstruction of the anterior descending artery usually does not radiate. When radiation to the inner aspect of the left arm or to the left epigastrial area is observed, it is suggestive of high-grade proximal arterial obstruction (usually over 90% of the lumen). (3) Pain due to right coronary artery obstruction can be localized and radiate to the right side only or to the right and left sides. The areas of pain in this situation are located in the right hemithorax, the upper limbs, cervical and mandibular regions. (4) In cases of circumflex artery obstruction, the pain radiation depends on the arterial dominance. If the right coronary is dominant, the pain radiates to the left, to the upper limb, neck and mandibule. If the left coronary is dominant, circumflex artery obstruction causes bilateral pain. (5) Pain localization and radiation mutability suggest the incidence of multiple obstructions. (6) There are cardiovascular and nervous system embryologic data supporting the above mentioned findings.

COMPARATIVE ELECTROPHYSIOLOGIC FEATURES OF THE WPW SYNDROME IN THE PEDIATRIC AND ADULT PATIENT.

William J. Mandel, MD, Michael M. Laks, MD, FACC, Burton Fink, MD and Kanji Obayashi, MD, Cedars-Sinai Medical Center and UCLA School of Medicine, Los Angeles, California.

The incidence of the WPW syndrome and associated arrhythmias has been reported to decrease with age. The purpose of this study was to determine the electrophysiologic basis for these clinical observations. Four children (ages 6-13; 2 type A, 2 type B) and 16 adults (ages 28-65; 7 type A, 5 type B and 4 type indeterminate) with the WPW syndrome were studied utilizing intracardiac recording techniques. The following observations were similar in the adult and pediatric patient: 1) the mechanism of the onset of tachycardia--a prolongation of the A-H interval and an antegrade bypass block, 2) absence of the delta vector during tachycardia, 3) the induction of tachycardias was observed regardless of the delta vector direction following right atrial premature depolarizations, 5) the AVRP curves, 6) pharmacologic interventions such as Edrophonium, isoproterenol, ouabain, procaine amide, and 7) the P-delta interval. In comparison with the adult, the pediatric patient had 1) a shorter QRS duration; 2) a greater rate of tachycardia; 3) higher incidence of induced tachycardia (4/4 vs 9/16) and 4) shorter V-A, A-V nodal and bypass refractory periods.

In summary 1) these electrophysiologic studies support the clinical observations of a diminished incidence of tachycardias with age, 2) the higher rate during tachycardias in the pediatric patients may be explained by the shorter conducting system refractory periods, 3) the decreased incidence of WPW with increasing age may be the result of the observed prolongation of bypass refractory period in the adult population.

THE EFFECT OF SYSTEMIC ARTERIAL PRESSURE ON COLLATERAL CORONARY FLOW IN MAN.

Peter R. Maroko, MD; Lawrence H. Cohn, MD, FACC, Dept Med & Surg, Harvard Med Sch & Peter Bent Brigham Hosp, Boston, MA.

The survival of myocardium in the area supplied by an occluded coronary artery depends on the quantity of blood delivered from the adjacent arteries through collaterals and is a function of the richness of the collateral network. However, it is not known how changes in arterial pressure (AP) can affect this collateral coronary flow (CCF) in patients. The methods used to measure CCF in man have been necessarily indirect. However, in patients undergoing aorto-coronary bypass a unique opportunity exists to measure directly the retrograde coronary flow, and the influence of changes in AP. Accordingly, in 6 patients, following the suture of the venous graft to the coronary artery, and before its connection to the aorta, an 18-gauge intracath was placed in the venous graft and the retrograde flow determined directly in a graduated cylinder. AP was raised from 45 to 115mmHg by altering flow in the heart-lung machine from 1000 to 4500ml/min. An increase in AP from 65 to 85mmHg induced an increase in CCF from 16.2±2.2 to 23.2±4.8ml/min ($p<.01$). Thus, an increase in 20mmHg of AP augmented CCF by 48%. One patient showed no CCF and developed a non-fatal infarction postoperative. It is concluded that in each individual the quantity of blood supplied to an ischemic area through collaterals is not only dependent upon the number of collaterals but also upon arterial pressure, thus the latter may play a role in determining the amount of tissue which survives or evolves to necrosis following coronary occlusion.

EARLY REVASCULARIZATION IN ACUTE INFARCTION, HELP OR HAZARD: A RANDOMIZED STUDY

Virendra S. Mathur, M.D., Gene A. Guinn, M.D., Baylor College of Medicine and VA Hospital, Houston, Texas

Recently myocardial revascularization (REVAS) has been advocated in very early stages of acute infarction (MI) to reduce infarct size and complications. The role of maximal REVAS by restoring normal blood supply 2 hours (H) after MI was tested in conscious intact dogs. A previously implanted balloon-cuff around left anterior descending was inflated to produce MI and amongst the survivors it was left inflated in 13 controls (C) for 7 days, it was deflated 2 H following MI in 17. Some of the results of serial studies of LV pressure, its peak dp/dt and dp/dt at developed pressure of 40 mmHg(dp/dt-40), stroke work (SW), ejection fraction (EF) and myocardial O_2 and lactate (L) extraction (EXTR) are tabulated (mean±SEM).

	CONTROL			REVAS		
	2 H	3 H	7 Day	2 H	3 H	7 Day
LVedp mmHg	16±2	17±3	16±2	15±2	15±1	18±2
Peak dp/dtx10^{-2}	19±2	19±3	25±3	18±2	15±2	25±3
dp/dt-40x10^{-2}	16±2	17±3	21±3	16±2	14±2	21±3
SW g.m.	74±4	76±5	97±7	69±4	57±6	69±5
EF %	46±4	44±3	47±4	40±3	45±3	53±2
O_2EXTR %	73±2	70±2	65±3	71±3	59±3	67±2
L EXTR %	11±4	19±3	15±3	18±5	12±5	11±3

Differences between C and REVAS dogs were not significant. Ventricular tachycardia (VT) and dyskinesis developed and persisted in each C and REVAS dog and 23% C(3of 13) and 18% REVAS (3of17) died. The average infarct size was .29 of LV in C, larger (.36 of LV) in 6 of 17 REVAS dogs and smaller (.08 of LV) in 11 of 17 REVAS dogs. Conclusion:Early REVAS fails to prevent VT,death and hemo dynamic,metabolic and angiographic deterioration in acute canine MI and REVAS increases infarct size in one-third.

ULTRASTRUCTURAL FEATURES OF CARDIAC MUSCLE CELLS IN LEFT VENTRICULAR MYOCARDIUM OF PATIENTS WITH CHRONIC AORTIC VALVULAR DISEASE.

Barry J. Maron, MD; Victor J. Ferrans, MD; and William C. Roberts, MD, NHLI, Bethesda, Md.

There is no information available on the ultrastructure of ventricular muscle cells of living pts with chronic aortic valvular disease. Therefore, apical left ventricular myocardium was resected at operation from 19 pts with aortic valvular disease and examined by light and electron microscopy. In 10 pts (6 with aortic stenosis, 4 with aortic regurgitation) only hypertrophied cardiac muscle cells and small amounts of interstitial fibrosis were present. In muscle from the other 9 pts (all with aortic regurgitation), however, both hypertrophied and degenerated cardiac muscle cells were observed. Hypertrophied cells demonstrated enlarged nuclei and increased numbers of normally appearing myofibrils, mitochondria, and ribosomes. Most degenerated cells were normal-sized, surrounded by large amounts of interstitial fibrosis and often had lost their connections with adjacent cells. These cells showed loss of normal myofibrillar structure with markedly reduced numbers of thick (myosin) filaments, streaming and clumping of Z band material and disorganization of thin (actin) filaments. The most severely degenerated muscle cells were atrophic with a few or no intact myofibrils. It is concluded that these alterations in the structure of Z bands and myofibrils reflect a degenerative process which probably results from the inability of certain hypertrophied cardiac muscle cells to meet functional demands imposed upon them. Furthermore, these degenerated cardiac muscle cells may be partly responsible for impaired myocardial function in pts with chronic valvular heart disease, left ventricular volume overloading, and congestive heart failure.

REVERSIBILITY OF LEFT VENTRICULAR ASYNERGY ASSESSED BY POST-NITROGLYCERIN LEFT VENTRICULOGRAPHY.

Robert G. Matthews, MD; Sudhakar P. Reddy, MD; James D. O'Toole, MD; Rosemarie Salerni, MD; James A. Shaver, MD, University of Pittsburgh, Pittsburgh, Pennsylvania

Left ventricular (LV) angiograms were performed before and after sublingual trinitroglycerin (TNG=0.4 mg) in 22 patients (pts) during routine cardiac catheterization for evaluation of coronary artery disease (CAD). Five pts had no organic heart disease (N). Seventeen pts had CAD with LV dysfunction in the first angiogram; 5 of them had previous myocardial infarction (MI), and 12 of them had angina (AN) alone. Basal (A), mid (B), apical (C) minor axes were measured from LV angiograms. Percentage systolic shortening (PSS) and change in PSS with TNG were calculated for each axis. The results for Group N were as follows:

	Percentage Systolic Shortening			Change in PSS with TNG		
	Mean	SD±	Range (PSS)	Mean	SD±	Range
A	48.3	3.3	(45 to 55)	-0.4	2.8	(-5 to +11)
B	38.2	8.7	(30 to 53)	13.2	6.6	(+6 to +24)
C	48.4	16.5	(38 to 81)	10.25	5.6	(-5 to +57)

Less than 40, 30, and 35 PSS was defined as asynergy and increase in PSS of more than 5, 20, and 25 with TNG was defined as supernormal response for A, B, and C respectively. Five MI pts had 14 asynergetic axes and did not change with TNG. There were 24 asynergetic axes in 12 AN pts; 8 showed normal and 16 supernormal response to TNG. In 4 AN pts reversal of asynergy was total and complete with TNG.
Thus, the post-nitroglycerin left ventriculography is a simple, safe, and useful test to assess the reversibility of left ventricular asynergy in pts with CAD.

METABOLIC DYSFUNCTION OF CORONARY OCCLUDED AND NONOCCLUDED SEGMENTS OF THE HEART

Samuel Meerbaum, PhD, FACC; Tzu-Wang Lang, MD, FACC; Costantino Costantini, MD; Steven Rubins, MD; Jules Osher, BA; Eliot Corday, MD, FACC, Cedars-Sinai Medical Center, Los Angeles, California.

Studies were designed to determine progressive alterations in regional cardiac function following LAD coronary occlusion in closed chest dogs. Simultaneous lactate (LB) and potassium (KB) balances were determined in both the occluded (O) and nonoccluded (NO) myocardial segments.

During three hours of occlusion, cardiac output (L/min) dropped from 2.70 ± 0.18 (mean ± SEM) to 2.3 ± 0.15, max LV dP/dt (mm Hg/sec) from 2840 ± 135 to 2310 ± 125. LVEDP (mm Hg) rose from 7 ± 0.6 to 11 ± 0.9, and systemic vascular resistance (dynes sec cm^{-5}) increased from 3740 ± 240 to 4270 ± 295. The diastolic phase of pressure distal to occlusion rose from 16 to 18 mm Hg, indicating no significant increase in collateral supply to the ischemic zone within three hours.

Regional metabolic measurements indicated severe dysfunction in O. A significant reduction in LB, from 34.4 ± 2.0 to 23.7 ± 3.1% was noted in NO. This was accompanied by reduction in KB from -.04 ± .02 to -.13 ± .03 mEq/L. Of 34 dogs, NO lactate production was noted in seven and abnormal metabolism in 22. O showed lactate production 17 and abnormal LB in 17. A potassium loss greater than 0.5 mEq/L occurred in O in 11, and in NO in 12 dogs. A 6.8% increase in oxygen extraction in both O and NO was noted following the occlusion.

Serious metabolic derangements are found in the nonoccluded segment following remote coronary occlusion. This finding is related to progressive deterioration of cardiac function which may result in clinical abnormalities such as cardiogenic shock.

PRECATHETERIZATION IDENTIFICATION OF OPERABLE STENOSIS OF THE LEFT ANTERIOR DESCENDING CORONARY ARTERY.

Richard R. Miller, MD; Dean T. Mason, MD, FACC; Louis A. Vismara, MD; Robert Zelis, MD, FACC and Ezra A. Amsterdam, MD, FACC. Univ. of Calif., Davis, Calif.

Since left anterior descending coronary artery(LAD) stenosis(>75%:S) is considered specially life-threatening, elective selection of patients(pts) for coronary angio and bypass(CB) would be greatly facilitated if clinical evaluation allowed predictability of these pts suitable for CB. Although previous anterior myocardial infarction (MI) denotes LAD-S, elective CB of LAD is usually not performed with old anterior MI. Thus other criteria are required to identify operable LAD-S. 68 pts with proximal or mid LAD-S without anterior MI had shorter angina duration(2.5 vs 3.6 yrs, $p<.05$) and greater frequency of inferior MI(67% vs 42%, $p<.05$) than 54 proven coronary pts without LAD-S. There were no differences in pt age, sex or presence of risk factors. 52/68(76%) LAD-S pts had operable LAD(<50% distal stenosis). Operability of LAD-S correlated inversely with angina duration and directly with presence of inferior MI(57% vs 36% in 16/68 inoperable pts). Since these data suggested a relation between prior inferior MI to operable LAD-S, an additional 55 pts with inferior MI having coronary angios were evaluated: 26 pts(47%) had operable LAD-S; no factors other than cholesterol >260 mg% indicated operable LAD-S. Thus, despite lack of a relation to most clinical indices, this study demonstrates a predictive value of previous inferior MI and short duration of angina in the precatheterization detection of operable LAD stenosis. Furthermore, a rationale is provided for early coronary arteriographic study of selected pts with prior inferior MI in the detection of high risk LAD-S.

THE EFFECT OF NITROGLYCERIN ON PREMATURE VENTRICULAR COMPLEXES IN ACUTE MYOCARDIAL INFARCTION

Michael J. Mihalick, MD; Susan Rasmussen, RN; Suzanne B. Knoebel, MD, FACC, Indiana University, Indianapolis, Ind.

Because of isolated clinical observations suggesting that nitroglycerin (TNG) may eliminate premature ventricular complexes (PVC) during acute ischemic chest pain, a study was designed to assess the effect of TNG on the incidence of PVC in patients with acute myocardial infarction (AMI). 46 patients with AMI were studied. Every other patient was given 1/150 gr TNG q 4 hr sublingually for 24 hr after admission to CCU. PVC were counted for 15 min prior to TNG and for the following 15 min. In the control group PVC were counted for identical time periods. Thus, during any 24 hr period, PVC were counted for 3 hr. The 23 patients receiving TNG had a total of 592 PVC prior to TNG and 276 after TNG ($p<0.005$). The 23 control patients had a total of 408 during the first 15 min period and 525 during the second 15 min period ($p<0.05$). The mean heart rate (HR) before TNG was 79 and 83 after TNG. Average decrease in mean blood pressure (BP) was 10 mmHg. The control group showed no change in HR or BP. Because of the possibility that the slight increase in HR induced by TNG was responsible for reduction of PVC, PVC/min and PVC/beat were calculated. PVC/min and PVC/beat were 39.5 and 0.50 before TNG, 20 and 0.24 for the first 2 min after TNG, 18 and 0.22 for the remaining 13 min of the 15 min period respectively. HR for the 2 min period and the subsequent 13 min were identical at 83/min. The control group had an increase in PVC/min and PVC/beat despite an identical HR of 84/min. This study indicates that TNG decreases PVC in AMI. The mechanism(s) for the TNG effect is obscure. The only significant measurable effect of TNG was decreased BP. This would result in a decreased time-pressure product, possibly improving oxygen requirement/blood flow ratio.

CLINICAL STUDIES AFTER FONTAN'S OPERATION FOR TRICUSPID ATRESIA

Robert A. Miller, MD; Dev Pahlajani, MD; Maria Serratto, MD, FACC; Constantine Tatooles, MD, Cook County Children's Hospital, Chicago, Illinois.

Five children with tricuspid atresia have been operated upon using a modification of Fontan's procedure: Superior vena cava - right pulmonary artery anastomosis, connection of right atrium to pulmonary artery by a graft containing a valve, insertion of a valve in the inferior vena cava at the right atrial junction, tying off the pulmonary artery at its origin and closure of the interatrial communication. Criteria for selection for surgery included normal pulmonary vascular resistance, normal LA mean and LVEDP. LVEDP was 10mmHg in the child that expired. All developed pleural effusion, hepatomegaly, and ascites in the immediate postop period. Three cases who did not have a prior SVC-RPA shunt developed a SVC syndrome which disappeared during the first postop week. Junctional tachycardia and other dysrhythmias were noted during the first 48 hours. Postop studies in three cases showed a marked elevation of right atrial pressure with "ventricularized" tall A-waves, as high as 37mmHg in one patient. All cases showed arterial oxygen desaturation after surgery, 88.5%, 87%, 92%, and 77%. Angiocardiograms showed streaming of dye through multiple sites along the suture line in the atrial septum in all three. A catheter could be passed from RA to LA and into pulmonary veins in all cases. Pulmonary vein desaturation was found in all three cases, severe (82%) in one. Although all 4 survivors were improved by the operation, three of them remarkably so, pleural effusion, right to left atrial shunting, and intrapulmonary shunting have been consistent problems in the early postoperative months.

RELATIONSHIP BETWEEN SEVERITY OF CORONARY ARTERY DISEASE AND ABNORMALLY CONTRACTING SEGMENTS OF THE LEFT VENTRICLE

Roger E. Moraski, MD; Richard O. Russell, Jr., MD, FACC; Charles E. Rackley, MD, FACC. Department of Medicine, University of Alabama, Birmingham, Alabama.

Twenty-three patients (pts) were studied two to 24 months following acute myocardial infarction to determine the relationship between the severity of coronary artery disease (CAD) in vessels supplying non-akinetic myocardium and the extent of abnormally contracting segments (ACS) of the left ventricle.

Coronary arteriograms were obtained using Judkins' technique. Both cineangiograms at 60 frames/sec and large roll film angiograms at two to six frames/sec in multiple views allowed precise definition of the arterial lesions. The severity of coronary lesions was scored as 0 = no lesions, 1 = < 50% stenosis, 2 = 50-90% stenosis, 3 = multiple 50-90% stenoses in one vessel, 4 = 90% stenosis, and 5 = 100% occlusion. From left ventricular biplane angiograms exposed at six frames/sec the %ACS was calculated as the ratio of length of ACS to total perimeter of the end-diastolic film. Segments of the left ventricle supplied by each major coronary artery were identified. In four pts with ACS $\geq$ 30%, CAD score to non-akinetic myocardium = 1.5 ± 1.2; in seven pts with %ACS between 16-29%, CAD score to non-akinetic myocardium = 2.7 ± 2.3; in 12 pts with %ACS $\leq$ 15%, CAD score to non-akinetic myocardium = 4.5 ± 3.3.

The inverse relationship between the severity of coronary artery disease in vessels to non-akinetic myocardium and the extent of ACS suggests that collateral circulation stimulated by increasing severity of coronary artery disease may limit the extent of ACS following acute myocardial infarction.

DOES IDIOPATHIC LEFT VENTRICULAR HYPERTROPHY EXIST?

Joel Morganroth, MD; Walter L. Henry, MD; Barry J. Maron, MD; Chester E. Clark, MD; and Stephen E. Epstein, MD, NHLI, Bethesda, Md.

When left ventricular (LV) hypertrophy occurs in the absence of valvular, hypertensive or infiltrative disease, it may be considered a manifestation of primary myocardial disease. One hundred twenty-eight patients in whom such a diagnosis was made clinically were evaluated. After patients with dilated ("congestive") cardiomyopathy, typical idiopathic hypertrophic subaortic stenosis (IHSS), and family members of patients with IHSS were excluded, 44 subjects remained. All had either the suspicion of LV hypertrophy clinically or met Estes ECG criteria for LV hypertrophy. Cardiovascular symptoms were present in 84%. Echocardiograms were obtained in 39 of 44 patients who were then classified into three groups: asymmetric septal hypertrophy (ASH) (septal thickening present with septal to LV free wall thickness ratio $\geq$1.3); concentric LV hypertrophy (septal and LV free wall thickened equally); and normal (septal and LV free wall thickness essentially equal and each less than 12 mm). Of the 39 subjects with echocardiograms, 33 had ASH, 6 were normal and none had concentric LV hypertrophy. LV mass calculated in the 6 subjects with normal echocardiograms (each of whom had LV hypertrophy solely by ECG criteria) was also normal, suggesting a false positive ECG diagnosis of LV hypertrophy. We conclude that most patients with clinical or electrocardiographic evidence of unexplained LV hypertrophy have either ASH or are normal. Thus, if idiopathic LV hypertrophy (symmetric thickening of both the septum and LV free wall) does exist as a separate disease entity, it must be distinctly uncommon.

EXTERNAL COUNTERPULSATION - A NON-INVASIVE FORM OF CARDIAC ASSISTANCE

Hiltrud Mueller, M.D., FACC; Robert Evans, B.A.; Stephen Ayres, M.D., FACC, The St. Vincent Hospital, Worcester, Massachusetts

It was previously demonstrated in man that intra-aortic balloon counterpulsation strikingly improves hemodynamics and myocardial metabolism in myocardial infarction shock. We evaluated the effect of non-invasive external counterpulsation (ECP) in acute myocardial infarction (AMI) without shock. Mean values of 13 patients are presented. Studies were performed before ECP, 90 min. during and one hour after termination of assistance. During ECP, aortic peak diastolic pressure averaged 137 mm Hg ($p < .001$). Both, systolic peak and mean aortic pressure fell slightly (5 and 6 mm Hg, $p < .01$). Left ventricular ejection resistance decreased 24%. Cardiac index improved from 1.9 to 2.3 L/min/M^2, $p < .001$, associated with fall of arterio-pulmonary artery oxygen difference from 6.2 to 5.3 ml/100 ml, $p < .01$. Pulmonary artery wedge pressure fell from 18 to 15 mm Hg, $p < .001$; right atrial pressure remained unchanged. Coronary blood flow increased from 82 to 101 ml/100g/min ($p < .05$) and remained improved one hour after termination of ECP. Lactate metabolism, abnormal in 8 patients, improved with ECP (-9 to +14%, $p < .05$). Coronary sinus oxygen tension increased from 23 to 25 mm Hg, $p < .05$. Conclusion: ECP increases diastolic aortic (coronary perfusion) pressure and improves myocardial oxygenation in AMI. These findings indicate that ECP may prove capable of salvaging endangered myocardial tissue.

METABOLIC CHANGES IN ISCHEMIC MYOCARDIUM BY NITROPRUSSIDE

Hiltrud Mueller, M.D., FACC; Anna Religa, M.D., Ph.D.; Robert Evans, B.A.; Stephen Ayres, M.D., FACC, The St. Vincent Hospital, Worcester, Massachusetts

It was previously demonstrated that nitroprusside has a beneficial effect on the failing heart, decreasing afterload and filling pressure of the left ventricle while improving systemic blood flow and - presumably - myocardial oxygenation. We studied the metabolic effect of nitroprusside on ischemic myocardium in 8 dogs with myocardial infarction. Blood samples were taken simultaneously from the femoral artery, from the local vein draining the ligated left descending coronary artery and from the coronary sinus. Blood was withdrawn before, 15 and 30 minutes after coronary artery ligation and during 15 minutes of continuous intravenous infusion of 3-5 mic g/min nitroprusside. After ligation, left ventricular diastolic pressure rose. The metabolic changes in the venous drainage of the ischemic area were as previously described: myocardial oxygen extraction increased an average of 7%, lactate extraction shifted to production and glucose utilization increased. During nitroprusside infusion, left ventricular systolic and diastolic pressures fell. The response of heart rate varied. The most striking metabolic effects were a change from lactate production (-38%) to extraction (43%) and a decrease of glucose utilization. Myocardial oxygen extraction and coronary venous oxygen tension did not change consistently. Similar, but less conclusive findings were observed sampling mixed coronary sinus blood. Conclusion: These findings suggest that nitroprusside improves myocardial metabolism of ischemic myocardium and thus may be able to decrease infarct size.

METABOLIC EFFECT OF PROPRANOLOL ON ISCHEMIC TISSUE IN HUMAN AND EXPERIMENTAL MYOCARDIAL INFARCTION

Hiltrud Mueller, M.D., FACC; Anna Religa, M.D., Ph.D.; Robert Evans, B.A.; Stephen Ayres, M.D., FACC, The St. Vincent Hospital, Worcester, Massachusetts

We previously demonstrated in human myocardial infarction that propranolol improved myocardial metabolism of the left ventricle. In order to determine how much of this improvement occurred in the ischemic area, blood was sampled in nine dogs from the local vein draining the ligated left descending coronary artery as well as from the coronary sinus. Samples were taken before, 15 and 30 min. after ligation and 15 and 30 min. after 1.0 mg/Kg I.V. propranolol. The following results were observed draining local venous blood: After ligation, oxygen extraction increased (68 to 75%, $p < .05$), lactate extraction shifted to production (28 to -70%, $p < .05$), and glucose extraction sharply increased (4 to 13%, $p < .05$). Free fatty acid extraction did not change. After propranolol, improved oxygen availability was demonstrated by change from lactate production to extraction (-70 to 4%, $p < .05$) and by decrease of glucose extraction (13 to 10%). Oxygen extraction did not change. Both epinephrine and l-norepinephrine content decreased with propranolol. Similar but less conclusive metabolic changes were observed in mixed coronary sinus blood. Propranolol decreased heart rate an average of 54 beats per min ($p < .001$); left ventricular systolic pressure did not significantly change, while end diastolic pressure rose in average 5 mm Hg ($p < .05$). None of the dogs developed left ventricular failure. Conclusion: These results clearly demonstrate that propranolol improves myocardial metabolism in the ischemic zone and is of therapeutic benefit in certain patients with acute myocardial infarction.

ECHOCARDIOGRAPHIC RECOGNITION OF CONGENITAL BICUSPID AORTIC VALVE

Navin C. Nanda, MD; Raymond Gramiak, MD; James Manning, MD; Elliot O. Lipchik, MD; Earle B. Mahoney, MD; James A. DeWeese, MD, University of Rochester Medical Center, Rochester, New York

Fourteen patients (age 7 to 25 years) with bicuspid aortic valve proved by surgery and angiography (10) or angiography alone (4) were studied by echocardiography. Eight of them had aortic valve stenosis, 4 had pure aortic incompetence and 2 were associated with isolated coarctation of aorta. A comparison group of 12 patients (6 with aortic valve disease and 6 without aortic valve disease) who had proved tricuspid aortic valve was also studied. Echocardiograms in tricuspid aortic valve patients showed the closed position of the cusps near the middle of the aortic lumen. In contrast marked eccentricity of the aortic valve cusp echo in diastole could be demonstrated in all with bicuspid aortic valve. The Eccentricity Index (1/2 aortic lumen diameter/minimum distance of diastolic cusp echo from anterior or posterior aortic margin) was low (range 1.0-1.15) with tricuspid aortic valve and high (range 1.5-3.6) with bicuspid aortic valve ($p < 0.001$). This index was not significantly affected following successful valvotomy. In systole, the cusps in bicuspid aortic valve patients opened briskly to the periphery of the aortic lumen so that the valve leaflets appeared markedly asymmetric. Echocardiography is of value in the recognition of bicuspid aortic valve.

INFLUENCE OF LEFT VENTRICULAR FUNCTION ON EARLY PROGNOSIS IN ATHEROSCLEROTIC HEART DISEASE

John A. Murray, MD, FACC; Nina Chinn, PHN; Donald R. Peterson, MD, MPH, Seattle Heart Watch, University of Washington, Seattle, Washington.

Of the 246 men followed for 18 months after study by coronary and left ventricular (LV) angiography, 24 died. Survival averaged 5 months. Surgical deaths were excluded from the analysis.

Evaluation of clinical status, resting electrocardiogram, exercise test, coronary arterial anatomy and both qualitative and quantitative LV function demonstrated that the most striking differences between living and dead groups were in LV studies.

	Living	Dead	P
EDV, cc/m^2	79±24	101±39	<0.0001
ESV, cc/m^2	35±23	60±35	<0.0001
Ejection Fraction	58±15	43±17	<0.0001
Contraction Grade	2.3±1.2	3.3±1.4	<0.0002

Men with diffuse, moderate focal and mild focal contraction abnormalities had mortalities of 37%, 17%, 11% respectively, in contrast to 4% in those with a normal LV contraction pattern. Duration of survival was similar for each group.

For 64 cases with ejection fractions less than 50%, the mortality was 23%. Of the 24 total deaths 20 had ejection fractions below the median of the 246 men.

Thus the level of LV performance is an important determinant of survival even in the absence of surgical therapy.

POST-OPERATIVE BLOOD PRESSURE FOLLOWING COARCTECTOMY IN YOUNG CHILDREN

Maurice A. Nanton, MB; Peter M. Olley, FRCP(C) The Hospital for Sick Children, Toronto, Canada

We have reviewed all patients who have undergone successful coarctectomy at The Hospital for Sick Children excluding those who were operated on at less than a year old and those with a post-operative follow up of less than 6 months. The mean follow up was 4.3 years (range 0.5-13.5 years). Latest post-operative systolic and diastolic blood pressures recorded in the right arm were compared with the 96th percentile for age. Forty-eight of 187 (25.3%) of the patients were found to have systolic hypertension and 84 of 183 (46%) to have diastolic hypertension. In order to decide whether age at operation influenced the post-operative blood pressure 2 groups of patients were compared. Group I consisted of 22 patients operated on between the age of 4 years and 6 years 11 months and Group II, 20 patients operated on when aged 11 to 13 years 11 months. The mean follow up for Group I was 4.3 years and for Group II was 3.7 years. Diastolic blood pressure was expressed as a percentage of the normal mean diastolic pressure for age and the mean fall in this percentage value compared for the 2 groups using Students T test. There was no significant difference between the 2 groups. A large majority of patients following coarctectomy remain significantly hypertensive raising the question of need for medical hypotensive therapy. Operation early (4-7 years) does not seem to improve the chances of the post-operative pressure becoming normal.

PULMONARY VALVOTOMY FOR ISOLATED PULMONARY STENOSIS: AN ANALYSIS OF 110 PATIENTS TREATED BY THE INFLOW STASIS TECHNIQUE.

William A. Neal, MD, J. Jacques Mistrot, MD, Gary Lyons, MD, James H. Moller, MD, Aldo Castaneda, MD, Richard L. Varco, MD, and Demetre Nicoloff, MD, FACC
University of Minnesota Hospitals, Minneapolis, Minnesota

This study assessed the pre and postoperative clinical, ECG, and cardiac catheterization data in 110 patients with isolated pulmonary stenosis (PS) operated between 1961 and 1972 using the inflow stasis technique. The patients ranged in age from 2 days to 36 years, and 11 (10%) were less than 1 year. Operative mortality was 3.6% (4/110), two deaths occurring in infants less than 1 week of age. Preoperative cardiac catheterization was performed in each patient and 69 (63%) had postoperative catheterization. The mean preoperative systolic gradient was 93 mm Hg and calculated pulmonary valve area (PVA) 0.38 cm^2/m^2. Postoperatively, the mean gradient was 23 mm Hg and PVA 1.1 cm^2/m^2. Results were considered good in 78% (<30 mm Hg gradient), fair in 15% (30 - 50 mm Hg gradient),and poor in 7% (>50 mm Hg gradient). Six of 7 patients with pulmonary valve dysplasia had unsatisfactory results, and we now recommend valvotomy on cardiopulmonary bypass when dysplastic PS is suspected. Four patients required reoperation for high residual gradient, 1 of whom had a dysplastic valve. Significant reduction in the QRS/T angle was the most characteristic ECG finding after surgery. Favorable operative results, low morbidity and mortality, and freedom from the problems of cardiopulmonary bypass are cited as reasons for use of this technique in the treatment of isolated pulmonary valvar stenosis.

VENTRICULAR ARRHYTHMIAS ASSOCIATED WITH SUDDEN DEATH IN SURVIVORS OF ACUTE MYOCARDIAL INFARCTION

G. Charles Oliver, MD, FACC; Floyd M. Nolle, DSc; Alan J. Tiefenbrunn, BA; Robert E. Kleiger, MD; Thomas F. Martin, MD: Ronald J. Krone, MD; J. Philip Miller, AB; Jerome R. Cox, Jr., ScD, Washington University School of Medicine, St. Louis, Missouri

A prospective study of the frequency and type of ventricular arrhythmias in ambulatory survivors of myocardial infarction has been made to investigate their relationship to sudden death. Holter tape recordings were obtained at the onset of infarction, at two weeks, at one month, and at monthly intervals thereafter. Eight patients died suddenly, and their arrhythmias are compared with 8 patients who have survived for two years. Holter tapes were analyzed by Argus/H, a unique high speed computer system for automatic identification of premature ventricular contractions. All computer identified PVCs were verified. A total of 103 tapes have been analyzed, representing over 5 million heart beats. Both survivors and sudden death patients had approximately the same high incidence of early PVCs (EPVC) and PVC rates ≥ 10/hr during the acute phase. However, striking differences were noted between survivors and sudden death patients during the early ambulatory phase (2 weeks - 3 months post infarction).

	# Pts	# Tapes	% Pts with EPVC	% Pts with PVC ≥ 10/hr
Survivors	8	28	13	13
Sudden Death	8	22	75	75

These differences are highly significant ($p < .02$). It is concluded that striking differences in early PVCs and PVC rates exist between these surviving and sudden death patients in the early ambulatory phase of recovery which may allow ready identification of patients prone to sudden death.

"SLUGGISH" SINUS NODE SYNDROME AS A PART OF CONGENITAL HEART DISEASE

E.W.Nugent,M.D.,P.J.Varghese,M.D.,D.R.Pieroni,M.D.,R.D. Rowe,M.D.,Dept. of Pediatrics Johns Hopkins Hospital, Baltimore, Md.

Sinus node(SN) dysfunction was suspected in 4 children with congenital heart disease(CHD) who presented with atrial dysrhythmias: junctional rhythm(1 patient),sinus bradycardia with ectopic atrial escape(1 patient), and atrioventricular(AV) dissociation with slow, irregular atrial rate and junctional rhythm(2 patients). One child had paroxysmal supraventricular tachycardia. SN function was evaluated by:(1)submaximal exercise,(2)intravenous atropine(0.01 mg/Kg), and (3)overdrive atrial pacing (OAP) at rates of 120-150/min. Exercise did not change the atrial rate in 1 child and increased it by less than 20% for brief periods in the other 3. Atropine administration resulted in very similar changes in atrial rate and increased the junctional rate in 3. The sinus recovery time after OAP was abnormally prolonged in all (range 900-1240, average 1050). Escape to the His occurred earlier than to the SN in 1 patient. AV nodal function was normal as OAP at different rates produced 1:1 AV conduction with normal atrial-His and His-ventricular intervals. SN dysfunction is the basis for the dysrhythmias in these children, but the etiology is unclear. The association with CHD suggests that it could be a congenital defect of the SN or the effect of prolonged hemodynamic alterations on the SN. The latter seems more likely since all 4 of our patients had pressure or volume overload on the right side. Prognosis is guarded because of possible brady-tachyarrhythmias. This syndrome should be considered in the presence of any atrial dysrhythmia. Exercise and atropine offer a simple way of obtaining supportive evidence.

FIVE YEAR EXPERIENCE WITH A DISC-TURTLE NECK MITRAL VALVE

Sonny S. Oparah,M.D., David M. Sokol,M.D.,Virender K. Saini,M.D., Thomas J. Ryan,M.D., Robert L. Berger,M.D.. Boston University Medical Center, Boston, Mass.

The performance of the composite Harken disc valve with Magovern turtle neck cuff (HMDV), inserted by continuous suture technique, has not been described. Between 1968 and 1973 HMDV was implanted electively in 100 patients (pts.). Of these 45 had previous mitral valve surgery and the pulmonary artery systolic pressure was greater than 50 mm. Hg. in 57 patients. The early and late mortalities were the following:

	No. Pts.	Early Mortality %	Late Mortality %
MVR*	79	7.5	6.5
MVR + CABG+	7	0	14.0
DVR‡	14	7.1	14.0
Class III (NYHA)	51	7.8	1.9
Class IV (NYHA)	49	8.1	14.0

*mitral valve replacement, +coronary bypass graft, ‡double valve

Pulmonary hypertension and previous cardiac operations did not influence mortality. In 2168 pt. month follow up there were 7 thromboembolic episodes. Peribasilar leaks were not encountered. Postoperative catheterization in 12 pts. revealed satisfactory hemodynamic function. These results indicate that HMDV is a satisfactory prosthesis and has definite advantages over other widely used artificial mitral valves.

BANDING OF THE PULMONARY ARTERY IN NEW ENGLAND

Lucy Parisi, MD; Robert D. Corwin, MD; Donald C. Fyler, MD, Children's Hospital Medical Center, Boston, Mass.

Banding of the pulmonary artery has proved effective in decreasing excess pulmonary blood flow and preventing development of pulmonary hypertension in critically ill infants. The New England Regional Infant Cardiac Program experience with this procedure (7/68-6/72) has been reviewed. The overall mortality for banding in 206 infants is 36% including 64 early deaths and 10 late ones. The latter includes those who expired during corrective surgery. Infants with ventricular septal defect (88) represent the largest group; mortality among 48 with simple defects was 8% compared to 42% among 40 with associated lesions. In all infants mortality is appreciably higher when the ductus is interrupted at the time of banding (45 vs. 31%) probably reflecting sicker and younger patients. Transpositions with atrial septectomy have a lower mortality than the group without (38 vs. 47%). Significant improvement in mortality results when the figures are corrected for low birthweight and serious associated anomalies, particularly among those with endocardial cushion defect (Downs). The mortality for banding among infants with essentially uncorrectable lesions is 49% (range 12-80%) with virtually all deaths occurring early. Although the mortality figures for the total group are high and lead one to aim at complete correction at a earlier age, for most of the lesions it should be borne in mind that pulmonary artery banding is still the only palliative procedure for a host of presently inoperable lesions. With further improvement in surgical techniques and post operative management many of the patients successfully palliated may become candidates for corrective surgery.

DYNAMIC RESPONSIVENESS OF DISTANT MYOCARDIUM DURING TRANSIENT ANTERIOR WALL ISCHEMIA

Frederic Pashkow, MD; Roger Holland, BS, Harold Brooks, MD
University of Chicago, Chicago, Illinois

The regional responses of distant myocardium (DIST) supplied by the left circumflex artery to acute ischemia of anterior myocardium (ISCH) supplied by anterior descending artery (LAD) was studied in 12 open chest anesthetized pigs. Three markers of regional response were used for both areas; a newly-designed, low impedance surface ECG electrode, a force gauge sutured in series with outer wall fibers, and coronary inflow to the region. Flow was measured by electromagnetic flowmeter cuff-probes around the proximal coronary artery of supply, with special care taken in dissection and placement to minimize interruption of vascular innervation. With transient LAD occlusions (15 to 120 sec.) the characteristic rapid decline in contractile force and evolution of surface ECG changes in the ISCH area was almost invariably accompanied by a significant increase in contractile force in the DIST area (91% of 57 occlusions). DIST QRS-T voltage changes occurred less frequently (67% of 30 occlusions). In only 58% of 34 occlusions in which there was an increased DIST contraction, was there a concommitant rise in circumflex coronary inflow. High dose propranolol or phentolamine did not block the DIST responses. When the circumflex artery was cannulated and perfused from the carotid artery the DIST response was obliterated - suggesting interruption of vascular neural fibers by the tight cannulating ligature. The almost uniform finding of overcontraction of DIST normal myocardium during early ischemia is consistent with a reflex homeostatic mechanism for conservation of whole ventricular performance perhaps induced by the abnormal stretch of asynchronous contraction. The absence of a consistent rise in circumflex flow suggests the stimulation of anastomotic inflow.

THE ROLE OF ALPHA ADRENERGIC RECEPTORS IN MEDIATING POSITIVE INOTROPIC EFFECTS IN VENTRICULAR MYOCARDIUM

William W. Parmley, MD, FACC; Babeth Rabinowitz, MD, Leonard Chuck, BA, Cedars-Sinai Medical Center, Los Angeles, California.

It has been traditionally assumed that there are no alpha adrenergic receptors of importance in left ventricular myocardium. In order to evaluate this assumption, dose response curves to alpha agonists and antagonists were obtained in isolated cat papillary muscles studied in vitro. Methoxamine (n=6) produced a 30 and 45% increase in contractile force at doses of 10^{-5} and 10^{-4}M. These effects were unchanged following beta adrenergic blockade with 10^{-6}M propranolol, but were totally abolished by alpha adrenergic blockade with 10^{-6}M phentolamine or ergotamine. Phenylephrine produced the following increases in contractile force: 10% at 10^{-7}M, 30% at 10^{-6}M and 60% at 10^{-5}M (n=8). These effects were not altered by 10^{-6}M propranolol although they were reduced by at least half with alpha blockade by 10^{-6}M phentolamine or ergotamine. This suggests that the effects of phenylephrine were due to both alpha adrenergic and non-adrenergic receptor stimulation. The known positive inotropic effects of isoproterenol were unaffected by the addition of 10^{-6}M phentolamine. The known positive inotropic effects of norepinephrine (n=17) were partially blocked at low doses by 10^{-6}M propranolol and at high doses by 10^{-6}M phentolamine. Parallel measurements of the effects of these agents on myocardial adenyl cyclase activity confirmed that the beta agents stimulated adenyl cyclase activity while the alpha agonists did not increase adenyl cylcase activity. Thus, the present study suggests that alpha agonists have positive inotropic effects on the myocardium in a manner similar to beta adrenergic agents. These effects do not appear to be mediated by stimulation of adenyl cyclase activity.

DIGOXIN EFFECTS ON SINUS NODE REENTRY IN THE DOG

Karlen L. Paulay, MD; Anthony N. Damato, MD, U. S. Public Health Service Hospital, Staten Island, New York

Using the recently described experimental model for sinus node reentry (SNR) the effect of digoxin (D) was assessed in 10 dogs with extrinsic cardiac denervation (group I) and in five dogs with an intact cardiac nerve supply (group II). In all dogs, before D, after the last basic beat, A_1, a premature atrial beat, A_2, was followed by a sinus node reentrant beat, A_3, when A_2 fell within the reentry zone. Thirty-five minutes (av) after an i.v. bolus (7.5 ug/kg) and infusion (2.5 ug/kg/min) of D, toxicity developed manifest by either increased ventricular and/or ectopic atrial automaticity (14 dogs) or high degree A-V block (one dog in group II). D had relatively little effect on SNR in both groups, and SNR could be demonstrated at the onset of toxicity in all dogs. D delayed the appearance of A_3 during SNR (i.e. increased the A_2A_3 interval) by 40 msec (av for groups I and II) with a maximum delay of 200 msec in one dog in group II. This increase in the A_2A_3 interval which indicated delay along the reentrant pathway did not correlate with atrial refractoriness which increased 14 msec (av; atrial effective refractory period) in group I and decreased 22 msec (av) in group II. In seven dogs that developed increased ectopic atrial automaticity with D, premature atrial stimulation was followed by reentry that appeared to originate from the site of the ectopic atrial focus, and suggested that automaticity per se may predispose to reentry. The knowledge of the relative insensitivity of SNR to D, at least in this experimental model, contrasts with the previously reported sensitivity of SNR to quinidine, and may be important in the management of SNR in man.

EFFECT OF DIGITALIS ON THE RESPONSE OF VENTRICULAR PACEMAKERS TO SYMPATHETIC NERVE STIMULATION

D. L. Pearle, MD; R. A. Gillis, PhD, Georgetown University Medical Center, Washington, D.C.

It is established that digitalis antagonizes the chronotropic effect of adrenergic stimulation of the heart. This finding would suggest that the sympathetic nervous system does not play a significant role in ventricular arrhythmias produced by digitalis. However, this antagonism has been established by testing the response of sinus node pacemakers to digitalis and adrenergic stimulation. Since the clinically significant digitalis-induced arrhythmias are ventricular in origin, the response of ventricular pacemakers seems the critical parameter. To test this parameter, we electrically stimulated the postganglionic sympathetic nerves of 5 anesthetized dogs with complete A-V block using frequencies of 3, 10, and 20 Hz. before and after administration of ouabain (40 μg/kg I.V.). Before ouabain these frequencies increased ventricular rate by 17 ± 4.9, 37 ± 3.7, and 39 ± 3.9 %. After ouabain, ventricular rate increased by 11 ± 5.2, 42 ± 7.0, and 46 ± 4.6 %. Ventricular tachycardia occurred in two of these ouabain-treated animals during stimulation. These results indicate that the chronotropic response to adrenergic stimulation of ventricular pacemakers unlike that of atrial pacemakers is unaffected or enhanced by digitalis.

CORONARY HEMODYNAMIC AND METABOLIC EFFECTS OF PROPRANOLOL IN IDIOPATHIC HYPERTROPHIC SUBAORTIC STENOSIS.

Carl J. Pepine, M.D., C.R. Bemiller, M.D.,FACC, Naval Hospital, Philadelphia, Pennsylvania

To clarify the basis for symptomatic improvement following propranolol (P) in patients with idiopathic subaortic stenosis (IHSS) coronary flow as reflected by coronary sinus blood flow, left ventricular (LV)oxygen consumption ($LV\dot{V}O_2$), LV efficiency = LV work index (LVWI)/$LV\dot{V}O_2$, lactate extraction (XL), and LV hemodynamics were measured in 6 IHSS patients at rest and during atrial pacing induced tachycardia before and after P,(10mg). All had resting outflow tract obstruction (mean gradient 56.8 ± 11 mmHg) and normal coronary angiography. During tachycardia induced angina, $LV\dot{V}O_2$ increased,(Rest→pacing, 13.4±2.1→25.2±4.1ml/cc/min) LVWI was unchanged, (9.79±.66→9.66±.71 Kg-m/min/m^2) and LV efficiency declined 35% as XL declined abnormally in 5 of 6 patients. Following P, LV outflow tract gradient was not significantly changed (53.4±16 mm Hg) but $LV\dot{V}O_2$ declined 12% associated with proportional reduction of LV work (9.79±.66→8.92±.58, $p<.05$). At the same pacing rate after P, $LV\dot{V}O_2$ increased much less (+51%, $p<.05$)as LV work was unchanged and LV efficiency declined less (-21%, $p<.05$) then before P. XL increased in each patient compared to tachycardia before P, but outflow tract gradient was unchanged (50±18) and angina did not occur. These data indicate that in some patients with IHSS, P reduces oxygen wasting thereby decreasing LV inefficiency. This effect, independent of changes in outflow tract obstruction, may relate to clinical improvement in patients with IHSS.

THE ASYMPTOMATIC CORONARY PRONE MALE: CLINICAL,CORONARY ANGIOGRAPHIC AND HEMODYNAMIC CORRELATIONS.

Carl J. Pepine, MD, Naval Hospital, Philadelphia, Pennsylvania

A prospective study of young, high risk subjects who never had symptoms suggestive of coronary heart disease (CHD) was done to identify and characterize the preclinical phase of CHD. Coronary angiographic (CA),metabolic and exercise left ventricular (LV) hemodynamic and ECG studies were performed in 41 asymptomatic males (mean age 36 years) with hyperlipemia and a family history of CHD. Ten had xanthomas (24%), 15 were obese (34%), 18 had hypertension (43%), and 21 had abnormal GTTs(51%), while only 18% had abnormal submaximal exercise ECGs(4 with ST depression ≧ 1 mm and 3 with ST depression = 0.5mm). LV angiography and rest → exercise LV function (stroke work index 83 ± 5.0 → 110 ± 11.0 Gm-m/beat/m^2 and LV end diastolic pressure 10.2 ± 2 → 11.5 ± 2.6 mmHg) were normal. CA studies revealed significant coronary artery disease (CAD) in 51% (21 of 41 subjects). In those with CAD, 11 had reduced lactate extraction suggestive of ischemia. Nine of ten with xanthomas and 7 of 7 with abnormal exercise ECGs had CAD. Preclinical CHD (significant CAD and myocardial ischemia) occurs in the absence of LV functional abnormalities. The presence of xanthomas may be a useful predictor of advanced silent CAD in high risk males.

CORONARY HEMODYNAMICS AND METABOLISM IN PATIENTS WITH NORMAL CORONARY ARTERIES AND ANGINA PECTORIS.

Carl J. Pepine,M.D., C.R. Bemiller, M.D.,FACC, S.J.Schang, M.D., Naval Hospital, Philadelphia, Pennsylvania.

The basis for the occurrence of angina pectoris and myocardial ischemia in some patients with normal coronary arteriograms (NCA) remains obscure. To clarify the pathophysiology of this syndrome coronary sinus blood flow (CSBF), left ventricular hemodynamics oxygen consumption ($LV\dot{V}O_2$), and lactate extraction (XL) were measured at rest and during pacing induced angina pectoris in 11 patients with NCA, with ECG or metabolic evidence of myocardial ischemia and 10 patients with coronary artery disease (CAD). Differences occurred in CSBF rise with tachycardia at angina (NCA= 1.36±.18cc, CSBF ↑/beat vs CAD 0.85± .66cc, CSFF increase/beat, $p<.05$, as coronary resistance declined 40% in NCA and only 14% in the CAD patients, $p<.05$. These alterations during similar tachycardia stress (heart rate increased 81% in NCA and 73% in CAD), LV work (NCA = 5.5 ± .46 and CAD = 5.4 ± .43 Kg-m/min/m^2) and tension-time indices (NCA 3505 ±150 and CAD 3395 ± 204 mmHg-sec) were related to a marked increase, $p<.01$, in $LV\dot{V}O_2$ in the NCA patients (11.8 ± .08 →23.3±2.3ml/cc/min) compared to the CAD patients (12.4± 1.1 → to 15.8±1.6 ml/cc/min) during pacing. These data suggest that in some patients with NCA an inappropriate rise in LVO_2 usage (compared to patients with CAD) during tachycardia may exhaust available coronary blood supply and relate to the occurrence of angina pectoris and myocardial ischemia.

THE MICROSHOCK HAZARD: EXPERIMENTAL, ENVIRONMENTAL, AND EDUCATIONAL STUDIES

Russell R. Pfeiffer, Ph.D.; R. Martin Arthur, Ph.D; Richard E. Clark, MD; Washington University, St. Louis, Missouri

An investigation of the endocardial ventricular fibrillation (VF) threshold for 6 newborn pigs and 40 adult dogs and epicardial threshold for 40 dogs and 4 humans having heart surgery was made. The environmental studies measured the leakage currents and ground characteristics of a cardiac operating room and intensive care unit, a coronary care unit and more than 106 patient rooms in 10 hospitals. Unique electrical designs were used in renovations of 4 cardiac and neurological facilities. An educational program was initiated for all nursing and new hospital personnel and courses and clinical training implemented in the Biomedical Engineering curricula. The results of the animal and human studies show that the VF threshold range is 200-300 microamperes for endocardial and 2-3 X greater for epicardial stimulation. The principles of the tree-structured grounding and isolated environments have been used in critical patient areas. These designs have been shown to be cost-effective, minimize electrical interference in monitoring, and eliminated the need for isolation transformers and other expensive devices. It is concluded that (1) present leakage current requirements for monitoring devices are sufficient, (2) the vast majority of the non-critical care areas studied meet or are better than present standards, (3) new simplified and inexpensive methods have been found and tested to provide better electrical safety for the critically ill patients, and (4) a low-key but continuous educational program for hospital personnel and interaction of engineers in clinical areas can achieve a high order of safety.

CONTRACTILE AND BIOCHEMICAL EFFECTS OF CORONARY REPERFUSION

Pritpal S. Puri, MD, FACC, Wayne State University School of Medicine, Detroit, Michigan

Immediate and delayed recovery of contractility upon reperfusion following progressively increasing periods of coronary occlusion extending from 30 mins. to five hours was studied in dogs and related to changes in high energy phosphate metabolism. Contractility was recorded by means of a strain gauge tipped catheter probe which measures myocardial fiber shortening. Release of coronary occlusion at any time up to 45 mins. was followed by prompt return of contractility along with complete recovery of adenosine triphosphate and creatine phosphate. With 1-2 hrs. of occlusion a delayed return of contractility occurred at 2 weeks after reperfusion; with 3 hrs. of occlusion recovery was only partial. Reperfusion after coronary occlusion of longer than 3 hrs. failed to restore contractility. Recovery of adenosine triphosphate synthesis (control = 5.45 μmoles/g) was 87%, 75% and 56% of control in experiments with release of coronary occlusion at one hr., two hrs. and three hrs. respectively. Corresponding values for creatine phosphate (control = 7.54 μmoles/g) were 95%, 83% and 60% of control. In conclusion, prompt recovery of contractility and high energy phosphate occurred with reperfusion after 45 mins. of coronary occlusion; with 1-3 hrs. of occlusion a delayed return of contractility and high energy phosphate occurred at 2 weeks after reperfusion. With occlusion of longer than 3 hrs., loss of contractility was irreversible.

RETROGRADE CONDUCTION IN WOLFF-PARKINSON-WHITE SYNDROME DEMONSTRATED BY HIS BUNDLE RECORDINGS AND VENTRICULAR PAIRED PACING.

Bolivar Portillo-Acosta, MD; Otto Hernández-Pieretti, MD, FACC. "Hospital General del Sur" Maracaibo. Estado Zulia. Venezuela.

His Bundle Recordings (HBR) were performed in five patients with WPW complicated by frequent episodes of paroxysmal tachycardia (PT). The technique included 4 surface leads (I,II,III and V-1) recorded simultaneously with intracardiac leads: High right atrium (HRA), and His bipolar electrogram (HBE). An aditional HBE was often recorded by antecubital vein approach. Intermittent ventricular paired pacing at increasing rates and varying coupling intervals was performed in all pts. in order to determine the interval between the driving and testing stimuli (St-1 and St-2) at which reciprocation occurred. Various types of arrhythmias were observed. However, spontaneous and artificially-induced echoes and reciprocating tachycardias occurred in all pts. The onset and termination of the episodes could also be recorded in all cases. Reciprocal rhythms originated by ventricular paired pacing showed the following sequence : Ventricle (V) - low right atrial deflection (LRA) - HRA - His deflection- V , and the cycle started anew. The finding of a His deflection in the HBE after LRA, observed in all cases, demonstrates retrograde conduction through an accessory pathway (AP). Since reciprocal rhythms, rinduced by ventricular paired pacing, occurred at a critical St-1 to St-2 interval which ranged between 280 and 320 msecs., a difference of retrograde refractory periods between the AP and the normal A-V conducting system is suggested to explain the mechanism of reciprocating tachycardias.

EFFECTS OF VARIATIONS IN ARTERIAL pO_2 ON THE SEVERITY OF MYOCARDIAL ISCHEMIC INJURY FOLLOWING EXPERIMENTAL CORONARY OCCLUSION.

Paulo Radvany, MD; Peter R. Maroko, MD; Sharon L. Hale, BA, & Eugene Braunwald, MD, FACC, Dept Med, Harvard Med Sch & Peter Bent Brigham Hosp, Boston, MA.

Arterial oxygen tension is variable in patients with acute myocardial infarction. Hypoxemia in untreated and hyperoxemia in those receiving oxygen therapy are seen commonly. But the influence of variations in arterial pO_2 on the extent of myocardial damage following coronary occlusion is not known. Accordingly, in 28 open-chest dogs the left anterior coronary artery was occluded for 20 min repetitively while breathing room air, 10% O_2 and 40% O_2. Ten to 15 electrocardiographic epicardial leads were recorded in the distribution and vicinity of the site of occlusion. Average ST segment elevation ($\overline{ST}$) and number of sites showing ST segment elevation>2mV (NST), 15 min after occlusion, were used as indices of the severity and extent of ischemic injury. In 9 dogs during 2 occlusions with air breathing $\overline{ST}$ and NST did not change significantly (from 4.2±1.0 to 3.9±1.0mV and from 5.0±1.0 to 5.0±1.0 sites respectively). Ten percent O_2 lowered arterial pO_2 from 92±5 to 45±3mmHg, $\overline{ST}$ increased from 1.2±1.6 to 2.8±1.6mV($p<.01$) and NST from 2.2±2.8 to 6.5±2.6 sites ($p<.01$). Forty percent O_2 raised the pO_2 to 185±5mmHg, $\overline{ST}$ was reduced from 3.6±2.8 to 1.7±1.5mV($p<.01$) and NST fell from 5.3±3.1 to 2.7±2.7 sites ($p<.01$). Mean arterial pressure and heart rate showed no significant change throughout these experiments. It is concluded that following coronary occlusion hypoxemia is deleterious because it substantially increases myocardial damage and hyperoxemia is beneficial by limiting ischemic injury. These findings strongly suggest the danger of hypoxemia in patients with acute myocardial infarction and show the potential beneficial effects of oxygen therapy in reduction of myocardial damage.

UNSTABLE ANGINA: EXTENDED FOLLOWUP (1-4 YEARS) AFTER URGENT BYPASS OPERATION

S.H. Rahimtoola, M.D., Lawrence I. Bonchek, M.D., Richard P. Anderson, M.D., Albert Starr, M.D., FACC, J. David Bristow, M.D., FACC. University of Oregon Medical School, Portland, Oregon

57 patients with intermittent chest pain at rest persisting more than 24 hours after hospitalization and accompanied by transient ischemic ECG changes had urgent saphenous vein aortocoronary bypass more than one year ago. Recent cases with shorter followup are excluded. 29 (49%) had previous infarctions (MI). 30 patients had a single graft, 25 had double grafts and 2 had triple grafts. There were 3 operative deaths (5%) and one sudden late death (2%) one year postop in an asymptomatic patient.

Followup extends from 12 to 48 mos. (mean 24 mos.). One patient is lost to followup. 33 survivors are Functional Class (FC) I, 12 are FC II and 7 are FC III. One patient had an MI immediately postop by Q wave criteria, and 3 had late MI - one following graft occlusion and 2 in areas not supplied by a graft. The single late death was presumptively attributed to an MI. 25 patients had angiography 3 to 28 mos. postop. 25/35 grafts were patent; only 3 patients had no patent grafts.

The extremely low mortality early and late postop (7%), the low incidence of MI (9%), and the excellent functional results after extended followup contrast strikingly with reports by others of results in similar high risk patients managed without urgent operations.

THE PROTECTIVE EFFECT OF PROPRANOLOL ON THE HYPERTROPHIED HEART DURING CARDIOPULMONARY BYPASS

George J. Reul, Jr., M.D., FACC, Alexander Romagnoli, MD John C. Norman, M.D., FACC, Frank M. Sandiford, M.D., Don C. Wukasch, M.D. and Denton A. Cooley, M.D. FACC Texas Heart Institute, Houston, Texas

In an attempt to demonstrate the protective effect of Propranolol during anoxic cardiac arrest (ACA) for aortic valve replacement (AVR), 24 high risk patients were studied. All patients had severe calcific aortic stenosis with chronic congestive heart failure and left ventricular hypertrophy. AVR was done under moderate hypothermia (30°C) without coronary perfusion. All survived operative treatment. Twelve patients received intravenous Propranolol (0.5 mg.) just prior to aortic occlusion and were compared to the 12 non treated patients. Coronary sinus blood levels of calcium, phosphate, potassium, lactate and pyruvate were obtained prior to cardiopulmonary bypass, at the conclusion of ACA and at intervals following ACA. The Propranolol treated group had a significantly higher increase (mean 9.9 mg%) in coronary sinus blood phosphate when compared to the control (mean 3.2 mg%). The lactate/pyruvate ratio increased threefold in the Propranolol treated group (mean 79) when compared to the control (mean 24). Propranolol was used to treat 82 additional patients prior to ACA. Despite the severity of myocardial and aortic valve disease, none of these patients expired in the operative period. Ischemic contracture of the heart was abolished. Results of other parameters in the Propranolol pretreated patient demonstrated a protective effect on the hypertrophied myocardium during cardiopulmonary bypass.

THE ACCURACY OF VENTRICULAR VOLUME ANALYSIS BY QUANTITATIVE ECHOCARDIOGRAPHY IN PATIENTS WITH CORONARY ARTERY DISEASE WITH AND WITHOUT WALL MOTION ABNORMALITIES.

Robert A. Ratshin, MD; Charlie N. Boyd, Jr.; Charles E. Rackley, MD, FACC; Richard O. Russell, Jr., MD, FACC. David Grant USAF Medical Center, Travis AFB, CA and University of Alabama, Birmingham, Ala.

Left ventricular (LV) end-diastolic (EDV) and end-systolic volumes (ESV) by quantitative echocardiography (QE) and angiocardiography (QA) were compared in 99 patients (pts) with coronary artery disease (CAD). LVVs by QE were derived using a cubed function of the measured LV internal dimension. In 34 pts with CAD unassociated with regional abnormally contracting segments (ACS), EDV and ESV by QE and QA correlated with r=0.939 and 0.930 respectively. In 65 pts with CAD+ACS, EDV and ESV by QE and QA correlated with r=0.922 and 0.795 respectively. The accuracy of EDV and ESV by QE was related to ACS location and, in 33 pts, to ACS extent (%ACS). Calculated EDV by QE and QA correlated significantly in pts with isolated anterior (A), inferior (I) or apical ACS and in pts with combined ACS with r-values >0.900. ESV by QE and QA correlated by only 0.714 in pts with AACS, 0.738 in pts with IACS and by 0.801 in pts with combined ACS. ESV by QE and QA correlated more significantly at 0.921 in pts with isolated apical ACS. Neither differences between LVEDVs, nor between LVESVs by QE and QA were statistically related to %ACS nor did there appear to be significant correlation (r=0.620) between differences in LV stroke volumes by QE and QA and calculated %ACS.

Quantitative echocardiography allows accurate quantitation of LVEDV over a wide range of LV sizes in pts with CAD. In the majority of pts with CAD+ACS, ESV by QE and QA did not correlate as significantly as did EDV suggesting that ESV by QE is affected by ACS in all pts save those with isolated apical ACS. The accuracy of ESV by QE thus appears related to ACS location but not to ACS extent.

OBSERVATIONS ON THE EFFECT OF OCCLUSION, NITROGLYCERIN AND PAPAVERINE ON CORONARY ARTERY BYPASS GRAFTS

Anthony Rickards, MB, MRCP; John Wright, FRCS; Raphael Balcon, MD, FACC. London Chest Hospital, London, England.

17 patients receiving 25 saphenous vein coronary artery bypass grafts have been studied at the time of surgery during the interval between the end of cardiopulmonary bypass and chest closure. Measurements have included aortic (AOP) and right atrial (RAP) pressures, left ventricular (LV) pressure measured by direct insertion of a catheter-tip manometer, heart rate and vein graft flow (VG flow) measured with an electromagnetic flowmeter. Following individual vein graft occlusions for 3 minutes there was no significant effect on AOP, RAP or LV dp/dt. LVEDP rose from 15 to 19mm Hg ($p<0.001$) and the relationship LV dp/dt max/LVEDP fell 152 to 135 sec^{-1} ($p<0.001$) indicating an adverse effect on LV function. HR rose from 88 to 91/min ($p<.05$). After release of the graft clamp the VG flow rose to 102ml/min from the resting value of 75ml/min ($p<0.01$) and fell to resting levels in 27 secs. Direct injection of nitroglycerin (NG), average dose 0.12mg, into the VG produced a rise in VG flow from 68 to 121ml/min lasting 66 secs ($p<0.01$). AOP, RAP and LV dp/dt fell significantly but there was no change in LVEDP or LV dp/dt max/LVEDP suggesting no alteration in LV function. Following direct injection of papaverine, average dose 7.6mg, into the VG, flow rose 70 to 149ml/min ($p<0.01$). The other changes observed were ECG T wave changes and a large rise in LV dp/dt min from -1120 to -750mm Hg sec^{-1} ($p<0.001$) suggesting interference with ventricular relaxation.

LEFT VENTRICULAR FUNCTION IN PATIENTS WITH NONTRANSMURAL MYOCARDIAL INFARCTION

Pierre Rigo, M.D., H. William Strauss, M.D., Dean R. Taylor, M.D., David T. Kelly, M.D., Myron L. Weisfeldt, M.D., Bertram Pitt, M.D. Johns Hopkins University and Hospital, Baltimore, Md. 21205

Patients with nontransmural myocardial infarction (NTMI) as diagnosed by ST-T wave changes on the electrocardiogram and elevation of serum enzymes are thought to have less left ventricular dysfunction and a better prognosis than those with transmural myocardial infarction (TMI) with Q waves. Myocardial performance was assessed in 11 patients with NTMI, 7 of whom were uncomplicated (Class I) and 4 of whom had evidence of mild to moderate congestive heart failure. (Class II); and in 25 with TMI, 14 in Class I, and 13 in Class II. The left ventricular filling pressure (LVFP) and cardiac index (CI) were measured with a Swan-Ganz thermodilution catheter. Left ventricular ejection fraction (LVEF), end diastolic volume (EDV), and percent of left ventricular wall akinesis were measured by gated cardiac blood pool scanning (GBPS) with I.V. technetium 99m albumin.

	NTMI	TMI
LVEF %	39±8	37±6
EDV ml	116±28	127±38
% Akinesis	24±13	30±11
LVFP mm Hg	14±5	16±8
CI liters/min/M^2	2.8±1	2.7±.6

There were no significant differences between the values in those with NTMI and TMI. LVEF and EDV in both groups were significantly different ($P<0.01$) from that obtained in 10 normal patients using GBPS 56±3% and 81±4 ml respectively. In conclusion this study suggests patients with NTMI have the same degree of myocardial dysfunction as TMI and does not support functional separation of patients on these electrocardiographic criteria.

INCREASED CARDIAC OUTPUT DURING INDUCED IRREGULAR RHYTHMS

Keith Ritchie, MD; Robert Lux; G. Michael Vincent, MD; Kay Millar, MD, University of Utah, Salt Lake City, Utah.

Irregular rhythm (IR) can increase cardiac output (CO), probably by potentiating contractility. Additional evidence for increased inotropic state during IR was obtained in 10 dogs. Aortic flow and left ventricular pressure were measured during regular rhythm (RR) and IR induced by simultaneous atrial and ventricular pacing from computer generated stimuli. IR patterns included 1) random sequences of cycle lengths with a flat distribution (RF), 2) ordered sequences alternating short and long cycles from the same flat distribution (ASL), and 3) sequences alternating maximum and minimum cycle lengths present in those patterns (AMM). Stimulus patterns had the same mean cycle length and the RF and ASL patterns contained equal numbers of any given cycle length. CO was higher with IR than with RR in all experiments. Compared to RR, increases in CO were 5% during RF rhythm, 15% during ASL rhythm and 25% during AMM. Since the cycle lengths in RF and ASL rhythms were identical, it is likely that differences in CO were due to differences in inotropic state. However, the Frank-Starling mechanism could not be totally excluded. Evidence that differences were due to varying inotropic state was obtained in 3 experiments in which pressures were recorded in a balloon in an isovolumic left ventricle preparation. Average peak pressures, maximum dP/dt and dP/dt at selected pressures were higher with IR than with RR and in most observations higher with ASL than with RF. Findings confirm that IR results in changed inotropic state, and show the maximizing of this effect by optimal sequencing of cycle lengths. A new method for study of rhythm effects on the cardiac state by controlling the sequence of a set of identical cycle lengths is reported.

MYOCARDIAL IMAGING WITH ^{99m}Tc MACROAGGREGATES. CLINICAL, HEMODYNAMIC, ECG, SURGICAL AND AUTOPSY CORRELATIONS

James Ritchie, MD, Glen Hamilton, MD, John Murray, MD, Eugene Lapin, MD, VA Hospital, Seattle, Washington.

Scintillation camera myocardial perfusion images were performed in 51 patients (pts) with proven or suspected ischemic disease. 1.5 mCi ^{99m}Tc macroaggregated albumin was injected directly into one or both coronary arteries.

Myocardial images were classified as normal (26) or abnormal (25) and the location of abnormality noted. 25 pts with abnormal images had myocardial infarction based on history (16/25), Q wave (19/25), or local contractile abnormality (22/25) singly or in combination. No pt with a normal image had a Q wave and only one of 25 had a local contractile abnormality. There was no correlation between an image defect and the presence of exercise induced ST depression. Ejection fraction was reduced ($p<.001$) in pts with abnormal images (43±14% vs. 61±11%). Pts with image defects (11) had transmural scar (10) or inferior hypokinesis (1) observed at surgery or autopsy; pts with normal images all had normal ventricles at surgery (4/4). A single pt with preinfarction angina without evidence of infarction had an image defect. Pts with less than 50% stenosis all had normal myocardial images (19 of 19). Pts with complete occlusions had corresponding image defects. Two pts with complete occlusions without infarctions had normal images. Six patients with stenoses of 75-99% had image defects; 5 had normal images.

We conclude that this technique identifies myocardial scarring secondary to infarction rather than areas of ischemia. Its sensitivity in the diagnosis of myocardial scar was better than the ECG or clinical history and comparable to the presence or absence of local contractile abnormalities on ventriculography. It appears useful in identifying scar and as a baseline for stress studies which may induce ischemia.

LONG TERM SURVIVAL FOLLOWING AORTIC VALVE REPLACEMENT

Douglas L. Roberts, MD; James A. DeWeese, MD; Earl B. Mahoney, MD; Paul N. Yu, MD, FACC, University of Rochester, Rochester, New York.

Study is made of 77 long term survivors of aortic valve replacement. During follow up (24-98 mos, avg 50.2) angina was the leading cause of morbidity (21%) followed by symptoms of congestive heart failure (CHF) (19%). Complications consisted of peripheral emboli (8 pts), hepatitis (5 pts.), and endocarditis (3 pts.). Over one quarter of the patients had a persistent diastolic aortic murmur and 16% clinical evidence of hemolysis. Of the 7 deaths occurring in these patients over the follow up period, post mortem information was available in 6. These long term survivors (77) were compared to the group dying within 1 month of valve replacement (24) and those short term survivors (18) living less than 2 years. CHF was the most frequent preoperative disability and occurred with equal incidence in all 3 groups. Angina and syncope, however, were found with a statistically higher incidence in the short term survivors and hospital mortality groups, respectively. No statistical difference was found among the 3 groups in respect to patient age, functional class, hemodynamic lesion, duration of preoperative symptoms, left ventricular end diastolic pressure (LVEDP) or right ventricular systolic pressure (RVSP). There was, however, a significantly lower cardiac index (c.i.) of the hospital mortality group as compared with the 2 surviving groups. No significant correlation was noted between the duration of survival and the c.i., LVEDP, or RVSP. 59% of the patients were alive at the end of the follow up. Life table analysis showed marked drops at the end of 12 and 36 mos. It would appear that cardiac index is the best predictor of hospital mortality and that once a patient has survived 3 years, his chances for long term survival are excellent.

ENDOMYOCARDIAL DISEASE AND EOSINOPHILIA (LÖFFLER'S DISEASE): A Previously Rare Entity Which May Be Increasing In Frequency

William C. Roberts, M.D., F.A.C.C.; L. Maximilian Buja, M.D.; Bernadine H. Bulkley, M.D.; Joseph P. O'Connell, M.D.; Victor J. Ferrans, M.D., Ph.D., Section of Pathology, National Heart and Lung Institute, National Institutes of Health, Bethesda, Md.

In a 40-year period Löffler studied at necropsy 2 patients with "fibroplastic parietal endocarditis with blood eosinophilia," an entity which now bears his name. During the past 10 years we have studied at necropsy 9 American patients (6 during the past 4 years) with this condition. Their ages ranged from 13 to 52 years; 8 were males. Five initially had been referred to the Cancer Institute with a diagnosis of eosinophilic leukemia and one had a positive Philadelphia chromosome. Eight patients had symptoms from 11 to 44 months (avg. 29) and one, for < 1 week. Except for the latter patient, all had extensive ventricular endomyocardial fibrosis with or without superimposed fibrin-platelet thrombi. The patient with symptoms for < 1 week had only endocardial thrombi, which were extensive, and she may represent a very early stage of this condition. The highest leukocyte counts in the 9 patients ranged from 79,000 to 150,000 per cu. mm, and the highest percentage of eosinophils on smear of blood, from 19 to 90%. All 9 patients died from congestive cardiac failure. The condition observed in our 9 patients is similar to the African condition, endomyocardial fibrosis. It is suggested that Löffler's fibroplastic parietal endocarditis, eosinophilic leukemia (without abnormal myelopoiesis), and endomyocardial disease of the African are the same disease at different stages of development.

THE ELECTROPHYSIOLOGIC BASIS FOR THE SUPPRESSION OF CARDIAC ARRHYTHMIAS BY VERAPAMIL

Michael R. Rosen, M.D.; Joseph P. Ilvento; Charles Merker, M.D., Columbia University, New York, New York

Verapamil (V) is efficacious in the therapy of cardiac arrhythmias. Electrophysiologic studies have shown that V suppresses inward calcium (Ca) currents in cardiac and other excitable tissues. We used standard microelectrode techniques to determine the effects of V, 2×10^{-7} to 1×10^{-5} M on the electrophysiologic properties of isolated canine cardiac Purkinje fibers (PF). V<2×10^{-6}M had no effect on the PF action potential (AP). V=2×10^{-6}M enhanced phase 1 repolarization, bringing it to a more negative value, and increased the slope of phase 2. V≥6×10^{-6}M had more pronounced effects on repolarization and decreased AP amplitude, resting membrane potential, maximum rate of rise of phase 0, and membrane responsiveness. Changes in the effective refractory period were comparable to those in AP duration. Conduction velocity was slowed only by V≥6×10^{-6} M. V effects on phase 4 depolarization and automaticity induced by low potassium perfusates and/or ouabain (O), 2×10^{-7}M were studied as were O induced low amplitude potentials (LAP). V=2×10^{-6}M suppressed automaticity and LAP. V effects on the AP and LAP were partly reversible by increasing perfusate Ca concentration. These studies support the suggestion that V acts via mechanisms different from other antiarrhythmic drugs. Its effects on the AP plateau are consistent with blockade of an inward Ca current and suggest that V may suppress arrhythmias due to Ca induced slow potentials. Lower V concentrations do not alter phase 0 depolarization or conduction, but they do suppress automaticity and LAP's. The latter effects may also result from blockade of an inward current during diastole and are additional mechanisms whereby arrhythmias may be suppressed.

ARTERIAL ENDOTHELIAL AND SMOOTH MUSCLE CELLS: ARE THEY METABOLICALLY AND FUNCTIONALLY SIMILAR?

Abel Lazzarini Robertson, Jr., MD, PhD, FACC; Case Western Reserve University, School of Medicine, Cleveland, Oh.

Ultrastructural and histochemical studies have emphasized the unique characteristics of arterial endothelium as well as its differences in pharmacological responsiveness with smooth muscle cells from the same arterial segment.

We have recently carried out in vivo and in vitro studies on the functional and metabolic characteristics of such cells from large arteries. They suggest that known cytological dissimilarities may result from local environmental influences and occupational variations rather than from genetically coded, unyielding cell differences. The response of endothelial and smooth muscle cells from the same arterial segment to nanogram concentrations of several vasoactive agents, incorporation of colloidal electron markers and labeled homologous lipoprotein fractions was compared with similar cells obtained from large veins. While arterial cells showed similar responses, including significant increases in proliferative rates after short exposures to VLDL and LDL fractions, matching cell populations from the venous system resembled cardiac myocytes.

These studies suggest that endothelial and smooth muscle cells from large arteries may share a common ancestry. In the adult artery, they may represent specialized transitional stages of metabolically and functionally similar cell populations that may profoundly influence the development of vascular disease.

CONTROL OF THE TACHYARRHYTHMIAS ASSOCIATED WITH THE WOLFF-PARKINSON-WHITE BY AMIODARONE

Mauricio B. Rosenbaum, MD; Pablo Chiale, MD; David Ryba, MD; Marcelo V. Elizari, MD, FACC Ramos Mejía Hospital, Buenos Aires, Argentina

Amiodarone hydrochloride proved to be more effective than any of the drugs previously utilized for the prevention and treatment of the arrhythmias of the Wolff-Parkinson-White (WPW) syndrome. 11 patients with WPW and recurrent tachyarrhythmias were treated with oral doses between 300 and 600 mg daily. Paroxysmal supraventricular tachycardia in 6, atrial fibrillation in 4, and atrial flutter in 1, were the most significant arrhythmias. In most patients the arrhythmia caused a serious problem due to extremely rapid ventricular rate, frequency and duration of the episodes and ineffectiveness of other antiarrhythmic agents. In the 11 patients the arrhythmias were totally, easily and safely controlled during 2 to 8 months. The patients response was remarkably enthusiastic, in contrast with the less successful result of all preceding treatments. Tolerance was excellent. Amiodarone causes a significant prolongation of refractoriness in the normal (AV node and His-Purkinje system) as well as in the anomalous pathway, thus creating favorable conditions for prevention and interruption of any reentry mechanism requiring participation of both pathways.

INTERNAL MAMMARY ARTERY VERSUS AUTOGENOUS VEIN FOR CORONARY ARTERY BYPASS GRAFT

Stephen J. Rossiter, M.D., William R. Brody, M.D., Jon C. Kosek, M.D., Martin J. Lipton, M.D. and William W. Angell, M.D., Veterans Administration Hospital, Palo Alto, Calif. and Stanford University Medical Center, Stanford, Calif.

A controversy exists concerning which vessel is best suited for coronary artery bypass surgery. This study deals with the morphologic alteration and susceptibility to atheromatous degeneration of the internal mammary artery graft (IMAG) as compared with the aortocoronary venous graft (ACVG). Six of 12 surviving dogs with IMAG's were fed a hyperlipidemic diet and 6 were placed on a regular diet. Three dogs in each group have been sacrificed 3-15 months post-surgery. Eight of 24 long-term surviving dogs with ACVG's were also on hyperlipidemic diets, and all were sacrificed 3-18 months post-surgery. Arteriography and electron microscopy were performed in selected cases, and histology was performed in all cases. All long-term IMAG's remained patent; 2 of 3 "regular" diet arteries were normal, with no intimal proliferation, while 2 of 3 "hyperlipidemic" IMAG's had atheroma and intimal proliferation. All ACVG's showed medial fibrosis and intimal fibrotic proliferation. In addition, 6 of 8 "hyperlipidemic" ACVG's had diffuse atheroma. Severity of arteriosclerotic involvement of the native coronary circulation was far less than that of the IMAG or ACVG. It may be concluded that: 1) In the normolipidemic condition, the IMAG undergoes significantly less severe histologic change than the ACVG, 2) Both the IMAG and the ACVG are susceptible to atheromatous degeneration, 3) Both types of grafts are apparently more prone to atheromatous change than the native coronary circulation. In these series, patency was not influenced by severity of histologic changes, and no grafts were occluded by virtue of the arteriosclerotic process.

PRINZMETAL'S VARIANT ANGINA: A PATHOPHYSIOLOGICAL AND CLINICAL KALEIDOSCOPE

Charles W. Ruggeroli, MD; Keith Cohn, MD, FACC; Manly Langston, MD, Pacific Medical Center, San Francisco, California

Fifteen patients with Prinzmetal's variant angina, defined as resting chest pain with ST elevation but without enzyme elevation, were studied clinically and by coronary angiography. Three groups were evident: 1) a stable form (1 patient), 2) unstable, accelerated angina (8 patients), and 3) a "post-infarctional" ischemic syndrome (with persistent anterior wall T inversion and intermittent ST elevation). All 3 patients treated medically from Group 3 expired within 6 weeks, while the 3 having surgery are well. Coronary angiography revealed negligible coronary disease in 4; single, double, or triple vessel focal disease in 10; and diffuse coronary atherosclerosis in 1. Coronary spasm was seen in 3. The onset or exacerbation of angina was temporally related to the initiation of sympatholytic antihypertensives in 2; to propranolol in 3; and all improved, at least transiently, after institution of nitrates; 1 after sympathomimetic vasodilators. Other manifestations of angina included fleeting ischemia - lasting seconds (2 patients), coexistent exertional pain in 9, and ischemia-induced ventricular tachycardia and/or fibrillation in 8. We conclude that Prinzmetal's variant angina represents a pathophysiological and clinical spectrum, at times amenable to medical therapy, and at other times presenting as malignant preinfarctional disease necessitating emergency bypass surgery.

NORMALIZATION OF THE ELECTROCARDIOGRAM DURING ANGINA PECTORIS IN PATIENTS WITH SUBENDOCARDIAL INFARCTION.

Donald A. Rothbaum,MD; R. Joe Noble, MD, FACC; Paul L. McHenry, MD, FACC; Gary J. Anderson, MD. Indiana University School of Medicine, Indianapolis, Indiana.

Thirteen patients with ECG evidence of recent or old subendocardial infarction(SEI), defined as ST depression and T wave inversion in the precordial leads, have been observed to normalize their precordial ECG during angina pectoris(AP). By normalization, it is meant that the precordial ST segment returned to the isoelectric line and the T wave became upright. In 10 of these patients, the ECG normalized during spontaneous attacks of AP; in 3, the ECG normalized during AP produced by treadmill exercise(TME). Three of the 10 patients with SEI and spontaneous AP demonstrated reciprocal inferior lead ST depression in association with precordial ECG normalization. Coronary cineangiography in 6 patients(3 with spontaneous AP and 3 with TME AP)revealed total obstruction of the left anterior descending coronary artery(LAD) in each case. Two patients had single vessel disease(LAD); 4 had multiple vessel disease. Five of the 6 patients had a large area of akinesis or hypokinesis on left ventriculography. However, in 2 patients with precordial ST normalization and reciprocal inferior lead ST depression with spontaneous AP, there was no posterior left ventricular wall dysfunction or significant CAD in the vessels supplying this region. Of clinical significance in patients with SEI, the ECG during AP may either appear normal or falsely suggest acute inferior wall ischemia. With TME the ECG response may be normalization rather than further ST depression. Patients with SEI and ECG normalization with AP usually have extensive CAD with LAD occlusion and left ventricular dysfunction.

VALIDITY OF STRUCTURE IDENTIFICATION FOR MULTI-CRYSTAL ECHOCARDIOGRAPHY

David J. Sahn, MD; Richard Terry, MD; Susan Shackleton; and William F. Friedman, MD, FACC, Division of Pediatric Cardiology, University of California, School of Medicine, San Diego, California.

Phased, multiple crystal echocardiography is a major new advance in diagnostic ultrasound. Structure identification was verified in the present study in four cross sections: 1) long axis saggital of left and right ventricles (LV, RV), 2) coronal in the fourth intercostal space (ICS), 3) saggital along RV outflow tract, and 4) coronal of great vessel orientation in the second ICS. During hemodynamic study structure verification was achieved in nine patients by visualizing catheter echoes or indocyanine dye transit. Passage of dye through LA, LV and aorta was visualized in the saggital long axis and coronal (4 ICS) views. Right-sided structures were visualized clearly in patients with left-to-right shunts after left-sided dye injections. Right atrial echoes were observed behind the tricuspid valve in coronal section. Passage of dye through the right ventricular outflow tract and main pulmonary artery as well as visualization of catheter artifacts identified all landmarks in a precise fashion. Thus, this study supports the accuracy of real-time cross-sectional localization of all chambers and all valves in the positions used for cardiac imaging with multiple crystal echocardiographic systems. Because visualization of dye passage appears not unlike an angiogram, this system may find additional use in the catheterization laboratory in order to avoid excessive numbers of injections of contrast medium in patients with congenital heart disease.

CORONARY RISK PROFILE IN THE YOUNG ADULT POPULATION: THE MAJOR IMPORTANCE OF SERUM CHOLESTEROL. Antone F. Salel, MD; Dean T. Mason, MD, FACC; Carolyn K. Clifford, PhD; Andrew J. Clifford, PhD; Ashfaq Husain, PhD; Thomas Y. Cooper, MD.; Nemat O. Borhani, MD, FACC and Robert Zelis, MD, FACC. Univ. of Calif. School of Medicine, Davis, Ca.

Epidemiologic studies have established a strong relationship between serum cholesterol (CHOL) and premature coronary artery disease (CAD) in middle-age populations. In order to investigate the implications of this relationship in a young adult population, a total of 1456 entering UCD students (mean age 22 yrs) were screened. The screening included CHOL (true CHOL by the automated Levine-Zak method following isopropanol extraction) and a multiple risk factor (MRF) self-administered questionnaire. CHOL was correlated (simple, partial, multiple) with multiple risk factors (age, sex, obesity, smoking history, nutritional history, serum glucose, serum uric acid). Mean CHOL was 184 $\pm$ 40 mg/dl ($\pm$ SD) (mode 180, median 189). A striking proportion of the population had significantly elevated CHOL, 2.3% greater than 275 mg/dl, 5.9% over 250, 15.9% over 225 and 35% over 200. Significant correlates ($P<.01$) of serum cholesterol for males and females were obtained only in the populations of individuals with a family history of CAD. No significant correlation was observed with the other family histories such as diabetes and hypertension. Therefore, serum CHOL, an established risk factor of premature CAD in an older population is significantly elevated in a large percentage of this young adult population. In addition, a strong relationship between serum CHOL and a family history of CAD was detected. Since the yield for risk factor screening was so high, it seems prudent to direct major primary prevention efforts to this age group where the likelihood of finding minimal or reversible coronary vascular disease is high.

RESECTION OF LEFT VENTRICULAR ANEURYSM: REPORT OF 275 PATIENTS
Frank M. Sandiford, MD; George J. Reul, Jr., MD, FACC; John T. Dawson, MD; Don C. Wukasch, MD; Luigi Chiariello, MD; Grady L. Hallman, MD, FACC; Denton A. Cooley, MD, FACC.
Texas Heart Institute, Houston, Texas

To evaluate the efficacy of combined aortocoronary bypass (ACB) with left ventricular aneurysm (LVA) resection, 275 patients (pts) who had LVA resection from 1958 to 1972 were reviewed and divided into 3 groups. Group I consisted of 102 pts who underwent LVA resection alone during the pre-ACB period from 1958 to 1969. From 1969 to 1972 there were 122 pts (Group II) who had LVA resection with ACB and 51 pts (Group III) who had LVA resection alone because of insignificant associated coronary artery disease (CAD) in other vessels. Multiple vessel CAD was present in 96% of Group II and in 77% of those pts in Group I who underwent selective arteriography. Preoperative congestive heart failure was present in 95% of Groups I and III and in 66% of Group II, while angina was present in 32% of Group I and in 90% of Group II. In Group I there was an early operative mortality of 17% as compared to Group II (12%) and Group III (10%). Follow-up data from 1 to 12 years demonstrated significantly higher late mortality in Group I. Factors affecting early and late survival in all groups included age, cardiac index, size of LVA, ejection fraction, coronary artery score and length of time after myocardial infarction. The anatomic location of the aneurysm in relation to the occluded and bypassed vessels and the estimated size of the left ventricle after resection have also been related to early and late mortality. Combined ACB with LVA resection significantly improved survival when compared to LVA resection alone.

THE CLINICAL SPECTRUM AND HEMODYNAMICS OF WOMEN WITH CHEST PAIN AND NORMAL CORONARY ARTERIES. Karen Sample, MD; H. Dominic Covvey; E. Douglas Wigle, MD; Allan G. Adelman,MD, Toronto General Hospital, Toronto, Canada.

Forty-nine women with chest pain and suspected ischemic heart disease were found to have normal coronary arteries by selective coronary angiography. Twenty-five had an alternative clinical or hemodynamic basis for chest pain: 10 had significant gastroesophageal disease; 2 had recurrent tachyarrhythmias; 5 had a prolapsed mitral valve leaflet on left ventricular angiography; 3 had cardiomyopathies with significantly elevated left ventricular end-diastolic pressures (mean (m) 24.7 mmHg); and 5 had hyperkinetic heart syndromes with high cardiac indices (CI)(m 5.59 L/min/m^2), increased ejection fractions (EF)(m 84.6%) and low arterial-venous oxygen (A-V O_2) differences (m 2.75 vol%).

Twenty of the remaining 24 patients (pts) had non-specific ST-T changes on their electrocardiogram. These pts had normal intracardiac pressures, CI's and A-V O_2 differences but, increased heart rates (HR)(m 92/min), prolonged corrected ejection times (ET)(m 426.1 msec) and decreased ejection rates (ER)(m 127.5 ml/sec/m^2). As a result the tension time index (TTI) was increased (m 1906.5 mmHg/sec/min), the diastolic pressure time index (DPTI) was reduced (m 2473.3 mmHg/sec/min) and the ratio of DPTI/TTI (an indication of the myocardial O_2 supply and demand relationship) was decreased (m 1.3). These pts also had small hearts with decreased end-diastolic (m 84.4 cc's), end-systolic (m 19 cc's), and stroke volumes (m 65.3 cc's) and high EF's (m 77.9%). The prolonged ET in the presence of an increased HR results in increased O_2 demand, diminished supply and may produce subendocardial ischemia and angina in these pts.

AORTIC VALVE REPLACEMENT WITH CONCOMITANT AORTOCORONARY BYPASS
Frank M. Sandiford, MD; George J. Reul, Jr., MD, FACC; Don C. Wukasch, MD; Luigi Chiariello, MD; Grady L. Hallman, MD, FACC; Denton A. Cooley, MD, FACC.
Texas Heart Institute, Houston, Texas.

One hundred consecutive cases of aortic valve replacement (AVR) with aortocoronary artery bypass (ACB) were reviewed to evaluate factors that influence early and late survival. Of these patients (pts), 65 had aortic stenosis (AS); 21 aortic insufficiency (AI); and 14 combined AS and AI. The majority (64%) were in Functional Class (FC) III and 44% were in FC IV. The predominant manifestations were angina and congestive heart failure (CHF) in 68%, angina alone in 17% and severe CHF alone in 15%. All pts had significant coronary artery disease. Of the 100 pts, 64 had single ACB; 33, double ACB; and 3, triple ACB performed simultaneously with AVR. Early surgical mortality was directly related to the FC IV status [15 deaths among 34 pts (23%)] and to the predominant presenting symptom of CHF alone [8 deaths among 15 pts (53%)]. In the group of pts in FC III who had combined symptoms of angina and CHF (43%), the early surgical mortality was only 7%. Long-term follow-up of the survivors from 1 to 4 years (mean 2.5 years) demonstrated that in 85% of the pts symptoms had disappeared or significantly decreased while in 8.5% symptoms remained unchanged or became worse. The late mortality of 6.4%, mainly due to progressive myocardial failure in FC IV pts, reflected a similar postoperative attrition of 2.5% per year observed in another group of 2273 pts who underwent ACB without concomitant procedures at this Institution. Despite the high operative risk in pts with advanced stages of coexisting aortic valve and CAD, the observed late survival rate appears to justify surgical therapy.

INCREASING HEMOLYSIS AND PREDICTABILITY OF ANEMIA IN THE CLOTH COVERED STARR-EDWARDS PROSTHETIC AORTIC VALVE
John T. Santinga, MD; Jairus P. Flora, PhD: John G. Batsakis, MD; Marvin M. Kirsh, MD, University of Michigan, Ann Arbor, Michigan

This is an evaluation of the frequency and severity of increasing hemolysis in patients with hemolytic anemia from prosthetic valve replacement. In addition the serum lactic dehydrogenase (LDH) levels were evaluated in an effort to predict future anemia. Patients attended the postoperative clinic and had regular screening studies for hemolysis including serum LDH levels (normal 23-65). Patients were placed into anemic and non-anemic groups. LDH values for the anemic group include all yearly values for that patient including pre-anemia levels. The median LDH values for the groups are in the table and the numbers in parentheses are the patients studied that year.

Postop Year	1	2	3	4
Anemic	383 (16)	478 (19)	560 (12)	653 (11)
Non-anemic	181 (20)	150 (18)	187 (11)	147 (5)

The yearly increase in the anemic group is significantly different from the non-anemic group ($p < 0.005$). A subset of these patients showed a one-year increase of 3 LDH units in 15 non-anemic patients and 242 units in 17 anemic patients. The predictive value of the LDH level was assessed from values obtained prior to diagnosis. A value of 250 units predicted anemia on the next yearly visit with a 28% false positive and 4% false negative accuracy. The increasing hemolysis in the anemic patients may represent cloth wear (found in 5 of our 6 reoperated patients). Our current prevalence of anemia in the totally cloth covered aortic valve is 36/90 patients (40%). Therefore, monitoring of the LDH level is suggested. Values in excess of 250 units (4 times the upper limit of normal by other LDH methods) and/or increasing levels would suggest future anemia.

NON-TRAUMATIC DETERMINATION OF CARDIAC OUTPUT AND LEFT VENTRICULAR EJECTION FRACTION BY RADIONUCLIDE ANGIOGRAPHY.
Heinrich R.Schelbert,MD; John W.Verba,PhD; Gary W.Brock; Allen D.Johnson,MD; Frank J.Rose,MD; Naomi P.Alazraki MD; William L. Ashburn,MD; University of California, San Diego, School of Medicine-VA Hospital, San Diego, CA

Previous reports indicated that cardiac output(CO)and left ventricular(LV)ejection fraction(EF)can be determined non-traumatically by radionuclide angiography(RCG). By recording the passage of a radioactive bolus through the heart a time-activity curve corresponding to LV volume changes can be derived.The purpose of the study was to develop a computer program for calculating CO and EF and to examine effects of background activity, scattered radiation and assignment of regions-of-interest(ROI)on these determinations. ^{99m}Tc human serum albumin was injected in 8 patients into the sup.vena cava during cardiac catheterization and the precordial activity recorded by an Anger camera interfaced with a small digital computer. Only that period of precordial activity, during which the bolus passage through the LV, was analyzed.After assigning LV and background ROI, EF was calculated automatically in time segments for the entire LV time-activity curve. The correlation coefficient between EF obtained from biplane cineangiograms (area-length-method) and EF calculated only during the early downslope of the LV time-activity curve and corrected for background activity was 0.92. EF was overestimated when the background ROI was too close to the LV and underestimated when the LV ROI encompassed other cardiac structures.There was good agreement between CO determined by RCG and dye-dilution($r=0.96$).It is concluded that although CO and EF can be measured by this non-hazardous technique with great accuracy,proper selection on the time-activity curve and proper assignment of the LV and background ROI are important.

MAIN LEFT CORONARY ARTERY DISEASE.
Patrick J. Scanlon, M.D., James V. Talano, M.D., John F. Moran, M.D., and Rolf M. Gunnar, M.D., FACC. Loyola University Stritch School of Medicine, Maywood, Illinois 60153

In a 3 1/2 year period, 76 patients (pts) were found to have greater than 50% obstruction of the main left coronary artery (LCA) by coronary arteriography (CA). Clinical presentation was one of pre-infarction angina (PIA) in 30 pts (39%). Total occlusion of the LCA was found in two pts. Severe obstruction of other coronary vessels was present in most pts. Total occlusion was present in the right coronary artery in 32 pts (42%) and in the left anterior descending artery in 18 pts (24%). Isolated obstruction of the LCA was seen in four pts. Calcification of the LCA was seen fluoroscopically in 18 (24%). Intercoronary collaterols were visualized in 51 (67%). Of 70 pts undergoing left ventriculography, 49 (70%) had obvious contraction abnormalities. One pt (1%) became hypotensive and died at the termination of the procedure. Another pt developed myocardial infarction six hours after study and died within 24 hours. 66 pts (87%) were considered operable; 51 underwent surgery with an operative mortality rate (MR) of 12% and a total long term MR of 16%. 24 pts who survived CA were not revascularized; 6 (25%) eventually died. Of 30 pts with PIA, surgical MR was 13% (3 of 23), and nonsurgical MR was 57% (4 of 7) ($p<0.05$). It is concluded that LCA disease, especially when presenting as PIA, is a lethal condition which can be cautiously studied with an acceptable MR, and which usually can be treated surgically at an acceptable risk.

BUNDLE BRANCH BLOCK DUE TO HIS BUNDLE LESIONS
Benjamin J. Scherlag, PhD; Nabil El-Sherif, MD; Ralph Lazzara, MD, Mount Sinai Medical Center, Miami Beach, and Veterans Administration Hospital, Miami, Florida

We have previously reported that ischemic lesions in the His bundle (Hb) could result in bundle branch block patterns or even delta wave formation (Circulation,In Press). To more definitively study this problem, 10 in vivo and in vitro dog hearts were studied with extra- or intracellular recordings from the proximal and distal Hb as well as the right (Rb) and left (Lb) bundle branches (BB). Vagal slowing or atrial pacing showed normal intraventricular conduction within a wide range of heart rates, 20-300/min. Lesions were induced by ischemia (ligation of the anterior septal artery) or by trauma (needle puncture). In vivo,Hb damage was manifested as fragmented or split Hb potentials (H_1,H_2). Atrial pacing or proximal Hb pacing induced H_1-H_2 delay with concomitant Rb or Lb block. However, distal Hb pacing at comparable or even higher rates produced a normal QRS. In 3 dogs traumatic His lesions induced a split Hb potential which showed bradycardia-dependent right bundle branch block with concomitant delay and temporal alternation between H_1 and H_2. In vitro, using a modified Elizari preparation containing the Hb, proximal and distal Rb and Lb, normal conduction from Hb to proximal BB (10-15 msec) and Hb to earliest ventricular muscle activation (26-33 msec) was observed at pacing rates from 30-220/min. Resting potentials of Hb cells ranged from 65-85 mV. Punctate lesions placed above the branching Hb caused bradycardia-dependent (10-30 beats/min) delays to the distal Hb, 2:1 block as well as complete Rb or Lb block. In addition, some portions of the distal Hb were activated after the bundle branch potentials. We conclude that lesions in the Hb can cause bundle branch block probably due to dissociation of normally synchronous conducting pathways in the common bundle.

EFFECTS OF PROPRANOLOL ON HEMOGLOBIN-OXYGEN AFFINITY IN THE ANGINAL SYNDROME

John D. Schrumpf, BS; David S. Sheps, MD; Steven Wolfson, MD, FACC; Alfred L. Aronson, MD; Lawrence S. Cohen, MD, FACC, Yale Univ. Sch. of Med., New Haven, Conn.

Propranolol alters red blood cell hemoglobin (Hb) affinity for oxygen (O_2) in vitro, shifting the oxyhemoglobin dissociation curve to the right, increasing the pO_2 at which Hb is 50% saturated (P50) and enhancing O_2 delivery to tissues. In vivo, a similar effect on Hb P50 has been demonstrated in normal subjects. The present study was designed to determine the effect of propranolol in patients (pts) with documented coronary artery disease (CAD) and the anginal syndrome.

While on daily propranolol ($\geq$ 40 mg.) for at least 6 months and after stopping propranolol for at least 10 days, the patients' Hb P50 was measured by the mixing technique (Edwards and Martin). In the three pts in whom propranolol levels were determined the mean concentration was 25.3 nanograms/ml ($\pm$ 11.7 SEM), generally considered within therapeutic range. All pts had $\geq$ 75% stenosis of one or more major coronary vessels, were non-smokers, had normal pO_2 at rest, and no evidence of hemoglobinopathy. Data in four pts were: Off Propranolol: Mean P50=25.3 mm.Hg. ($\pm$1.67 SEM); On Propranolol: Mean P50=29.1 mm.Hg. ($\pm$0.62 SEM); (p value <0.05). Each patient showed an increase in P50 on propranolol.

This demonstrated shift would increase O_2 delivery 20-30% to marginally perfused myocardium. In addition, decreased Hb-O_2 affinity could maintain systemic oxygen delivery while sparing myocardial work. Thus propranolol, in addition to its negative chronotropic effects, may increase myocardial tissue oxygen delivery in pts with anginal syndrome.

DEEP VENOUS THROMBOSIS AS A DIAGNOSTIC CLUE TO PULMONARY EMBOLISM.

G.V.R.K. Sharma, M.D., D.C. O'Connell, M.S., H.B. Wheeler, M.D., J.S. Belko, M.S. and A.A. Sasahara, M.D., FACC. From the VA Hospital, West Roxbury and the Dept. of Medicine, Harvard Medical School, Boston, Mass.

Current techniques of diagnosing pulmonary embolism (PE) are either non-specific (e.g. lung scanning) or invasive (e.g. pulmonary angiography). Since the majority of pulmonary emboli originate in the legs, identification of deep vein thrombosis (DVT) may serve as a clue to coexistent PE.

Fifty-eight patients who were suspected to have PE on clinical grounds underwent electrical impedance plethysmography (IPG) and pulmonary angiography for diagnosing DVT and PE respectively. Of these, 36 had PE and 38 had DVT. Close association (95%) between the two diseases was seen, as shown below:

PTS		With DVT		Without DVT	
With PE	(36)	34	(95%)	2	(5%)
Without PE	(22)	4	(18%)	18	(82%)

Further analysis indicated that in these patients, diagnosis of DVT established the diagnosis of PE in 90%, whereas patency of the veins excluded the possibility of PE in an equal percentage, as shown below:

PTS		With PE		Without PE	
With DVT	(38)	34	(90%)	4	(10%)
Without DVT	(20)	2	(10%)	18	(90%)

It may be inferred from the above that in patients with cardiopulmonary findings suggestive of PE, recognition of DVT points to coexistent PE in 90%. It may also be stated that in a patient with suspected PE, if the deep veins are patent by IPG, the probability that the patient does not have PE is 90%. Thus, in view of its simplicity and specificity IPG may prove to be a valuable screening procedure in the diagnosis and management of venous thromboembolism.

A NEW POSITIVE INOTROPIC DRUG, RO2-2985/1 (X537A) WITH POTENTIAL USE IN THE TREATMENT OF CARDIAC DISEASE.

Arnold Schwartz, PhD, FACC; Henry G. Hanley, MD; Robert M. Lewis, Ronald Munson and Frederick Dial, Baylor College of Medicine, Houston, Tx.

An antibiotic ionophore, RO2-2985/1 releases calcium (Ca) from sarcoplasmic reticulum (SR), inhibits Na^+,K^+-ATPase and produces positive inotropism. Parameters measured in anesthetized dogs before and after right atrial or femoral vein injections of RO2-2985/1 (0.25-1.0 mg/kg) (Paired "t" test) were:

	N	Avg. of Controls	Avg. of Max. Values after RO2-2985/1	"p"
Mean blood pressure	17	104	141 mm Hg.	<.01
Heart rate	16	150	178 beats/m.	<.01
Aortic blood flow	11	1.9	3.2 L/min.	<.01
Vascular resistance	11	59	67 "R" units	NS
L.Circumflex flow	9	100	228 ml/min.	<.01
L. Ventricular force	17	100	168%	<.01
R. Ventricular force	17	100	189%	<.01
L. Ventricular dF/dt	17	100	204%	<.01
R. Ventricular dF/dt	17	100	214%	<.01

Doses up to 5 mg/kg caused no arrhythmias or alteration in response to isoproterenol (ISO), epinephrine (E) or norepinephrine (NE). Similar responses were noted in normal and shock. Effects were sustained in animals up to 9 hrs.; tyramine, NE, E or ISO at this time resulted in normal effects. Awake, chronically instrumented dogs responded similarly. β-blocked dogs also showed marked response to RO drug. Suggested mechanism of action: Very slow release of some neurotransmitter, secondary to a Ca^{++}-H^+ exchange. These findings of prolonged increased blood pressure, coronary and aortic flow and dF/dt have potential importance in the treatment of certain types of heart disease.

PHYSIOLOGICAL LIMITATIONS OF INTERNAL MAMMARY ARTERY AS CORONARY BYPASS

Harjeet Singh, M.D., Robert J. Flemma, M.D., Alfred J. Tector, MD, & Derward Lepley, MD.FACC - Department of Thoracic-Cardiovascular Surgery, Medical College of Wisconsin, Milwaukee, Wisconsin

Because of its higher patency rate, internal mammary artery-coronary artery (IMA-CA) anastomosis has recently found favor in the revascularization procedures of the myocardium. Nevertheless, it is important to establish that internal mammary artery provides for the myocardial demands for revascularization notwithstanding the many other advantages it offers. Two-hundred fifty-two IMA-CA anastomoses were performed through December, 1972. Postoperative selective coronary arteriography, left ventricular (LV) angiography and necropsy findings in patients followed from 3 weeks to 2 years were correlated with preoperative distribution of coronary artery disease LV angiography and blood flows determined intra-operatively. Lower mammary blood flows were recorded in those who died or developed angiographic occlusions. Although the use of IMA is justified if considering patency rates only, its physiologic limitations in terms of flows need to be recognized. Mean flows were substantially lower if relatively long and narrow vessel was used as well as when preoperative LVEDP was elevated. The IMA provides lower blood flows than vein grafts and when mammary flow is below a critical level, the rate of angiographic narrowing is high. Simultaneous successful vein grafts have been found to compensate for this decreased mammary flow and the postoperative ventricular status depended more on the vein grafts. When vein grafts had narrowed postoperatively, LV supplied by mammary had deteriorated despite mammary-coronary anastomosis being patent. Criteria for its use in the individual patient and its place in myocardial revascularization is assessed.

PRESERVATION OF CARDIAC CELLULAR INTEGRITY BY METHYLPREDNISOLONE IN ACUTE MYOCARDIAL ISCHEMIA. James A. Spath.Jr., Ph.D., David L. Lane, B. A. and Allan M. Lefer, Ph.D. Univ. of Va. Sch. of Medicine, Charlottesville, Virginia

Methylprednisolone (MP) 30 mg/kg, or its vehicle was administered intravenously to cats subjected to acute myocardial ischemia(MI) by occlusion of the left coronary artery. Experimental groups included: sham MI + MP, MI + vehicle, MI + MP at 30 minutes pre-occlusion, and MI + MP at 60 minutes post-occlusion. MP induced no significant hemodynamic effects. Coronary artery occlusion resulted in a significant decrease in heart rate and arterial blood pressure as well as a significant elevation of the S-T segment of the ECG. Pre- or post-treatment of cats with MP resulted in a decline in S-T segment to control values within 4-5 hours,while the S-T segment of diluent-treated cats remained elevated. Moreover, creatine phosphokinase (CPK), cathepsin D and β-glucuronidase activities were reduced 43%, 41% and 33% respectively in ischemic myocardium when compared with non-ischemic regions. In contrast, pre- or post-treatment of cats with MP prevented the activities of the lysosomal hydrolases of β-glucuronidase, cathepsin D and CPK from decreasing in ischemic cardiac tissue five hours after occlusion. Furthermore, plasma CPK activity increased 8-fold in diluent-treated cats following occlusion, but pre- or post-treatment of cats with MP limited the increase in plasma CPK activities to values not significantly different from that of sham-operated cats. These data indicate that methylprednisolone prevents the release of CPK and lysosomal hydrolases from ischemic myocardium. Thus, glucocorticoid stabilization of lysosomal and cellular membranes limits the spread of injury of cardiac tissue which is mediated by release of lysosomal acid hydrolases following infarction. (Supported by a grant from NHLI.).

GLUCOSE-INSULIN-POTASSIUM, PATIENT SURVIVAL, AND THE ACUTE MYOCARDIAL INFARCTION
Alfred W. Stanley, MD; Richard O. Russell, Jr., MD, FACC; Charles E. Rackley, MD, FACC. Department of Medicine, University of Alabama, Birmingham, Alabama.

Twenty-five patients (pts) with symptoms of acute myocardial infarction (AMI) less than 12 hrs in duration were selected for a continuous infusion of glucose-insulin-potassium (GIK). Ten pts received 225 mg glucose (G)/min or 1.5 ml/min of a solution containing 15 g G, 25 U regular insulin (RI), 40 mEq potassium chloride (KCL)/L, and 15 pts received 500 mg G/min or 1.7 ml/min of a solution containing 30 g G, 50 U RI, 80 mEq KCL/L into the right atrium for 48 hrs. Time lapse from original pain to initial infusion ranged from three to 12 hrs. Serial pulmonary artery end-diastolic pressure (PAEDP), cardiac index (CI) and EKG were recorded. G and free fatty acids (FFA) were measured every four hrs. Electrolytes, osmolality, and enzymes were measured every 12 hrs. Additional therapy (lidocaine, procaine amide, quinidine, furosemide) was used if necessary. Many of these pts were considered at high risk (S_3 gallop, 13/25; PAEDP >20, 11/25; precordial bulge, 9/25; cardiomegaly by x-ray, 7/25; pulmonary edema by x-ray, 8/25; cardiac arrest, 7/25; complete heart block, 3/25; plasma FFA >1.2 mEq/L, 11/25. Despite expected mortality from above findings, 23/25 (92%) pts survived the acute episode and were discharged from the hospital. One pt with four hours of cardiogenic shock died two hrs after GIK was begun. Autopsy revealed a left main coronary stenosis. A second pt with a large anterior infarction and previously documented severe three vessel disease with diffuse ventricular akinesis died after 18 hrs of GIK infusion. CONCLUSION: These data from certain high risk pts with AMI suggest that a continuous infusion of GIK may contribute to pt survival.

TWO ANOMALOUS ATRIOVENTRICULAR CONNECTIONS IN PATIENTS WITH THE WOLFF PARKINSON WHITE SYNDROME.
Roworth A.J.Spurrell,BSc,MRCP; Dennis M.Krikler,MD,FRCP, FACC;Edgar Sowton,MD,FRCP,FACC.Guy's Hospital,London.

2 patients with Type B WPW and 1 patient with Type A WPW have been studied using intracardiac recordings and programmed electrical stimulation of the heart.In patient 1.atrial premature beats showed a Type B WPW electrocardiographic pattern. At an atrial premature beat interval of 350 msec this changed to a Type A WPW pattern and at an atrial premature beat interval of 230 msec supraventricular tachycardia was initiated.During tachycardia retrograde left atrial activation occurred 65 msec before right,suggesting that the bypass functioning retrogradely during tachycardia was on the left side of the heart as occurs in Type A WPW. Similar findings were obtained in Patient 2. Both patients therefore have a right sided AV bypass which is used antegradely during sinus rhythm. During tachycardia this bypass is not used but a left sided bypass functions. Patient 3 had Type A WPW and during tachycardia retrograde left atrial activation occurred 40 msec before right,consistent with a left sided bypass. However during premature atrial stimulation with antegrade conduction solely in the His pathway the A-H time did not prolong and the H-V time was short at 15 msec. Ajmaline administration led to normal prolongation of the A-H time with atrial premature beats and the H-V time became 30 msec. These findings suggest the presence of an AV nodal bypass inserting low in the bundle of His in addition to the left sided Kent bypass. The former bypass appeared not to be used during tachycardia. These findings emphasize the importance of an electrophysiological study in patients with the WPW syndrome considered for surgery for their dysrrhythmia. If only surface electrocardiograms are relied upon the wrong bypass may be cut at surgery.

POSTOPERATIVE HEMODYNAMIC AND ELECTROPHYSIOLOGIC EVALUATION OF THE MUSTARD PROCEDURE
Cecille O. Sunderland, MD; Dale P. Henken, MD; G. Michael Nichols, MD; Dharam S. Dhindsa, PhD; Lawrence I. Bonchek, MD; Victor D. Menashe, MD; S. H. Rahimtoola, MD, FACC; Albert Starr, MD, FACC, Univ. of Ore., Portland, Oregon.

Cardiac catheterization, including venous, retrograde and His bundle studies, has been accomplished 1 to 4 years postoperatively in 6 of 14 children in whom the Mustard procedure was performed in infancy or early childhood for transposition of the great arteries. The His bundle potential was recorded in the new right atrium near the mitral valve. P_{50} was normal in all children. Right to left shunting at the SVC-baffle junction, present in 3 children, was minimal in 2, 36% of the cardiac output in the third. An atrial hydrogen positive left to right shunt was present in 1 child. SVC obstruction was clinically manifest in 1 child and an SVC-RA mean pressure gradient ranging from 6 to 12 mm Hg was present in 3. Subvalvular pulmonic stenosis, present in 3 children, had decreased from preoperatively in 1, had increased in 1, and remained unchanged in 1. Pulmonary vascular resistance was normal in all children. Left ventricle ejection fraction was .4 to .6. Right ventricular end-diastolic pressure ranged from 4 to 17 mm Hg before angiography and after angiography ranged from 12 to 20 mm Hg. Though all children have experienced atrial dysrhythmias, none were present during His bundle recording. All intracardiac intervals were normal at rest. Conduction was intact with pacing rates up to 170. Sinus node recovery time was also normal. These findings indicate intactness of the AV node-His bundle-Purkinje system, despite the occurrence of atrial dysrhythmias. Though most children are clinically well, hemodynamic abnormalities may be present.

AN ENERGY DOSE FOR HUMAN VENTRICULAR DEFIBRILLATION

Willis Arnold Tacker, Jr., M.D.; Dan McNamara, M.D.; Emilio Guiliani, M.D.; Leslie Alexander Geddes, Ph. D., Baylor College of Medicine, Houston, Texas

An electrical dose for trans-chest electrical ventricular defibrillation has been reported in animal subjects, but not in humans. In this study trans-chest ventricular defibrillation attempts in 111 human subjects were reviewed to determine the relationship between body weight and electrical countershock strength required for success. The percentage of successful defibrillations decreased progressively as body weight increased in the following way: 100 % success for patients weighing less than 50 kg; 75 % for 50 to 59 kg; 70 % for 60 to 69 kg; 82 % for 70 to 79 kg; 63 % for 80 to 89 kg; 40 % for 90 to 99 kg; and 0 % for greater than 99 kg. Decreasing success within the 50 to 90 kg range and complete failure to defibrillate patients heavier than 90 kg indicates that most commercial defibrillators have inadequate output for use on adult humans. The threshold dose required for defibrillation was establishes for 11 subjects. The dose relationship of average threshold energy and body weight is expressed by the relationship $U = 1.88\ W^{1.15}$, where U is energy (watt-seconds) and W is body weight (kilograms). Suggested guidelines for dosage in humans are 3.5 to 6.5 watt-seconds delivered energy per kg body weight up to 50 kg and the maximum energy output of the defibrillator (or 400 watt-seconds in most commercial units) for greater than 50 kg of body weight.

AGE-RELATED CHANGES IN SENSITIVITY TO DIGOXIN

Paul Tecklenberg, M.D., John Coltart, M.D., James Bolen, M.D., Esther Schweizer, B.S., Robert H. Goldman, M.D., Cardiology Division, Stanford University School of Medicine, Stanford, CA

Clinical studies indicate that infants are less sensitive to digitalis than adults. In order to study the mechanism by which age alters sensitivity to digoxin (D), 1 month old puppies (P) and adult (A) mongrel dogs were anesthetized. Half the dogs in each group were then given H^3-D intravenously at a rate of 2.5 µg/kg/min until ventricular tachycardia (VT) occurred. The other half served as controls. At VT, the animals were sacrificed and left ventricular myocardium analyzed for D and (Na^+,K^+)-ATPase activity. Time to VT was 96.3 ± 4.3 min in P and 58.2 ± 2.2 min in A ($p < 0.01$). (Na^+,K^+)-ATPase activity was 13.1 ± 1.9 in P and 11.4 ± 0.5 µM Pi/mg protein/hr in A not given D (p=NS). At toxicity (Na^+,K^+)ATPase was inhibited 56.5 ± 5.8% in P and 55.2 ± 4.1% in A (p= NS). Myocardial D was 828.2 ± 40.5 ng/gm in P and 503 ± 25.4 ng/gm in A ($p<0.01$). Microsomal-bound D was higher in P than A, 60.3 ± 3.3 vs. 32.0 ± 2.5 ng D/mg protein ($p<0.01$), while plasma D at toxicity and microsomal protein yield were similar in animals given D. These studies suggest that (Na^+,K^+)-ATPase inhibition at toxicity is similar in P and A, but that (Na^+,K^+)-ATPase is less sensitive to D in P than it is in A.

PARALLELISM BETWEEN CYCLIC AMP-DEPENDENT PROTEIN KINASE-CATALYZED PHOSPHOLAMBAN PHOSPHORYLATION AND STIMULATION OF CA-TRANSPORT IN CARDIAC SARCOPLASMIC RETICULUM

Michihiko Tada, MD, PhD; Madeleine A. Kirchberger, PhD; Arnold M. Katz, MD, FACC, Div. Cardiol., Dept. Med., Mount Sinai School of Medicine, N.Y., N.Y., 10029

We have recently shown that bovine cardiac cyclic AMP-dependent protein kinase (PK) stimulates both Ca-uptake and Ca^{2+}-activated ATPase of dog cardiac microsomes enriched in sarcoplasmic reticulum (SR). Enhanced Ca-transport is associated with phosphorylation of phospholamban, a 22,000 dalton protein in which the γ-P of ATP is incorporated as phosphoserine. To demonstrate a causal relationship between phospholamban phosphorylation and Ca-transport stimulation, cardiac SR (0.5 mg/ml) was incubated at 25° C for 10 min. in 40 mM histidine (pH 6.8), 120 mM KCl with and without 1 µM cyclic AMP and 0.01-2.0 mg/ml cardiac PK in the presence of 5 mM MgATP containing [γ-^{32}P] (Reaction A) or no label (Reaction B). Reaction A was stopped by 10% TCA, and hydroxylamine-stable phosphoprotein was determined. Aliquots of Reaction B were added to $^{45}CaCl_2$ + oxalate for Ca-uptake measurement. When PK concentration was varied, phospholamban phosphorylation was closely correlated with increased Ca-uptake. Saturating cardiac PK concentrations (>0.5 mg/ml) caused approx. 4-fold increases in both. Furthermore, the curve relating phospholamban phosphorylation to Ca-uptake stimulation by rabbit skeletal muscle PK was virtually identical to that obtained with bovine cardiac PK. (For combined data N=21, r=0.96, p<0.001). Enhanced Ca-transport thus correlates highly with phosphoprotein formation, providing further evidence that protein kinase-catalyzed phospholamban phosphorylation stimulates Ca-transport by cardiac SR.

ACTION POTENTIALS AND ELECTROGRAMS PRECEDING VENTRICULAR FIBRILLATION DURING ACUTE MYOCARDIAL INFARCTION

John V. Temte, MD, PhD; Guillermo A. Cook, MD; Bernard Lown, MD, FACC, Harvard School of Public Health, Boston, Mass.

The presence of distinctive electrophysiologic changes anticipating ventricular fibrillation (VF) following myocardial infarction was explored by means of suction electrode recordings of monophasic action potentials (MAP's) and epicardial electrocardiography. After obtaining control records in 20 dogs anesthetized with pentobarbital, the left anterior descending coronary artery was externally occluded for 10 minutes. Two types of changes in MAP's and electrograms occurred in infarcted zones. The first response, Type A, anticipated development of localized VF within the infarct, the MAP's were characterized by increased amplitude and disappearance of the plateau. Morphology of the MAP's acquired a sinusoidal appearance with deep negative troughs. The electrograms consisted of tall bizarre R waves with smooth downstrokes and intermittent negative after-potentials. Type A changes occurred in 7 of 9 dogs. Of the 2 remaining dogs, 1 exhibited ventricular tachycardia and the other had leakage of the balloon occluder which lead to normalization of Type A changes. The second response, Type B, had a lesser predisposition to VF occurring in 2 of 11 dogs. The MAP's were characterized by a temporal decrease in amplitude and maximal rate of depolarization. Duration of MAP's responded in a biphasic manner, first increasing due to development of a "hump" or prolongation of terminal phase three repolarization and then progressively decreasing. Type B electrograms exhibited increased amplitude of R complexes with elevated ST segments and upright T waves. The present study provides a distinctive electrophysiologic marker which antedates VF.

LOCAL MYOCARDIAL FUNCTION DURING ACUTE CORONARY OCCLUSION IN THE CONSCIOUS DOG

Pierre Theroux, MD: Dean Franklin; Daniel McKown; William Kemper; and John Ross, Jr., MD, FACC, Sch. of Medicine, University of California San Diego and Scripps Clinic Research Foundation, La Jolla, California

Local, segmental function of the myocardium was characterized in 9 awake, healthy dogs before and during acute coronary occlusion (CO). The dogs were instrumented with a micromanometer, a hydraulic cuff around the origin of the left circumflex artery, and 3 pairs of 2mm ultrasonic crystals. These were implanted 1cm apart near the endocardium in an ischemic segment (IS), a distant control segment (CS), and a marginally ischemic segment (MS) as determined by epicardial ECG mapping at surgery. End-diastolic length (EDL) and extent of shortening (ΔL) were measured; instantaneous power was derived by analog computations as segment velocity x LV pressure; external segmental work was obtained by integration. During CO heart rate increased from 78 to 105 ($p<.001$). In IS, CO resulted within a few beats in decreased ΔL and appearance of a late systolic bulge, followed within 1 min by a holosystolic expansion; EDL increased by 0.6mm (6%, $p<.01$) and stroke work decreased by 768 gm-cm (-90%, $p<.001$) implying passive deformation. In MS, EDL increased by 0.4mm ($p<.01$) while ΔL decreased by 0.8mm (-50%) and stroke work decreased 295 gm-cm (-45%) ($p<.01$). In CS, an initial increase in ΔL occurred at constant EDL; subsequently EDL increased by .34mm ($p<.001$), and ΔL increased by 0.26mm (15%, $p<.01$); the latter increase was linearly related to the increase in EDL ($r=.94$) indicating use of the Frank-Starling mechanism in the CS. These findings characterize local segmental responses of the left ventricle to acute CO, and provide a practical and sensitive approach to quantification of functional effects of coronary occlusion in the awake animal.

EVIDENCE FOR SEVERAL LEVELS OF BLOCK WITHIN THE AV NODE, FOLLOWING PREMATURE ATRIAL STIMULI, AS SHOWN BY MULTIPLE MICROELECTRODE RECORDING IN THE ISOLATED RABBIT HEART.

Paul Touboul, Michiel J. Janse, Jacques Billette, Frans J.L. van Capelle and Dirk Durrer - University of Amsterdam-Amsterdam - The Netherlands.

In order to define the site and mechanism of atrioventricular (AV) block, the pattern of AV nodal activation was mapped in isolated rabbit hearts, following premature atrial stimulation, by multiple intracellular recording, using a 10 microelectrode "brush". After every 10 th basic beat, the atrium was prematurely stimulated after three different intervals. All three premature impulses were concealed within the AV node. The premature beat with the longest preceding cycle traversed nearly the whole AV node, before being blocked close to the beginning of the His bundle. On shortening the interval, the impulse was blocked in the middle of the node, while the earliest premature beat was blocked close to the atrial margin of the node. In all instances, a large area in which action potentials showed an increasingly lower amplitude and rate of rise was interposed between the area of normal action potentials and the area of no response. This area of gradually decreasing responses was smallest for the late premature beat, and largest for the earliest premature beat. Our results show that depending on the coupling interval of the premature beat, block may occur at severals levels of the node, and that the zone of block is typically accompanied by a zone of decremental conduction.

ANGIOTENSIN IN THE TREATMENT OF HYPOXIA IN PATIENTS WITH TETRALOGY OF FALLOT

Dorothy G. Tompkins, MD, Rajindar Singh, MD, Martha A. Carpenter, MD, FACC, J. Francis Dammann, MD, FACC, University of Virginia Hospital, Charlottesville, Va.

Prompt therapy of hypoxic spells in patients with Tetralogy of Fallot (TOF) is frequently lifesaving. With the improvement in surgical management, especially correction of TOF in infants and small children, good medical treatment while preparations for surgery are underway is mandatory. However, medical management remains less than optimal. In a search for a more useful form of medical management we have administered angiotensin to eleven patients with TOF with varying degrees of systemic arterial desaturation to assess its hemodynamic effects. After completing routine cardiac catheterization and establishing the diagnosis of Tetralogy of Fallot, baseline systemic arterial saturations were obtained. Angiotensin (Hypertensin, Ciba Pharmaceutical Co, N.J.) was administered through the venous catheter at a rate of 0.2-0.5 microgram/kg/min to raise the systemic systolic pressure 20-40 mm Hg above the baseline pressure. Systemic arterial saturation was significantly increased in all patients. The percentage increase varied from 8% to 124% and averaged 36%. Four patients with protracted spells and very ill despite the usual methods of treatment (O_2 by mask, parenteral morphine) responded dramatically and were maintained on intermittent or sustained angiotensin administration until surgery could be performed. Our experience shows that angiotensin should be tried in the emergency treatment of patients with acute hypoxic spells who fail to respond to the generally accepted methods of treatment.

HIS BUNDLE RECORDINGS IN CORRECTED TRANSPOSITION OF THE GREAT VESSELS.

João Tranchesi, MD, FACC; Educardo Sosa, MD; Giovanni Bellotti, MD; Siguemituzo Arie, MD; Fulvio Pileggi, MD, FACC; Radi Macruz, MD, FACC; Luis Décourt, MD, FACC.

University of São Paulo, Brasil.

His bundle electrograms (HBE) were recorded in five patients with corrected transposition of the great vessels. In the four patients with normal sinus rhythm and normal P-R interval, the HBE showed functional changes of atrioventricular conduction: (1) increase in the A-H interval in two cases; (2) increase in the H-V interval in one case, more evident during a spontaneous episode of A-V block of the Mobitz I type; (3) increase in the internodal conduction time, namely between the sino-atrial and atrioventricular nodes (P-A interval) during atrial stimulation in the fourth case; and (4) the fifth patient had complete A-V block, the block was post-Hisian with conduction disturbance at the level of the His bundle, related to changes in the morphology and duration of the H spike.

The conduction disturbances observed in the region of the A-V node and in the His bundle and its branches can be explained by the histopathological changes described in cases of corrected transposition of the great vessels.

EFFECTS OF INOTROPIC INTERVENTIONS ON THE NORMAL AND ISCHEMIC MYOCARDIUM IN CONSCIOUS DOGS. Stephen Vatner, M.D., Robert McRitchie, M.B., Peter Maroko, M.D., Thomas Patrick and Eugene Braunwald, M.D., FACC. Dept. of Med., Harvard Med. Sch., & Peter Bent Brigham Hosp., Boston, Ma.

While cardioactive sympathomimetic amines and exercise improve function in the normal heart, their action on the ischemic myocardium is not clear. 9 conscious dogs were studied 2-4 weeks after implantation of endocardial left ventricular(LV) diameter(D) gauges for LVD and dD/dt, i.e. velocity, miniature LV pressure(P) gauges for LVP, dP/dt and dP/dt/P, arterial(A) P catheters, Doppler L circumflex coronary(C) flow(F) probes, and occluders on L main C artery. In normal dogs isoproterenol(ISO), .4ug/kg/min, decreased mean AP (-15mmHg), LV end diastolic(ED) D (-2.8mm), and increased CF from 38 to 96ml/min, dP/dt/P from 60 to 133sec^{-1} and heart rate(HR) from 73 to 167B/min. Mild exercise(EXC) doubled CF, dP/dt/P and HR without changing AP or LVEDD significantly. Dobutamine(DOB), 40ug/kg/min, a cardiospecific β adrenergic agonist with minimal chronotropic and peripheral vascular activity, increased CF (+20 ml/min) and dP/dt/P (+72sec^{-1}) without changing LVEDD, AP or HR. Norepinephrine(NE), .8ug/kg/min, increased mean AP (+48mmHg), CF (+12ml/min), dP/dt/P (+59sec^{-1}) without changing LVEDD or HR. Partially occluding the C artery to reduce CF from 38 to 26ml/min induced marginally impaired LV function as reflected in a fall in dP/dt/P (-5sec^{-1}) and a rise in LVEDD (+1.3mm). Then, ISO and EXC produced paradoxical responses, dP/dt/P falling by 33 and 36sec^{-1} and LVEDD rising 1.1 and 2.2mm respectively. NE still improved LV function, dP/dt/P rose (+33sec^{-1}) and DOB produced an intermediate response changing dP/dt/P only slightly. Thus, inotropic interventions (ISO,EXC) that increase HR and contractility without increasing AP can elicit paradoxical deleterious responses in global myocardial ischemia, while NE, which increases contractility and C perfusion, improves function in the ischemic as well as the normal myocardium.

AORTOCORONARY BYPASS IN THE DIABETIC PATIENT
Joseph J. Verska, MD, FACC; Wallace G. Gosney, MD; Weldon J. Walker, MD, FACC, White Memorial Medical Center, Los Angeles, California

The hospital records of 112 consecutive elective aortocoronary bypass grafts were reviewed to evaluate the effect of diabetes mellitus (DM) on operative results. Excluded were associated left ventricular aneurysm resection, valve replacement, or emergency procedures. 35 patients (31%) had DM (8 of these newly discovered during workup for angina). Preoperatively the DM and non-diabetic (NDM) patients were of similar average age and sex, had similar incidence of hypertension, smoking, family history of coronary disease, and number and distribution of vessels involved. The DM group (NDM in parentheses) had a greater frequency of prior MIs 63% (NDM 45%), preinfarction angina 20% (3%), dyskinetic left ventricles 49% (40%), LVH 54% (42%), obesity 63% (44%), CHF 15% (9%), mitral insufficiency 14% (6%), and a greater number of Class IV patients 23% (7%). Intraoperatively, DM patients received more triple grafts 26% (17%). Duration of bypass was the same in both groups. Average flow rates of grafts were similar: RCA 74 cc/min (72), LAD 67 (60), circumflex 61 (55). Operative mortality: 4 DM - 11% (3 NDM - 4%). One late death occurred in each group. Postoperatively, the DM group had more serious complications: CVA 6% (0); increased blood loss 11% (4%); wound infections 9% (3%); sternal separations requiring reoperation 6% (NDM - 1 flail chest, no reop); elevated BUN 20% (10%), one DM required peritoneal dialysis; longer postop hospitalization 16 days (13); DM patients had fewer post-surgical myocardial infarctions 6% (12%). Patients with DM can be selected for aortocoronary bypass using the same criteria as NDM. Our flow rates in grafts were similar, placing doubt on the significance of small vessel involvement in the myocardium. New DM was found in 7% of our patients.

ANALYSIS OF VULNERABILITY CHANGES DURING ACUTE CORONARY OCCLUSION AND RELEASE
Richard Verrier, PhD; Ramon Corbalan, MD; Bernard Lown, MD, FACC, Harvard School of Public Health, Boston, Mass.

Antiarrhythmic drugs affect differently ventricular fibrillation (VF) arising from coronary occlusion (CO) and from release (R) of the obstructed vessel. The basis for this disparity of drug action is undefined. The present study examined the mechanism accounting for the differences in ventricular vulnerability during CO and R. A balloon catheter was placed around the left anterior descending coronary artery 7 days prior to definitive study. Under pentobarbital anesthesia VF threshold (VFT) was determined by the technique of sequential R/T pulsing. Four periods of 10 minute CO followed by R were studied in 10 dogs. CO resulted in an abrupt fall in VFT from a control value of 63 ± 3 (S.E.) to 2 mA within 1.2 ± 0.1 min. Spontaneous recovery of VFT to control value occurred at 7.0 ± 0.1 min. Upon successive CO there was a progressive delay in the onset and decrease in duration of vulnerability. In comparison, R at 10 min resulted within 0.2 ± 0.1 min in a transient decrease of VFT to 2 mA. Repeated CO did not affect the time course of vulnerability changes during R. In 6 dogs the duration of CO was varied; 3 min of CO was the minimum time which resulted in reduction of VFT after R. In a series of 10 other dogs, propranolol (0.2 mg/kg) prevented decrease in VFT following 10 min CO but did not prevent change in VFT after R. The present findings support the view that the predisposition to VF produced by CO and R are mediated by different mechanisms; CO producing its effect through adrenergic factors; the basis for VF during R needs further definition, but may be due to washout products of cellular ischemia.

AUTONOMIC MANIPULATION IN THE INHERITED LONG QT-RECURRENT SYNCOPE SYNDROMES
G. Michael Vincent,MD; J.A.Abildskov,MD; M.J.Burgess,MD; Kay Millar,MD, University of Utah, Salt Lake City, Utah.

Regional autonomic dysfunction in the inherited long QT syndromes is suggested by experimental animal data, and a report of successful treatment in one case by unilateral stellectomy. However, results of stellate block in several other cases have been variable. This paper describes the results of right (R) and left (L) stellate block (SB) and percutaneous stellate stimulation (SS) in two symptomatic patients.

SS was performed using stimuli at 12 Hz and up to 5 Volts. SB was produced by 1% Xylocaine. A Horner's syndrome was seen with each block.

The results of the interventions on the rate corrected QT interval (QTc) are shown in the following table.

	SS			SB		
	CONTROL	RSS	LSS	CONTROL	RSB	LSB
Pt 1	0.52	0.59	0.52	0.53	0.51	0.47
Pt 2	0.50	0.50	0.50	0.50	0.46	0.46

It is seen that RSS in Pt 1 prolonged the QT interval, and that block of both RS and LS shortened the QT interval in both patients, being greater with LB in Pt 1. In addition, RSB in Pt 2 increased the heart rate from 70 to 95 beats/min. These results are different than expected from previous animal experiments. In the animals, RS ganglionectomy and LSS, but not LS ganglionectomy or RSS, produced QT prolongation, and RSS produced sinus tachycardia.

The results confirm that regional sympathetic dysfunction plays a role in these syndromes and suggests that the cardiac location of this dysfunction may differ in individual cases. In addition, the effects of SS in these pts are described, and the usefulness of this technic and SB in the evaluation of regional autonomic function is confirmed.

IMMEDIATE EFFECT OF CONTRAST INJECTION ON LEFT VENTRICULAR VOLUME. D.L.Vine, MD; H.T.Dodge, MD, FACC; D.K. Stewart, MD; J.A.Murray, MD, FACC. University of Washington, Seattle, WA

The immediate effect of injection of contrast medium on left ventricular (LV) volume and stroke volume (SV) was evaluated from the post-op LV biplane cineangiograms of 5 patients with 4-6 epicardial markers placed during coronary artery surgery. Spatial distances between markers were calculated for every cine frame of 7 consecutive beats beginning with the beat (0) preceeding injection of contrast. For each patient, the marker distances were related to angiographically determined volumes over one cycle (r=0.97-0.99). The regression equations determined from these relationships were used to compute LV volume from distances between the epicardial markers of beats prior to injection (0), during injection (1-4) and immediately after (5 & 6).

Control end-diastolic volume (EDV) (beat 0) ranged from 171-91 cc (mean=144cc). During injection (beats 1-4), maximum individual changes were small (+5, -10, -3, +8, & +2 cc) with mean changes (beats 1-6) of 0, +1, -2, -6, & -9 cc. The mean changes in end-systolic volume (ESV) (-1, -1, -3, -6, -7 & -9 cc), stroke volume (0, -1, +2, +4, +1 & 0 cc) and ejection fraction (EF) (0, 0, +1, +3, +3 & +4%) also show little change during injection. A relatively greater decline in EDV & ESV of beats 5 & 6 may be due to the valsalva effect seen in 3 patients but the injection, itself, produced no consistent change in LVEDV, ESV, SV or EF.

This is the first beat by beat analysis of the immediate effect on ventricular chamber volume of selective LV angiography and is an application of a new technique using epicardial metallic markers to quantitate LV volume changes.

IDENTIFICATION OF PREDISPOSING FACTORS TO VENTRICULAR ARRHYTHMIAS IN THE LATE HOSPITAL PHASE OF ACUTE MYOCARDIAL INFARCTION. Louis A. Vismara, MD; James L. Hughes, MD; Dean T. Mason, MD, FACC; Robert Zelis, MD, FACC and Ezra A. Amsterdam, MD, FACC, Univ. of Calif., Davis

Since serious ventricular arrhythmias persisting late after acute myocardial infarction(AMI) may predispose to sudden death, factors associated with these arrhythmias were sought in this study. Holter(H) 8 hour monitoring was performed in 77 AMI patients(pts) during the ambulatory period of hospitalization(average 11 days post-CCU). H identified: group I(30 pts) with complicated ventricular(V) extrasystoles(PVC)(multifocal, paired, R on T, >5/min)in 26 of V tachycardia(VT) in 4; group II (25) with uncomplicated PCV; group III(22) without ventricular ectopy. The 3 groups were similar in age, sex, AMI location, coronary risk factors and CCU vital signs, X-ray cardiomegaly and extent of necrosis(Q waves and myocardial enzymes). Continuous CCU monitoring(3-5 days) in all groups revealed common prevalence of complicated PVC (14/30, 8/25, 8/22), and VT(5/30, 3/25, 3/22. Thus late hospital PVC are not related to CCU ectopy. CCU right heart catheterization showed no difference of the groups in cardiac index but I compared to III had higher pulmonary capillary wedge pressure(PCW)(14.3, 8.9 mmHg, $p<.05$) and lower systemic arterial pO_2(57, 70, $p<.05$). Post CCU (5-16 days) there were no group differences in Q and T waves, X-ray heart size, myocardial enzymes, serum cholesterol or medications. However hospital predischarge ST segment abnormalities occurred more frequently in group I than III(3.5, 1.3 leads/tracing, $p<.05$). Thus late hospital serious ventricular arrhythmias following AMI correlate with prior CCU arterial hypoxia and elevated PCW and with persistent ST segment abnormalities, suggesting that these rhythm disorders may be related to persistent myocardial ischemia and pump dysfunction.

RELATION OF VENTRICULAR ARRHYTHMIAS IN THE LATE HOSPITAL PHASE OF ACUTE MYOCARDIAL INFARCTION TO POST-HOSPITAL SUDDEN DEATH. Louis A. Vismara, MD; James L. Hughes, MD; Jess Kraus, PhD; Nemat O. Borhani, MD; Robert Zelis, MD, FACC, Dean T. Mason, MD, FACC and Ezra A. Amsterdam, MD, FACC, Univ. of Calif., Davis, Calif.

To determine the prognostic significance of ventricular arrhythmias persisting during the hospital ambulatory phase of acute myocardial infarction(AMI), 64 AMI patients (pts) had continuous 8 hour Holter monitoring an average of 11 days after discharge from the coronary care unit (CCU). Pts were categorized according to ventricular ectopy: group I(27 pts) in whom extrasystoles(PVC) were complicated(multifocal, R on T, paired, $\geq$5/min) or had ventricular tachycardia(VT); II(22) had uncomplicated PVC; and III(15) had no ventricular arrhythmias. The 64 pts were followed an average of 25.8(13-38) months; there were 12 sudden deaths(SD), 8 deaths from other causes, and 44 survivors(S). All SD pts had ventricular ectopy recorded on hospital pre-discharge Holter(group I: 8 pts; II:4), while there were no SD in group III pts($p<.05$). SD and S pts were similar in age(60, 62 years), sex, location of infarction, coronary risk factors, severity of AMI(Q waves, cardiac enzymes), serum cholesterol, X-ray cardiomegaly, S_3 gallop and drug therapy. CCU arrhythmias did not separate SD from S pts: there were no differences in VT or ventricular fibrillation(3/12 pts, 6/44 pts) or complicated PVC(4/12, 12/44). Late hospital ECG revealed no differences in Q or ischemic T wave extent. However, SD pts had greater extent of ST segment abnormality than S pts(5.6, 1.8 leads/tracing, $p<.02$) suggesting their arrhythmias were related to persistent ischemia or segmental fibrosis. Thus ventricular arrhythmias persisting during late hospitalization for AMI are associated with subsequent sudden death.

MITRAL REGURGITATION IN PATIENTS WITH CORONARY ARTERY DISEASE: RELATION TO EXTENT OF MYOCARDIAL DYSFUNCTION. Louis A. Vismara, MD, Richard R. Miller, MD, Anthony DeMaria, MD, Dean T. Mason, MD, FACC, and Ezra A. Amsterdam, MD, FACC., Univ. of Calif., Davis, Calif.

To further investigate the mechanism and significance of mitral regurgitation(MR) caused by coronary artery disease(CAD), a group of 15 patients(pts) with major CAD-MR were compared to 15 controls(C) at coronary and left ventricular(LV) angiography. Pts were matched for age, sex, extent of CAD and all had markedly abnormal segmental contraction(ASC) of LV. LV diastolic volumes were comparably increased(MR 313, C 270 ml); however MR pts had a lower cardiac index(MR 2.3 $\pm$ .2, C 2.9 $\pm$ .3 L/min/M^2, $p<.05$); higher LV end diastolic pressure (mmHg) (MR 22.9, C 12 mmHg, $p<.01$). These hemodynamic differences did not result from MR alone since the LV ejection fraction was decreased (MR 25%, C 45%, $p<.05$). ASC, quantitated as percent of total LV perimeter (right anterior oblique), was greater in MR pts(MR 78%, C 53% $p<.05$). Since the extent of systolic akinesis and paradox in the two groups was similar it is uncertain if the greater hypokinesis (diminished systolic shortening) in MR pts was a manifestation of greater ischemia, and/or fibrosis. There was no difference in location of CAD, coronary collaterals, LV septal or lateral wall motion to explain the occurrence of mitral regurgitation. However, combined inferior and anterior wall ASC occurred in 13/15 MR but only 2/13 of C($p<.05$). Thus it is suggested that MR in stable CAD pts is directly related to the extent of LV with ASC and major MR occurs with combined posterior and lateral papillary muscle dysfunction. Furthermore, since major MR is associated with marked impairment in LV pump function, its presence indicates a poor prognosis.

THE EFFECTS OF METHYLPREDNISOLONE ADMINISTRATION ON CARDIAC PERFORMANCE AND ENERGETICS IN ACUTE INFARCTION.

John K. Vyden, MD; Koichi Nagasawa, MD; Babeth Rabinowitz, MD; William W. Parmley, MD, FACC; Eliot Corday, MD, FACC; H.J.C. Swan, MD, PhD, FACC. Cedars-Sinai Medical Center, Los Angeles, California 90029

As large dosage corticosteroids have been shown to reduce infarct size experimentally, a study of the hemodynamic effects of methylprednisolone (MP) appeared indicated. MP 50 mg/Kg IV was given to 15 dogs instrumented with flowmeters with LAD ligation induced infarction & the results contrasted with 11 untreated animals. Ninety minutes after administration MP increased cardiac index from 0.72 to 1.06 L/min/m^2, arterial blood pressure from 55 to 66 mmHg, stroke work index from 3.49 to 9.43 gm-m/beat/m^2, LV max dp/dt from 1159 to 1531 mmHg/sec, coronary arterial flow from 13.2 to 23.5 ml/min, while coronary arterial-sinus O_2 difference narrowed from 11.7 to 9.1 vol%. Cardiac efficiency (SWI/MVO_2) doubled from 1.98 to 3.92 units Mean heart rate fell from 123 to 103 beats/min & coronary vascular resistance dropped from 4.14 to 2.10 10^5 dynes cm^{-5} sec. After 90 min, LVEDP, SVR & mesenteric, renal, femoral & carotid resistances were unchanged. In parallel cat papillary muscle experiments, MP had no effect on peak developed force, df/dt, time to peak force but reduced relaxation time. Following potentiation with paired stimulation, calcium & isoproternol, diminished force development & max df/dt were seen after MP. MP had no effect on adenyl cyclase activity. MP was thought to improve the critical oxygen balance by first dropping afterload & preload evanescently in the initial 15 min with heart rate & then increasing coronary arterial blood flow, with a resultant marked increase in cardiac efficiency & performance. The major dilatory effect of MP is thus in the coronary bed as other regional circulations remain uneffected.

ELECTROPHYSIOLOGICAL DELINEATION OF THE LEFT BUNDLE-BRANCH IN MAN

Albert L. Waldo, MD; Robert B. Karp, MD; Nicholas T. Kouchoukos, MD; William A. H. MacLean, MD; George K. Massing, MD; Thomas N. James, MD, FACC. University of Alabama, Birmingham, Alabama.

The concept that the left bundle-branch (LBB) divides into well defined anterior and posterior fascicles has gained wide-spread clinical acceptance despite lack of anatomical support. This concept was assessed in nine patients (pts) during open-heart surgery (aortic valve replacement) by electrographic delineation of the anatomical course and sequence of activation of the LBB. During normally conducted atrial rhythm, an electrode probe was used to record bipolar electrograms (EG) from selected sites on the left ventricular (LV) endocardium simultaneously with three ECG leads. The electrode probe was initially placed just below the junction of the noncoronary cusp of the aortic valve with the anterior leaflet of the mitral valve. The probe was then moved anteriorly along the LV septum by increments of 5 mm (the probe diameter) to a point just below the junction of the right and left coronary cusps of the aortic valve. Four such rows were mapped, each row one probe diameter below the other. Thus, EGs were recorded from LV endocardial sites up to 2 cm below the aortic valves. Specialized conduction system EGs were recorded in all four rows in all pts. The electrophysiologically delineated LBB cascaded as one broad undivided sheet down the LV from the membraneous septum. The anterior and posterior extent of the LBB varied from pt to pt. Discrete anterior and posterior fascicles could not be demonstrated from either the electrophysiological localization or sequence of activation of the LBB. Our electrophysiological data are consistent with the anatomy of the LBB as previously reported from this laboratory.

CURRENT INDICATIONS FOR MECHANICAL CARDIAC ASSISTANCE ON THE BASIS OF EXPERIENCE WITH 104 PATIENTS

Waldemar J. Wajszczuk, MD, FACC, Joseph Krakauer, MD, Melvyn Rubenfire, MD, Michael Ciborsky, MD, Edward Malinowski, MD and Adrian Kantrowitz, MD, FACC
Sinai Hospital, Detroit, Michigan

Clinical application of intraaortic balloon pumping (IABP) began in 1967 to evaluate its hemodynamic effectiveness and safety. Strict criteria were utilized to select 58 patients (pts) in medically intractable cardiogenic shock. Temporary shock reversal was observed in 84%; circulatory stabilization allowed cessation of pumping in 51%; 22% (12 pts) were discharged. Reevaluation over 6 years revealed: 7 pts well; 3 dead at 8-18 months from unrelated causes, 1 of acute myocardial infarction (AMI) at 2.5 years; condition of 1 is unknown.

With experience and understanding of physiology, indications for support were extended to: (1) Cardiac surgery - preoperative support in 10 "inoperable" pts with severe left ventricular failure (LVF) and mitral insufficiency; 6 pts for discontinuation of cardiopulmonary bypass (CPB), 2 assisted for late postoperative complications. Marked hemodynamic improvement was seen in the preoperative group (60% survival) and assistance in weaning from CPB was successful in 50%; (2) 13 pts with AMI, preshock, intractable pulmonary edema and terminal LVF were effectively supported for as long as 71 days (31% survival); (3) 5 pts with chronic LVF were evaluated for permanent mechanical assistance by diastolic augmentation; (4) 1 pt was successfully treated for intractable recurrent ventricular fibrillation (5) 4 pts with inoperable intractable angina pectoris were stabilized for 1-6 months; (6) 3 pts with gram-negative sepsis and shock showed no beneficial effect; (7) 2 pts were supported in attempt to reduce infarct size as measured by precordial mapping. IABP was found to be hemodynamically effective in all pts with LVF. Complications were rare (3%) and predominantly peripheral vascular.

PROPRANOLOL IN THE LONG-TERM TREATMENT OF ANGINA PECTORIS

Stafford G. Warren, M.D.; David L. Brewer, M.D.; Edward S. Orgain, M.D., F.A.C.C., Duke University, Durham, N.C.

53 pts with stable, severe angina and CAD were studied prospectively with followup of 6-8yrs on propranolol hydrochloride (PH) to assess complication rate and long-term effectiveness after initial control period. Mean age was 56yrs; mean daily dose was 255 mg. Each pt had a dose threshold (between 160-480mg) at which maximum benefit was obtained. CHF had previously been documented in 21% and was compensated prior to PH therapy. 3 pts had a history of mild asthma. Average yearly mortality was 3.8% with a cumulative 5yr mortality of 18%. Pts with a $< 50\%$ reduction in pains on PH had almost a 4-fold greater mortality than those with $\geq 50\%$ decrease in pains ($p < .01$). 32% of pts/yr were angina-free on PH and 84%/yr had $\geq 50\%$ decrease in pains. There was no evidence for tachyphylaxis. CHF developed in 25% of pts, 68% of whom had either an acute MI(AMI) with CHF or previous CHF. All pts (4) with an initial C.T. ratio > 0.5 developed CHF during the first 3yrs of PH therapy. 12 pts on PH had an AMI during the study; 7 died, 6 with cardiogenic shock. Of 9 pts who developed CHF without AMI, 8 survived the initial episode. Significant side effects occurred in 19% and included CHF(6), GI symptoms(3), hallucinations (1), and postural hypotension(1). Some of the side effects not requiring drug discontinuation included transient eosinophilia(11),asthma(3),CHF(3)and 1st degree heart block(1).

PH is an effective form of long-term therapy for severe angina without tachyphylaxis and without increasing overall mortality, although it may increase the risk of cardiogenic shock in AMI. Previous CHF, a C.T. ratio > 0.5 without overt CHF, and mild asthma are relative contraindications. A $\geq 50\%$ reduction in pains on PH predicts a low mortality group.

MORTALITY FACTORS IN MYOCARDIAL INFARCTION - A FIVE YEAR STUDY

Sylvan Lee Weinberg, MD, FACC; Huascar E. Jessen, MD; Sylvia Stevens, Good Samaritan Hospital, Dayton, Ohio

Surgical alternatives in the management of coronary disease have made knowledge of natural history and prognosis vital in assessing risks and advantages of different forms of treatment. 212 patients with a confirmed diagnosis of acute myocardial infarction (MI) hospitalized 1967-68 were studied for 5 years. Factors associated with mortality were compared with those defined during the hospital phase. 46 (21%) of the original 212 patients died in the hospital. 10 were lost to followup. 43 (28%) of the remaining 156 patients died during the next 5 years. Acute phase mortality for anterior MI was 29% and for inferior MI 13%. 5 year mortality for anterior MI was 28% and for inferior MI 25%. Location affected acute but not long term prognosis. Patients with previous MI had a 36% acute mortality and 17% without prior MI. 5 year death rate for survivals of recurrent and first episode MI was 41 and 24% respectively. In-hospital mortality for intraventricular conduction defects (IVCD) was 47%, only 14% with normal IV conduction. Differential mortality was reduced for the next 5 years to 41% for IVCD, 25% without IVCD. Of 27 patients who left the hospital with IVCD, 12 had isolated left anterior hemiblock. 2 died. Of 15 with right bundle branch block, left bundle branch block or bifascicular block, 9 died. Among 11 patients with either LBBB or bifascicular block, 8 died. Attrition rate during the first posthospital year was very high accounting for 21 of the 43 deaths. The study identified mortality factors for a 5 year period after MI and showed that their prognostic significance differed materially from that during the acute hospital phase.

PERSISTENCE OF MYOCARDIAL INJURY FOLLOWING BRIEF PERIODS OF CORONARY OCCLUSION.

Jerold M. Weiner, MD, Carl S. Apstein, MD, John H. Arthur, MD, William B. Hood, Jr., MD, Boston University School of Medicine, Boston City Hospital, Boston, Massachusetts.

Epicardial electrogram studies have suggested that ischemic injury caused by repeated 20 min coronary occlusions (occl) in dogs is completely reversible. To examine this in a mechanical analogue, regional function of the ischemic left ventricle (LV) was measured in 6 open-chest dogs using two mercury-in-Silastic segment length (SL) gauges sutured to the LV epicardium, one in an ischemic (I) area supplied by the transiently occluded left anterior descending coronary artery and another in a normal (N) area. Initial occl caused a systolic aneurysmal bulge and a loss of the systolic shortening phase (SSP). N-SL showed no change. Reflow for 45 min caused a gradual decrease in I-SL amplitude, but not to control levels, and the SSP abnormality persisted. Subsequent occl demonstrated a similar pattern in I-SL tracings. Measurements of I-SL amplitude gave the following results (Mean±SEM):

	Pre-occl	Occl (20 min)
1st occl	0.11±0.01	0.23±0.05*
2nd occl	0.19±0.04**	0.23±0.04*
3rd occl	0.18±0.02**	0.20±0.03*

($p<0.05$, *occl vs pre-occl; **2nd and 3rd vs 1st pre-occl; data expressed in muscle lengths (ML), where ML= peak SL/end-diastolic SL).

The results show that 1) persistent mechanical dysfunction is demonstrated after occl lasting 20 min, 2) prolonged injury results from periods of occl shorter than heretofore demonstrated, 3) regional mechanical changes are a very sensitive indicator of ischemic injury.

PLASTIC RECONSTRUCTION OF THE AORTIC ROOT FOR THE RELIEF OF CONGENITAL SUPRAVALVULAR AORTIC STENOSIS: POSTOPERATIVE EVALUATION

Daniel Weisz, MD; Alexis F. Hartmann, Jr., MD, FACC; Clarence S. Weldon, MD, FACC, Washington University, St. Louis, Missouri

Plastic reconstruction of the aortic root is accepted management for supravalvular aortic stenosis. An evaluation of this technique by postoperative left heart catheterization and aortography in a series of operated patients has not been previously available. Eight children (ages 3-15) have had a surgical correction of congenital supravalvular aortic stenosis. In 2 patients, an aortic valvotomy was also performed to relieve congenital valvular stenosis. Preoperative gradients in systole across the supravalvular lesion ranged between 40 and 90 mm.Hg. (average 70 mm.Hg.). In all patients, the aorta was incised longitudinally across the stenosis and down into the posterior sinus of valsalva to the aortic annulus. No tissue was excised. An ellipse of prosthetic cloth was inserted which purposefully separated the commissural attachments of the posterior aortic leaflet. Six of these patients have now been evaluated postoperatively. Postoperative gradients range between 0 mm.Hg. and 20 mm.Hg. (average 11 mm.Hg.). Angiographic appearance of the aortic root is near normal in all patients. Two patients have declined restudy, but all patients are asymptomatic. Properly performed plastic reconstruction of the aortic root provides an excellent correction of supravalvular aortic stenosis.

SURGICAL CORRECTION OF COARCTATION OF THE AORTA IN INFANCY: SPECIAL CONSIDERATIONS FOR INTRAOPERATIVE AND POSTOPERATIVE MANAGEMENT

Clarence S. Weldon, MD, FACC; Alexis F. Hartmann, Jr., MD, FACC, Washington University, St. Louis, Missouri.

Over a 4 year period, 15 infants under 1 year of age and with intractable congestive heart failure were operated upon for repair of coarctation of the aorta. Nine infants were under 2 weeks of age. The smallest infant weighed 1100 gms. There were 2 early postoperative deaths and one late death (1 mo. post hospital discharge) (Total survivals 80%). Six infants with associated intracardiac shunts had pulmonary artery bandings to control pulmonary blood flow. Improving results are attributed to (1) methods of postoperative management, (2) the adaptation of microsurgical technique to coarctation repair in infancy, and (3) the use of pulmonary artery banding performed immediately prior to coarctation resection whenever there is a large intracardiac shunt. This procedure controls pulmonary blood flow and prevents acute left ventricular volume overload during the time of aortic resection. Twenty patients from an earlier era who survived coarctation resection in infancy were studied in childhood. Six patients (30%) had severe anastomotic stenosis recreating the pathophysiology of coarctation. Second operations were performed in all 6 children. Resection of the anastomosis was done in 2 children and prosthetic grafting was performed in 4 children. Gradients were relieved in all cases and upper extremity hypertension has disappeared in all cases. With appropriate technique, surgical management of coarctation of the aorta in infancy provides excellent results. With growth of the child, anastomotic stenosis is a frequent complication. Second operations to relieve this stenosis by resection or bypass grafting can be performed with ease and provide excellent results.

RELATION BETWEEN REFRACTORY PERIOD OF THE ACCESSORY PATHWAY AND VENTRICULAR FREQUENCY DURING ATRIAL FIBRILLATION IN PATIENTS WITH WOLFF-PARKINSON-WHITE SYNDROME.

Hein J. Wellens, M. D., FACC, and Dirk Durrer, M. D., FACC. University Dept of Cardiology and Clinical Physiology, Wilhelmina Gasthuis, Amsterdam, The Netherlands.

To assess the relation between the length of the refractory period (RP) of the accessory pathway (AP) and ventricular rate (VR) during atrial fibrillation (AF), two groups of patients (pts) with Wolff-Parkinson-White (WPW) syndrome, were studied. Group I consisted of 17 pts with documented episodes of AF. Group II was composed of 9 pts without a history of AF. In the latter group, following measurements of the RP of the AP, AF was induced by rapid atrial pacing (400 - 500/min). By way of the single test stimulus method (STSM) during atrial pacing the RP of the AP could be determined in 17 of the 26 pts. In 3 pts the RP of the AP was longer than 300 msec, in 8 pts in between 300 and 250 msec, and in 6 pts shorter than 250 msec. In 9 pts the RP of the AP could not be measured by the STSM, because the atrium became refractory at a time when AV conduction (AVC) was still occurring over the AP. In these pts regular atrial driving (AD) at increasing rates (up to 280/min) showed 1 to 1 AVC over the AP to AD rates of 240/min. in 2 pts and to 260/min in another 2 pts. In 5 pts 1 to 1 AVC over the AP was still present at AD rates of 280/min. A good correlation was found between the length of the RP of the AP and the shortest RR intervals during documented and induced episodes of AF. This indicates that measuring the RP of the AP is of value in identifying those pts with WPW who are at risk of developing life threatening high VR when AF supervenes.

REVERSAL OF ACUTE MYOCARDIAL ISCHEMIA BY RETROGRADE INTERCORONARY VENO-ARTERIAL PERFUSION

Leslie Wiener, M.D., FACC, Thomas Jefferson University Hospital, Philadelphia, Pa.

In 15 dogs with hearts in situ, selective retrograde intercoronary veno-arterial perfusion (RIVAP) was established by anastomosis of a carotid artery to the cardiac vein draining myocardium supplied by the left anterior descending coronary artery (LAD). Pulsatile flow through this channel averaged 23.1 cc/min ±6.1 and was similar in wave form and quantity to that previously measured from the LAD (21.9 ±2.1).

Control measurements of the effects of ligation of the LAD prior to RIVAP were made. Circumflex artery blood flow did not change (ave. 31.0 cc/min ±7.3). Myocardial tissue pO_2 decreased -48.4% ±10.4 $p < 0.01$. Epicardial ECG ST segments increased +99.3% ±13.7 $p < 0.01$. Ventricular arrhythmia was invariable and required lidocaine for control. The region of myocardial ischemia became dyskinetic, manifesting paradoxical systolic expansion.

On the other hand, despite continued LAD ligation RIVAP significantly ($p < 0.01$) reversed myocardial hypoxia and the ischemic ECG effects. Myocardial tissue pO_2 returned to normal (-1.3% ±2.3). ST segment elevation decreased from +99.3% above baseline levels to +23.8% ±7.6. The myocardium supplied by RIVAP developed a normal contraction pattern and lidocaine was no longer required to control arrhythmia.

These experiments indicate that acute myocardial ischemia is reversed by RIVAP and suggest an alternative to aorto coronary bypass surgery.

ECHOCARDIOGRAPHIC PATTERNS OF PULMONIC VALVE MOTION IN PULMONIC STENOSIS

Arthur E. Weyman, MD; James C. Dillon, MD; Harvey Feigenbaum, MD; Sonia Chang, BA, Indiana University Medical Center, Indianapolis, Indiana

Echocardiograms of pulmonic valves were obtained on 14 patients with catheterization proven isolated pulmonic stenosis (PS), 18 normal subjects and 65 patients with various forms of heart disease but no PS. Because of the plane of pulmonic valve motion and the angle of the ultrasonic beam, usually only one posterior pulmonic leaflet was recorded. In normal subjects atrial systole imparted a slight degree of posterior motion to this leaflet in late diastole (average 3 mm, range 0 to 7 mm). This atrial posterior motion varied with respiration and was not present with pulmonary hypertension. Without PS the leaflet always returned to a "closed position" prior to ventricular systole at sometime during the respiratory cycle. In patients with moderate or severe PS (gradient 50 to 142 mm Hg) the posterior atrial motion increased (average 10 mm, range 8 to 13 mm) and in patients whose gradient was greater than 65 mm Hg the pulmonic leaflet never returned to the "closed position" prior to ventricular systole. In mild PS (gradient less than 50 mm Hg) the degree of atrial opening of the leaflet fell within the normal range. The exaggerated posterior pulmonic leaflet motion following atrial systole is probably due to the increased right ventricular end-diastolic pressure together with a normal or decreased pulmonary artery pressure, producing a positive gradient across the valve following atrial systole. Although the pulmonic valves can be difficult to record echocardiographically, during this study there were only two patients with PS in whom satisfactory echoes were not recorded. These findings suggest that echocardiography may be helpful in the clinical evaluation of PS.

HEMODYNAMIC EFFECTS OF NITROGLYCERIN IN ACUTE MYOCARDIAL INFARCTION: DECREASE IN PRELOAD AT THE EXPENSE OF CARDIAC OUTPUT.

David O. Williams, MD; Jorge Otero, MD; James Lies, MD; Robert Zelis, MD, FACC; Dean T. Mason, MD, FACC Ezra A. Amsterdam, MD, FACC, Univ. Calif., Davis, Calif.

Nitroglycerin (NTG) has recently been proposed to decrease myocardial ischemia and enhance cardiac pump function during acute myocardial infarction (AMI). Thus, the hemodynamic effects of sublingual NTG (0.4 mg) administered to 16 supine patients (pts) during the first 72 hrs of AMI were determined serially (5-10, 10-15, 20-30 min) over 30 min. Data were evaluated for the entire group (n=16) as well as for pts with normal pulmonary artery wedge (PAW) pressure (n=6)($\leq$12 mm Hg, mean 7) and pts with elevated PAW (n=10)($\geq$13 mm Hg, mean 19). Heart rate (HR) increased significantly in the normal PAW group (71→80, $p < .05$) but there was no change in the group with elevated PAW. In the entire group of pts, regardless of initial PAW, significant decreases ($p < .05$) occurred in: mean arterial pressure (MAP)(95→82 mm Hg), PAW (14→7 mm Hg), cardiac index (CI)(1.79→1.46 L/min/M^2), stroke index (SI) (24→18 cc/M^2) and stroke work index (SWI)(24→18 gm-M/M^2). There was no significant change in peripheral vascular resistance. Thus, in pts with AMI the major effect of NTG was to reduce preload with subsequent decrease in SI, CI and MAP. Pts with normal PAW responded with an increase in HR. The lack of increase in HR in pts with elevated PAW may be due to attenuated sympathetic reflex function which we have documented in AMI. NTG is effective in decreasing hemodynamic determinants of myocardial oxygen demand, especially in those pts with pulmonary congestion, but this occurs at the expense of cardiac output. Its use in AMI, therefore, requires careful pt selection.

THE HEMODYNAMIC RESPONSE TO SUBLINGUAL ISOSORBIDE DINITRATE IN UNSTABLE ANGINA PECTORIS

William H. Willis, MD; Richard O. Russell, Jr., MD, FACC; John A. Mantle, MD; Robert A. Ratshin, MD; Charles E. Rackley, MD, FACC; University of Alabama, Birmingham, Alabama.

The sustained supine hemodynamic response to 10 mg sublinqual isosorbide dinitrate (IS) in comparison to that of a sublingual placebo (plbo) was measured in 15 patients with unstable angina. Alternately eight patients received IS and seven plbo. A Swan-Ganz thermodilution catheter was positioned in the pulmonary artery (PA). PA systolic (PASP) and end-diastolic pressures (EDP), heart rate, thermodilution cardiac output, echo end-diastolic volumes (EEDV), and cuff arterial blood pressures were measured at five min intervals for the first 30 min then every 30 min for a total of four hrs. Cardiac index (CI), stroke index (SI), stroke work index (SWI), mean arterial blood pressure (MAP), and total systemic resistance (TSR) were calculated. The mean change in these hemodynamic parameters was compared at each time period between the IS and plbo groups. The mean significant ($p<0.05$) difference in systolic arterial pressure (SAP) was -16 to -18 mmHg from 30 min to two hrs. The MAP mean significant ($p< 0.05$) difference was -9 to -15 mmHg from 30 min to four hrs. The PASP mean significant difference ($p<0.05$) was -6 to -8 mmHg from 10 min to 90 min. The significant ($p < 0.05$) mean PAEDP difference was -4 mmHg at 60 min. CI, SI, SWI, EEDV, and TSR demonstrated a similar reduction after IS; however, because of a large patient to patient variation, these values did not reach significance. The duration of IS reduction in SAP and PAEDP was six times longer than that after sublingual nitroglycerin in a reported study from this laboratory. Sublinqual IS causes a prolonged decrease in both left ventricular preload and afterload in patients with unstable angina.

LONG TERM PERVENOUS CORONARY SINUS PACING

Yutaka Yamamoto, MD; Ron J. Vanden Belt, MD; Richard D. Judge, MD, FACC, St. Joseph Mercy Hospital, Ann Arbor, Michigan.

Permanent transvenous coronary sinus pacing was found to be effective, relatively stable and surprisingly free of complications in 21 of 23 patients with sick sinus syndrome, bradycardia-tachycardia syndrome and carotid sinus syncope. In two cases, it was not possible to position the catheter in the coronary sinus. Partial or complete relief of symptoms was achieved in 90 percent of patients and all but 1 became free of syncope, dizziness and weakness. Complicating ectopic arrhythmias were controlled in all but one patient. An unexpectedly high incidence of angina was encountered (63%) which responded to pacing alone in 6 of the patients. No evidence of atrioventricular (A-V) block or intraventricular conduction defect was observed during the follow-up period. No major complications of rupture, thrombosis, embolism, myocardial injury, new arrhythmias or ischemia were identified after 243 patient months of follow-up. Although thresholds were initially high ($\pm$ 3.0 mA), exit block problems did not develop with time, and 6 of 7 patients who had pacemaker replacements showed no significant threshold change.

Satisfactory atrial capture was ultimately attained in all but 1 patient (who developed chronic atrial fibrillation.) Sensing problems were common but relatively innocuous and they have not produced clinical symptoms nor have they interfered with long term benefit to the patient. Most sensing problems could be eliminated by a pacemaker with a refractory period of more than 300 msec; this would eliminate inconsistent sensing of QRS of paced beats.

COMPLICATIONS OF CLOTH-COVERED PROSTHETIC VALVES

Don C. Wukasch, MD; Frank M. Sandiford, MD; George J. Reul, MD, FACC; Grady L. Hallman, MD, FACC; Denton A. Cooley, MD, FACC, Texas Heart Institute, Houston, Texas.

Following experiments in 1967 with cloth-covered prosthetic valves, a number of investigators including Braunwald, Starr, Spencer and others have advocated their use. The principal advantage offered by such valves is a decreased incidence of thromboembolism.

Complications, however, have included cloth wear, hemolysis, increased pressure gradients compared to other prostheses, "stuck ball syndrome" and a rare intractable infection. Stenosis at the prosthesis is related to the added bulk compared to noncloth-covered valves.

In our experience with 4,235 valve replacements, the completely cloth-covered prostheses have proved unsatisfactory. Hemolysis was higher as demonstrated by lower mean hematocrit levels and higher mean reticulocyte and LDH values. Cloth wear over the struts, in particular, has occurred with unacceptable frequency. Hemolysis usually results from a jet of blood striking an unendothelialized fabric surface, and cloth-covered prostheses subject the blood to this undesirable condition.

A new mitral prosthesis has been designed which eliminates this undesirable characteristic and incorporates certain favorable features. The surfaces exposed to the jet stream are highly polished titanium and pyrolitic carbon. Other desirable features include a low profile, low gradient, full-orifice opening and a "self-washing" principle due to the controlled leakage around the periphery of the poppet. Experience with more than 300 valve replacements with this prosthesis will be reported.

A LARGE KINDRED WITH FAMILIAL TYPE II HYPERLIPIDEMIA WITH MINIMAL CLINICAL CARDIOVASCULAR DISEASE

James H. Zavoral, M.D., Richard A. King, M.D., Florine Peterson, R.N., Donald B. Hunninghake, M.D. University of Minnesota and St. Paul Ramsey Hospital Laboratory

The kindred under investigation to our knowledge is the largest to be reported with familial type II hyperlipidemia. The large midwest kindred has fifteen siblings, 279 individuals and 222 direct line relatives which were evaluated for familial hyperlipidemia.

Tendinous xanthomas were present in 4 members, xanthelasma in 2, one a 10 month boy. There has been one death following coronary artery bypass surgery and an additional member of the family had a myocardial infarction at age 58.

When the serum cholesterol values were age adjusted 32 had abnormal lipid values, 24 with Fredricksons type II_A and 8 with Fredricksons type II_B.

Genetic analysis of this pedigree reveals evidence for a single autosomal dominant gene producing hyperlipidemia characterized by elevated levels of cholesterol and triglycerides, xanthomas and a reduced degree of severe clinical cardiovascular disease. A bimodal distribution of cholesterol level was found in direct-line relatives of first generation affected but not in the direct-line relatives of first generation normals.

In this large kindred with familial type II hypercholesterolemia, out of 32 individuals with hyperlipidemia only 2 have had evidence of clinical cardiovascular disease.

RESULTS OF CORONARY BYPASS SURGERY FOR THE TREATMENT OF CORONARY INSUFFICIENCY.

E.J. Zerbini, M.D., FACC; Sergio Almeida Oliveira, M.D.; João Paulo Marrara, M.D.; Delmont Bittencourt, M.D., Radi Macruz, M.D., FACC; Fulvio Pileggi, M.D., FACC.

University of São Paulo, Brasil.

Aorto-coronary anastomosis was performed in 851 patients, with a total of 1496 anastomoses. Saphenous vein bypass was used in 831; of these, 41.5% received one bypass, 40.5% two, 17.4% three, and 0.6% four bypasses. Fifteen patients were treated with mammary artery-coronary anastomosis, and five had combined procedures.

Chronic coronary insufficiency was present in 85.6% of the patients, 10.6% of the patients were considered to have impending infarction, and 3.8% had acute myocardial infarction. Immediate and late mortality had no relation with the number of bypasses performed. Late post-operative results were influenced by the number of diseased arteries and by the pre-operative ventriculogram. Post-operative cine coronary angiography, performed in 273 patients with a total of 331 bypasses, demonstrated 90.3% patency. Of these, 201 patients operated on in the last two years had 93% patency. Post-operative myocardial infarction was observed in 6.4% of the patients, observed up to 45 months. Of these, 44.7% became asymptomatic after the infarction and 42.1% failed to survive.

Subject Index: Abstracts

Accessory pathway, refractory period of, and ventricular frequency during atrial fibrillation in Wolff-Parkinson-White syndrome, 178
Action potentials and electrograms preceding ventricular fibrillation during acute myocardial infarction, 172
Age and sensitivity to digoxin, 172
Alpha adrenergic receptors and positive inotropic effects in ventricular myocardium, 161
Amiodarone for tachyarrhythmias in Wolff-Parkinson-White syndrome, 166
Anemia, hemolytic, and cloth-covered Starr-Edwards aortic valve prosthesis, 169
Aneurysm, left ventricular, resection of, 168
Angina pectoris
  and normal coronary arteries, coronary hemodynamics and metabolism in, 162
  maximal cardiac output in, before and after coronary artery surgery, 154
  normalization of electrocardiogram during, in subendocardial infarction, 167
  pacing-induced, rise in left ventricular end-diastolic pressure after, 124
  platelet aggregation in, after exercise testing, 137
  preinfarction
    and distribution of coronary artery lesions at autopsy, 155
    late results of surgery for, 149
  Prinzmetal's variant, pathophysiologic and clinical spectrum of, 167
  propranolol for, 122
    long-term treatment of, 176
    vs. digoxin and combined therapy for, 151
  regional ischemic free fatty acid metabolism with, 123
  syndrome
    and normal coronary arteriogram, left ventriculography in, 127
    propranolol and hemoglobin-oxygen affinity in, 170
  unstable
    extended follow-up after urgent bypass operation for, 164
    hemodynamics of sublingual isosorbide dinitrate in, 179
Angiogram
  coronary, and criteria for bypass surgery, 147
  early in onset of coronary syndromes, 138
  in asymptomatic coronary prone men, 162
Angiography
  and clofibrate in progression of coronary artery disease, 131
  and survival in left main coronary artery disease, 134
  radionuclide, nontraumatic determination of cardiac output and ejection fraction by, 169
  total body, in diffuse atherosclerosis, 80
Angiotensin for hypoxia in tetralogy of Fallot, 173
Antiarrhythmic agents
  and prodroma of ventricular fibrillation in ischemia, 144
  (*see also* specific agents)
Antithrombotic therapy and aortocoronary bypass surgery, 122
Aorta
  -right pulmonary artery anastomosis, long term problems and results after, 125
  thoracic, dissection of, medical vs. surgical treatment for, 133
Aortic insufficiency, calcific, 126
Aortic root
  plastic reconstruction of, for congenital supravalvular aortic stenosis, 177
  size, assessed by continuous echocardiographic recording method, 136
Aortic stenosis, congenital supravalvular, plastic reconstruction of aortic root for, 177
Aortic valve
  biscuspid, echocardiographic recognition of, 159
  disease, ultrastructure of left ventricular myocardial cells in, 156
  prosthesis, cloth-covered Starr-Edwards, predictability of anemia in patients with, 169
  replacement
    long-term survival after, 165
    with aortocoronary bypass, 168
Aprindine
  antiarrhythmic effects of, 140
  in acute myocardial infarction, 142
Arrhythmias
  after myocardial infarction, Holter monitoring vs. exercise testing for detecting, 132
  amiodarone for, in Wolff-Parkinson-White syndrome, 166
  and aortocoronary bypass graft blood flow velocity, 126
  diagnosed by multipurpose flotation electrode catheter, 130
  digitalis-induced, diphenidol for, 130
  electrophysiologic effects of Aprindine on, 140
  in acute myocardial infarction, Aprindine for, 142
  in symptomatic patients, Holter monitoring to assess, 136
  increased cardiac output during, 165
  ischemic, and myocardial metabolism, 139
  17,21-di-monochloroacetyl-ajmaline for, 133
  ventricular
    and sudden death in survivors of acute myocardial infarction, 160
    clinical significance of exercise-induced, 154
    in late hospital phase of acute myocardial infarction and sudden death after hospitalization, 175
    factors predisposing to, 175
  verapamil for, 166
  (*see also* specific type)
Arteries
  endothelium and smooth muscle cells of, 166
  (*see also* specific artery)
Arteriography, pulmonary, subselective, with balloon occlusion, to detect pulmonary embolism, 154

Asynergy
and Q waves, predictive value and hemodynamic significance of anatomic location, 128
left ventricular, assessed by postnitroglycerin left ventriculography, 156
reversibility of, in coronary artery disease, 125
Atherosclerosis
diffuse, total body angiography in, 141
influence of left ventricular function on early prognosis in, 159
(*see also* Coronary artery disease)
Atrial fibrillation in Wolff-Parkinson-White syndrome, refractory period of accessory pathway and ventricular frequency during, 178
Atrial septal defect
pulmonary blood flow in children with, 153
secundum, and prolapse of posterior leaflet of mitral valve, 126
Atrial stimuli, premature, and atrioventricular block, 173
Atrioventricular block
(*see* Heart block)
Atrioventricular connections, anomalous, and Wolff-Parkinson-White syndrome, 171
Atrioventricular node
block within, after premature atrial stimuli, 173
function and atrial pacing site, 123
Atropine
intravenous, in prehospital phase of acute myocardial infarction, 151
paroxysmal atrioventricular nodal reentrant tachycardia after, 122
Autonomic nervous system manipulation in long Q-T-recurrent syncope syndromes, 174

Balloon occlusion and subselective pulmonary arteriography to detect pulmonary embolism, 154
Biopsy, endomyocardial, clinical application of, 122
Blood
flow
coronary
after myocardial infarction, 146
dual isotope myocardial imaging to assess, 140
coronary collateral
and norepinephrine infusion after coronary occlusion, 151
effect of systemic arterial pressure on, 156
pulmonary, in children with atrial and ventricular septal defects, 153
regional myocardial
after coronary artery occlusion in normal and hypoxemic dogs, 127
effect of hypertonic mannitol on, 145
restoration of, to acutely ischemic myocardium, 146
velocity, aortocoronary artery bypass graft, arrhythmias and, 126
pressure
after coarctectomy in young children, 159
and segmental wall motion abnormalities in myocardial ischemia, 148
intracardiac, monitored with multipurpose flotation electrode catheter, 130
Blood
pressure
systemic arterial, and coronary collateral flow, 156
Bundle branch
block
bifascicular, H-V interval in, 134
due to His bundle lesions, 169
left, anatomic basis of, 151
right, and left anterior hemiblock after repair of tetralogy of Fallot, 129
left, electrophysiologic delineation of, 176
Bypass grafts
aortocoronary
effects of occlusion, nitroglycerin and papaverine on, 164
saphenous vein, long-term durability of, 146
vs. internal mammary artery, 167
blood flow velocity in, and arrhythmias, 126
internal mammary artery
physiologic limitations of, 170
vs. aortocoronary artery, 167
morphology of, 141
patency of, and early postoperative myocardial infarction, 124

Calcification of aortic valve, 126
Calcium
in reversal of verapamil-suppressed ventricular ectopy, 148
transport and cyclic AMP-dependent protein kinase-catalyzed phospholamban phosphorylation in sarcoplasmic reticulum, 172
Cardiac assistance
indications for, 176
(*see also* Counterpulsation)
Cardiac cell, methylprednisolone to preserve integrity of, in myocardial ischemia, 171
Cardiac output
after nitroglycerin in acute myocardial infarction, 178
determined by radionuclide angiography, 169
increased, during induced irregular rhythms, 165
maximal, before and after coronary artery surgery in patients with angina, 154
Cardiomyopathy in systolic click-murmur syndrome with mitral valve prolapse, 142
Cardiopulmonary bypass, protective effect of propranolol on hypertrophied heart during, 164
Catheter, multipurpose flotation electrode, for arrhythmia and intracardiac pressure monitoring, 130
Chagas heart disease, sick sinus syndrome in, 144
Chest pain
and clinical localization of coronary obstruction, 136
and coronary artery obstruction, 155
and normal coronary arteries in women, 168
Cholesterol, serum, and coronary risk profile in young adults, 168
Clofibrate and progression of coronary artery disease, 131
Coarctation of aorta, surgically corrected in infancy, 177
Coarctectomy in young children, blood pressure after, 159

Coffee and coronary artery disease, 133
Conduction
atrioventricular
after atropine, 122
after digitalis, 148
concealed intraventricular, 150
retrograde, in Wolff-Parkinson-White syndrome, 163
sinoatrial, digitalis and, 128
Congenital anomalies of great vessels, real-time, two-dimensional echocardiogram in diagnosis of, 143
Congenital heart disease
"sluggish" sinus node syndrome as part of, 160
supravalvular aortic stenosis, plastic reconstruction of aortic root for, 177
Contractility
abnormal, and severity of coronary artery disease, 158
and coronary artery reperfusion, 163
and differential effects of digitalis after coronary artery ligation, 125
Contrast medium, immediate effect of, on left ventricular volume, 175
Coronary arteriogram, normal, and anginal syndrome, left ventriculography in, 127
Coronary artery
collateral vessels
and norepinephrine infusion after coronary occlusion, 151
as determinants of reversibility of asynergy in coronary artery disease, 125
blood flow in, effect of systemic arterial pressure on, 156
in absence of occlusive coronary artery disease, 140
disease
and coffee, 133
angiogram early in onset of, 138
asymptomatic men prone to, 162
clofibrate in, 131
coronary pathology and left ventricular function in, 138
critical, submaximal exercise testing for identification of, 133
determinants of reversibility of asynergy in, 125
effect of external counterpulsation on myocardial oxygen in, 153
echocardiogram of anterior left ventricular wall in, 132
left anterior descending, surgical vs. medical treatment for, 149
left main, 169
indications for surgery in, 125
survival in, role of coronary angiography, coexisting coronary artery disease and revascularization, 134
mitral regurgitation and myocardial dysfunction in, 175
occlusive, absence of, and coronary collateral vessels, 140
quantitative echocardiographic analysis of ventricular volume in, 164
"random" nature of treatment for, 155
risk profile in young adults, 168
Coronary artery
disease
severity of, and abnormally contracting segments of left ventricle, 158
hemodynamics
and metabolic effects of propranolol in idiopathic hypertrophic subaortic stenosis, 162
and reperfusion after myocardial infarction, 146
left anterior descending
aortocoronary saphenous vein bypass to, and systolic murmur, 147
precatheterization identification of operable stenosis of, 157
lesions, distribution at autopsy, and preinfarction angina pectoris, 155
ligation, and differential effects of digitalis on contractions of ischemic, border and nonischemic ventricular zones, 125
normal
and angina pectoris, coronary hemodynamics and metabolism in, 162
and chest pain in women, 168
obstruction and characteristics of cardiac pain, 155
occlusion
and aortocoronary bypass grafts, 164
and regional left ventricular length-tension relations after nitroglycerin, 124
arterial PO_2 and severity of myocardial ischemia after, 163
isoproterenol after, and coronary steal, 131
left anterior descending, surgery vs. medical treatment of, 149
local myocardial function during, 173
metabolic dysfunction after, 157
norepinephrine infusion after, and collateral flow, 151
persistence of myocardial injury after brief periods of, 177
protective zone after, 150
regional myocardial blood flow after, and hypoxemia, 127
regional pathophysiologic effects of myocardial revascularization after, 150
transmembrane potentials in His bundle after, 150
ventricular fibrillation during, and lidocaine, 128
ventricular vulnerability during, 174
patency of, and early postoperative myocardial infarction, 124
perfusion
pressure and flow and resistance in coronary artery stenosis, 153
retrograde venoarterial, to reverse myocardial ischemia, 178
reperfusion, contractile and biochemical effects of, 163
stenosis, perfusion pressure, flow and resistance in, 153
Coronary heart disease
(*see* Coronary artery disease)
Coronary insufficiency, coronary bypass surgery for, 180
Coronary sinus pacing, long-term pervenous, 179
Coronary steal and isoproterenol after coronary artery occlusion, 131

Counterpulsation
and myocardial oxygen in coronary artery disease, 153
noninvasive form of cardiac assistance, 158
sequenced and nonsequenced, hemodynamic studies of, 131
Coxsackie virus B3 causing myocarditis, depressed myocardial function after, 121

Death, sudden
and sports, 129
and ventricular arrhythmias
in late hospital phase of acute myocardial infarction, 175
in survivors of acute myocardial infarction, 160
Diabetes, aortocoronary bypass in, 174
Digitalis
and response of ventricular pacemakers to sympathetic nerve stimulation, 162
and sinoatrial conduction, 128
differential effects on contraction of ischemic, border and nonischemic ventricular zones after coronary ligation, 125
diphenidol for arrhythmias induced by, 130
dissociation of inotropic effect and effect on atrioventricular conduction, 148
Digoxin
age-related changes in sensitivity to, 172
and sinus node reentry in the dog, 162
vs. propranolol and combined therapy in angina pectoris, 151
Diphenidol for digitalis-induced arrhythmias, 130

Echocardiogram
and pulmonic valve motion in pulmonic stenosis, 178
in bicuspid aortic valve, 159
in endocardial cushion defect, 135
of anterior left ventricular wall in coronary artery disease, 132
real-time, two-dimensional, and differential diagnosis of anomalies of great vessels, 143
Echocardiography
continuous recording method to assess aortic root size, 136
Doppler, to detect mitral regurgitation, 146
multicrystal, validity of structure identification for, 167
quantitative, for analysis of ventricular volume in coronary artery disease, 164
Ejection fraction
and survival in cardiovascular disease, 143
determined by radionuclide angiography, 169
preload dependence on, 139
Electrical shock
dose for human ventricular fibrillation, 172
microshock hazard, experimental, environmental and educational studies, 163
Electrocardiogram
in recurrent myocardial infarction, autopsy study of diagnostic value of, 142
normalization of, during angina pectoris in subendocardial infarction, 167
Electrode system, loop, for temporary right atrial pacing, 126
Electrogram
and action potentials preceding ventricular fibrillation during acute myocardial infarction, 172
His bundle
and norepinephrine in denervated human heart, 129
in corrected transposition of great arteries, 173
Electrophysiology
in cardiac dysrhythmias, 140
in localization, detection and sizing of myocardial infarction, 131
of left bundle branch, 176
of suppression of cardiac arrhythmias by verapamil, 166
to evaluate Mustard procedure, 171
Embolism, pulmonary
deep venous thrombosis as diagnostic clue to, 170
subselective pulmonary arteriography with balloon-occlusion for detection of, 154
Endocardial cushion defect, echocardiogram in, 135
Endomyocardial biopsy, clinical application of, 122
Endomyocardial disease and eosinophilia, 166
Endothelium, arterial, and smooth muscle cells, 166
Eosinophilia and endomyocardial disease, 166
Exercise
in myocardial ischemia, 174
rubidium-81 for myocardial perfusion scans during, 154
testing
and platelet aggregation in angina pectoris, 137
submaximal, to identify critical coronary artery disease, 133
treadmill, clinical significance of arrhythmias induced by, 154
vs. Holter monitoring for detecting arrhythmias after myocardial infarction, 132
Extrasystoles, ventricular, and ventricular tachycardia in late recovery phase of myocardial infarction, 149

Familial type II hyperlipidemia and minimal cardiovascular disease, large kindred with, 179
Fibrillation threshold, anodal, 137
Free fatty acid metabolism, regional ischemic, with angina pectoris, 123
Friedreich's ataxia, hemodynamics and metabolic abnormalities in, 132

Ganglionic depressor reflex, intracardiac, 147
Glucose-insulin-potassium in acute myocardial infarction, 171
Great vessels
anomalies of, real-time, two-dimensional echocardiogram in diagnosis of, 143
(*see also* Transposition of great arteries)

Heart
block
atrioventricular
in acute myocardial infarction, widened QRS complexes during, 152

Heart
block
atrioventricular
several levels of, after premature atrial stimuli, 173
second degree, evolution of, in proximal His-Purkinje system, 135
disease
Chagas, sick sinus syndrome in, 144
ejection fraction as predictor of survival in, 143
unusual, and sports, 129
failure, congestive, sustained loss of myocardial norepinephrine after relief of, 132
rate and prodroma of ventricular fibrillation in acute ischemia, 144
Hemiblock, left anterior, and right bundle branch block after repair of tetralogy of Fallot, 129
Hemodynamics
after Mustard procedure, 171
after 17,21-di-monochloroacetyl-ajmaline for arrhythmias, 133
coronary, and myocardial perfusion after reestablishing coronary flow in myocardial infarction, 146
in asymptomatic coronary prone men, 162
in Friedreich's ataxia, 132
of chest pain and normal coronary arteries in women, 168
of nitroglycerin in acute myocardial infarction, 178
of sequenced and nonsequenced external counterpulsation, 131
of sublingual isosorbide dinitrate in unstable angina pectoris, 178
Hemoglobin-oxygen affinity and propranolol in anginal syndrome, 170
Hemolysis and predictability of anemia in patients with cloth-covered Starr-Edwards prosthetic aortic valve, 169
His bundle
lesions, bundle branch block due to, 169
recording and retrograde conduction in Wolff-Parkinson-White syndrome, 163
transmembrane potentials in, after coronary occlusion, 150
His-Purkinje system, proximal, evolution of second degree block in, 135
Holter monitoring
for assessing cardiac arrhythmias in symptomatic patients, 136
vs. exercise testing for detecting arrhythmias after myocardial infarction, 132
H–V interval in bifascicular block, short-term prognostic significance of, 134
Hyperemia, coronary, dual isotope myocardial imaging to assess coronary flow reserve during, 140
Hyperlipidemia, familial type II, and minimal clinical cardiovascular disease, large kindred with, 179
Hypertrophy
cardiac
and protective effect of propranolol during cardiopulmonary bypass, 164
myosin in, 143
idiopathic left ventricular, existence of, 158
Hypoglycemia, insulin-induced, increased myocardial ischemic injury during, 152
Hypoxemia and regional myocardial blood flow after coronary artery occlusion, 127
Hypoxia in tetralogy of Fallot, angiotensin for, 173

Idiopathic hypertrophic subaortic stenosis, coronary hemodynamic and metabolic effects of propranolol in, 162
Imaging
dual isotope, to assess coronary flow reserve during coronary hyperemia, 140
myocardial, with technetium-99m macroaggregates, 165
technetium-99m-tetracycline infarct, 144
Inosine, coronary venous, in myocardial ischemia, 134
Inotropic drug, positive, RO2-2985/1 (X537A) for cardiac disease, 170
Inotropic interventions for myocardial ischemia, 174
Insulin, hypoglycemia induced by, and increased myocardial ischemic injury, 152
Intraaortic balloon pumping, indications for, 176
Ischemia
arrhythmias during, and myocardial metabolism, 139
hypertonic mannitol and regional myocardial blood flow during, 145
myocardial
and myocardial reperfusion, 146
arterial pressure manipulations and segmental wall motion abnormalities in, 148
coronary venous inosine as metabolic indicator of, 134
during insulin-induced hypoglycemia, 152
inotropic agents for, 174
methylprednisolone and cardiac cellular integrity in, 171
nitroprusside in, 158
persistence of, after brief periods of coronary occlusion, 177
reversed by retrograde intercoronary venoarterial perfusion, 178
transient arterial wall, dynamic response of distant myocardium during, 161
prodroma of ventricular fibrillation in, 144
regional, and free fatty acid metabolism with angina, 123
T wave abnormalities after, pathogenesis of, 149
1-Isopropylamino-3(2-thiazoloxy)-2-propanol·HCl in experimental infarction, 128
Isoproterenol
after coronary artery occlusion, and coronary steal, 131
in myocardial ischemia, 174
Isosorbide dinitrate, sublingual, in unstable angina pectoris, hemodynamics of, 178
Isotope imaging, dual, to assess coronary flow reserve during coronary hyperemia, 140

Lidocaine and incidence of ventricular fibrillation during coronary artery occlusion, 128

Löffler's disease, 166
Long Q-T-recurrent syncope syndromes, 174
Lysosome abnormalities in cardiogenic shock, 145

Mannitol, hypertonic, and regional myocardial blood flow during myocardial ischemia, 145
Membrane potential and ouabain toxicity in Purkinje fibers, 138
Men
  asymptomatic coronary prone, clinical coronary angiographic and hemodynamic correlations, 162
  middle-aged, frequency and prognosis of ventricular ectopic beats in, 127
Metabolism
  after coronary artery reperfusion, 163
  after 17,21-di-monochloroacetyl-ajmaline for arrhythmias, 133
  and coronary venous inosine in myocardial ischemia, 134
  disorders of, in coronary occluded and nonoccluded cardiac segments, 157
  in ischemic myocardium after nitroprusside, 158
  myocardial
    during ischemic arrhythmias, 139
    in Friedreich's ataxia, 132
  of arterial endothelial and smooth muscle cells, 166
  of ischemic tissue after propranolol in myocardial infarction, 159
  regional ischemic free fatty acid, and angina pectoris, 123
Methylprednisolone
  and cardiac cellular integrity in myocardial ischemia, 171
  and hemodynamics in acute myocardial infarction, 176
Microelectrode recording and atrioventricular block after premature atrial stimuli, 173
Microshock hazard, experimental, environmental and educational studies, 163
Mitral regurgitation
  and myocardial dysfunction in coronary artery disease, 175
  caused by dilatation of mitral annulus, 129
  detected by Doppler echocardiography, 146
Mitral valve
  annulus, dilatation of, and mitral regurgitation, 129
  leaflet
    posterior, prolapse of, and secundum atrial septal defect, 126
    prolapse and systolic click-murmur syndrome, cardiomyopathy in, 141
  prosthesis, disc-turtle neck, 5 year experience with, 160
Murmur, systolic, of aortocoronary bypass to left anterior descending coronary artery, 147
Muscle cells, smooth, and arterial endothelium, 166
Myocardial depressant factor in cardiogenic shock, 145
Myocardial function, depressed, after experimental coxsackie virus B3 viral myocarditis, 121
Myocardial imaging with technetium-99m macroaggregates, 165
Myocardial infarction
  acute
    action potentials and electrograms preceding ventricular fibrillation during, 172
    antiarrhythmic effect of Aprindine in, 142
    evaluated with technetium-99m-tetracycline infarct imaging, 144
    factors predisposing to ventricular tachycardia in, 134
    glucose-insulin-potassium in, 171
    hemodynamics of nitroglycerin in, 178
    identification of predisposing factors to ventricular arrhythmias in late hospital phase of, 175
    inferior, widened QRS complexes during, 152
    methylprednisolone for, 176
    mortality factors in, 177
    nitroglycerin and premature ventricular complexes in, 157
    prehospital phase
      intravenous atropine for, 151
      mortality in, 152
    randomized study of early revascularization for, 156
    ventricular arrhythmias
      and sudden death in survivors of, 160
      in late hospital phase of, and sudden death, 175
  after reperfusion, and coronary hemodynamics, 146
  complicated, early surgical intervention for, 123
  early postoperative, and patency of aortocoronary bypass grafts and ungrafted coronary arteries, 124
  effect of propranolol on ischemic tissue in, 159
  exercise testing vs. Holter monitoring for detecting arrhythmias after, 132
  1-isopropylamino-3(2-thiazoloxy)-2-propanol·HCl in the treatment of, 128
  localization, detection and sizing of, with technetium-99m-tetracycline and electrophysiologic techniques, 131
  nontransmural, left ventricular function in, 165
  prostaglandin F2 in, 139
  recurrent, diagnostic value of electrocardiogram in, 142
  ventricular tachycardia and ventricular extrasystoles in late recovery phase of, 149
Myocardial ischemia
  (*see* Ischemia, myocardial)
Myocardial revascularization
  for acute myocardial infarction, randomized study of, 156
  left ventricular function after, 148
  regional pathophysiologic effects of, after acute coronary occlusion, 150
  (*see also* Surgery, aortocoronary bypass)
Myocarditis, coxsackie virus B3 viral, depressed myocardial function after, 121
Myocardium
  distant, dynamic responsiveness of, during transient anterior wall ischemia, 161
  local function of, during coronary occlusion, 173
  ventricular, role of alpha adrenergic receptors in mediating positive, inotropic effects in, 161
Myosin in cardiac hypertrophy, 143

Nitroglycerin
and premature ventricular complexes in acute myocardial infarction, 157
and regional left ventricular length-tension relations after coronary occlusion, 124
effect on aortocoronary bypass grafts, 164
for left ventricular wall motion abnormalities, 153
in acute myocardial infarction, hemodynamics of, 178
left ventriculography after, to assess left ventricular asynergy, 156
Nitroprusside and metabolic changes in ischemic myocardium, 158
Noninvasive techniques to assess clinical response to propranolol, 137
(*see also* specific type)
Norepinephrine
and His bundle electrogram in denervated human heart, 129
infusion after coronary occlusion and enhanced collateral flow, 151
myocardial, sustained loss of, after relief of congestive heart failure, 132

Ouabain
K^+-mediated release of, from Purkinje cells, 123
to induce ventricular ectopy, 148
toxicity and membrane potential in Purkinje fibers, 138
Oxygen, myocardial, in coronary artery disease, effect of external counterpulsation on, 153

Pacemaker
current in Purkinje fibers, 124
fixed rate, 8 to 12 year follow-up of 100 patients with, 152
implantable rechargeable transvenous, clinical experience with, 130
isotopic cardiac, clinical use of, 138

Keeps you right on the button.

The freeze and record buttons on our four-patient monitoring station are where they can be pushed most quickly and most accurately:

Right alongside of each patient's trace. Not the traditional distance away, with the traditional potential for error.

Unusual design thinking? Not at B-D—Becton, Dickinson and Company. We try to make all our equipment safe, efficacious, reliable and easy for the operator to use properly and promptly. We call that Operator/Machine Interface. The buttons are just one example. There are dozens of others.

You see, we know your problems firsthand. We have a large, full-time staff of MD's. And no new product leaves our place unless the MD's have approved it.

Maybe that's how B-D Electrodyne got to be the foremost supplier of ICU/CCU monitoring systems in the country. Why not let us send you our catalog?

B-D ELECTRODYNE, Division of Becton, Dickinson and Company, Sharon, Mass. 02067. (617) 828-9080.

the heart of your electrocardiograph diagnosis is made of paper

Accurate interpretation of analytical data presented by your electrocardiograph and subsequent proper diagnosis is manifested by the chart paper.

If there's a chance the chart paper is lacking in quality or accuracy, an inaccurate recording may well be the result.

Why take the chance. Specify the paper designed and produced expressly for the manufacturer of your instrument. The cost of total assurance simply isn't worth the few pennies substitutes may save.

This message was prepared in the interest of better recording instrument performance by . . .

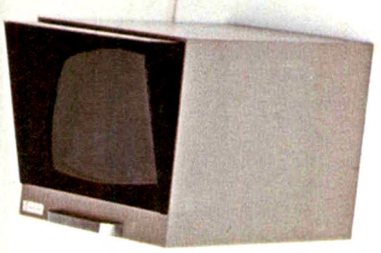
The secret of every revolution.

is effective use of power.



The revolutionary Profexray Lab-2 Ciné System is an integrated cath lab that doesn't require a separate control.

Every institution with a heavy patient load for heart-cath work could use a back-up lab. And a lot of smaller institutions would like to add ciné-angiography to their capabilities for a realistic investment. We've just answered these two needs.

Introducing the Lab-2 Ciné room.

A complete, self-contained system that doesn't need a complex, high-powered generator. Everything you *do* need—in controls, instrumentation and power—is right there in the Lab-2—built around the finest ciné system in the world. It's streamlined for maintenance and service. It's systems-engineered and pre-tested *before* installation. We're so certain of its unmatched reliability that Lab-2 is backed by a full two-year warranty.*

It's another part of the Profexray radiology revolution: equipment and concepts to completely overthrow an old order of doing things, and give you new standards of efficiency.

Get in touch with your Profexray representative for the details on the Lab-2 Ciné System. You'll find him a powerful ally.

Litton **PROFEXRAY**
Des Plaines, Illinois 60018

Litton technology: The 2nd American Revolution.

*The two-year warranty applies to all Profexray-manufactured equipment. X-ray tubes and image intensifiers are subject to manufacturers' warranties.

Processall gives you two keys to accurate diagnosis in Cine Fluorography.

High quality results. Fast processing.

In cine fluorography, you want fast results – but not at the price of fuzzy film detail. The Processall gives you fine grain yield, superior resolution for a sharp image and all the detail you need for an accurate diagnosis. With automatic processing and speeds up to 8 feet per minute, you get results fast.

Daylight-operated and self-threading, Processall was designed for maximum reliability and ease of operation. No special training is needed to get professional results. Compact, portable Processall fits almost anywhere.

A simple drive system and 316L stainless steel construction ensure complete reliability, long life, and minimum maintenance. Processall is designed for flawless high quality results. It includes a turbulent agitation processing technique, thermostatic control of solution temperature and an air impingement squeegee that removes moisture before the film or paper enters the turbulent heated air drying chamber. A positive drive, with a demand drive guarantees positive tracking. Electrocardiograph paper may also be processed.

No wonder major medical centers and hospitals are now using Processall. For more information contact us, or your nearest Oscar Fisher dealer.

NOW MENNEN-GREATBATCH BRINGS YOU NEW DIMENSIONS IN CATH LAB SYSTEMS

...ADVANCED INSTRUMENTATION SYSTEMS
...COMPLETE COMPUTERIZED SYSTEMS

Mennen-Greatbatch now offers a wide variety of systems to meet modern trends in cardiovascular diagnostics. They include advanced instrumentation for invasive and non-invasive procedures such as heart sound studies, His bundle electrograms and pulse cardiogram studies. MG also offers complete computerized systems and computerization for existing equipment to speed calculations and supply instant display of data. For more information, contact your local MG representative or Mennen-Greatbatch Electronics, Inc., Clarence, N.Y. 14031 U.S.A.

Convenient mobile consoles have functional instrument arrangement and work surface.

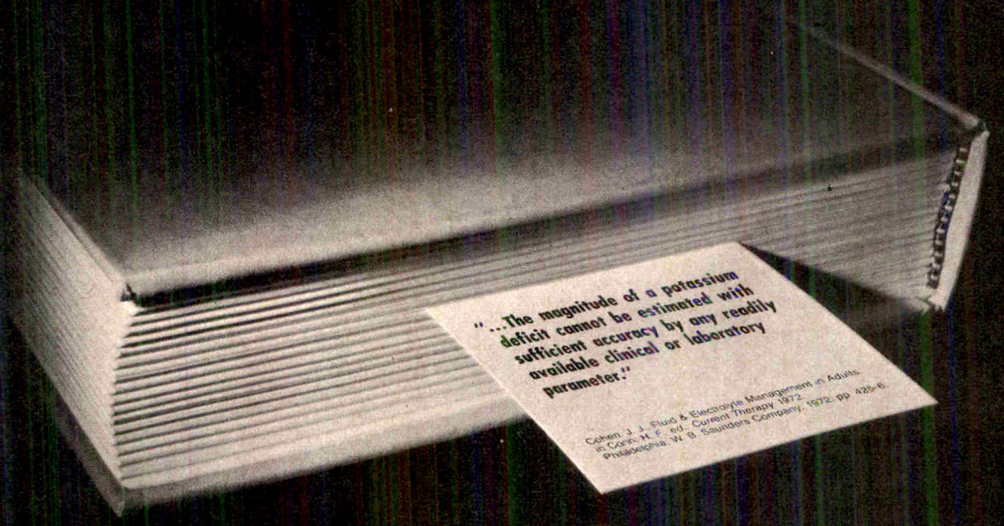
HIDDEN HYPOKALEMIA



Prescribe good-tasting

K^+LORVESS®

effervescent tablets

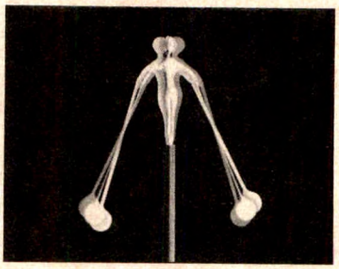
Each tablet contains 20 mEq. each of potassium and chloride supplied by potassium chloride 1.125 g., potassium bicarbonate 0.5 g., l-lysine hydrochloride 0.913 g.

1:1 ratio K^+ and Cl^- in solution

SIMPLE TO TAKE—Tablets dissolve in 3-4 oz. cold water
SPARKLING TASTE APPEAL—Fruitlike flavor
PATIENT ACCEPTANCE—Reduces chance of G.I. irritation. No added calories.
UNIT DOSE CONVENIENCE—Tablets individually foil-wrapped

KLORVESS offers what you and the patient like

Dorsey
LABORATORIES
Division of Sandoz-Wander, Inc.
Lincoln, Nebraska 68501



KLORVESS®
Effervescent Tablets

Description: Each dry effervescent tablet contains 20 mEq. each of potassium and chloride supplied by potassium chloride 1.125 g., potassium bicarbonate 0.5 g., l-lysine hydrochloride 0.913 g. Solution of the tablet in water provides the potassium and chloride available for oral ingestion as potassium chloride, potassium bicarbonate, potassium citrate, and l-lysine hydrochloride.

Indications: For prevention or correction of potassium depletion and hypokalemic alkalosis. Especially useful when thiazide diuretics or corticosteroids cause excessive excretory potassium losses.

Contraindications: Severe renal impairment with oliguria or azotemia, untreated Addison's disease, adynamia episodica hereditaria, acute dehydration, heat cramps, and hyperkalemia from any cause.

Precautions: In response to a rise in the concentration of body potassium, renal excretion of the ion is increased. With normal kidney function, it is difficult, therefore, to produce potassium intoxication by oral administration. However, potassium supplements must be administered with caution, since the amount of the deficiency or daily dosage is not accurately known. Frequent checks of the clinical status of the patient, and periodic ECG and/or serum potassium levels should be made. High serum concentrations of potassium ion may cause death through cardiac depression, arrhythmias or arrest. This drug should be used with caution in the presence of cardiac disease. Potassium supplements should be given cautiously to digitalized patients. To minimize the possibility of gastrointestinal irritation associated with the oral ingestion of concentrated potassium salt preparations, patients should be carefully directed to dissolve each tablet completely in the stated amount of water.

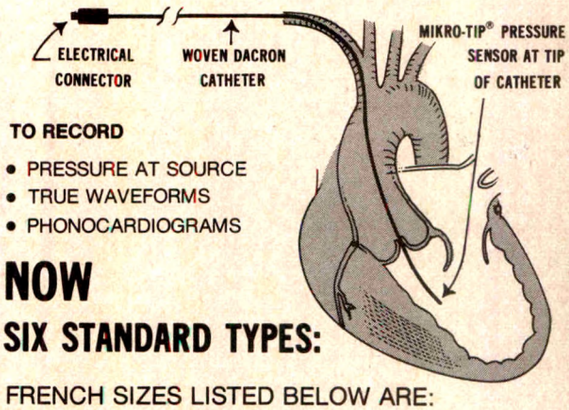
Adverse Reactions: Vomiting, diarrhea, nausea and abdominal discomfort may occur with the use of potassium salts. The symptoms and signs of potassium intoxication include paresthesias of the extremities, flaccid paralysis, listlessness, mental confusion, weakness and heaviness of the legs, fall in blood pressure, cardiac arrhythmias and heart block. Hyperkalemia may exhibit the following electrocardiographic abnormalities: disappearance of the P wave, widening and slurring of QRS complex, changes of the S-T segment, and tall, peaked T waves.

Dosage and Administration: Adults: 1 tablet (20 mEq. each of potassium and chloride) completely dissolved in 3 to 4 ounces of cold water 2 to 4 times daily depending upon the requirements of the patient. The approximate minimum adult daily requirement of potassium is 40 mEq. Deviations from this recommendation may be indicated, since no average total daily dose can be defined but must be governed by close observation for clinical effects.
NOTE: Klorvess should be taken with meals.

Overdosage: Potassium intoxication may result from overdosage of potassium or from therapeutic dosage in conditions stated under "Contraindications." Hyperkalemia, when detected, must be treated immediately because lethal levels can be reached in a few hours.

How Supplied: Klorvess Tablets (white, round) in boxes of 60 (2 Rx units of 30, NDC 43-100-87). Each tablet is individually foil wrapped.

MILLAR MIKRO-TIP®
CATHETER PRESSURE TRANSDUCERS



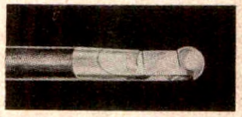
TO RECORD

- PRESSURE AT SOURCE
- TRUE WAVEFORMS
- PHONOCARDIOGRAMS

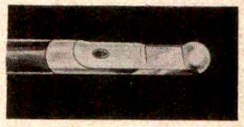
NOW
SIX STANDARD TYPES:

FRENCH SIZES LISTED BELOW ARE:
5F=1.67mm o.d., 7F=2.33 mm o.d., 8F=2.67 mm o.d.

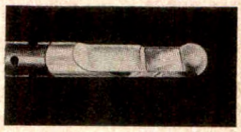
SINGLE PRESSURE SENSOR.
Available in 5F, 7F and 8F sizes



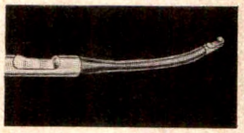
SINGLE PRESSURE SENSOR WITH LUMEN FOR BLOOD SAMPLING, EXTERNAL PRESSURE MONITORING OR SLOW DYE INJECTION.
Available in 7F and 8F sizes



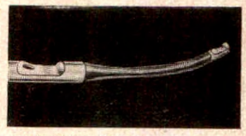
SINGLE PRESSURE SENSOR WITH LUMEN FOR HIGH SPEED INJECTION OF RADIOPAQUE CONTRAST DYE.
Available in 7F and 8F sizes



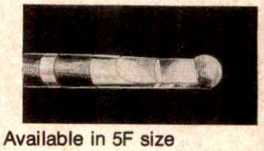
DUAL PRESSURE SENSORS FOR SIMULTANEOUSLY RECORDING OF PRESSURE AT TWO LOCATIONS. Available in 7F and 8F sizes, 5F size between Distal and Proximal Sensors



DUAL PRESSURE SENSORS FOR SIMULTANEOUSLY RECORDING OF PRESSURE AT TWO LOCATIONS. WITH LUMEN FOR BLOOD SAMPLING, EXTERNAL PRESSURE MONITORING OR SLOW DYE INJECTION.
Available in 7F and 8F sizes, 5F size between Distal and Proximal Sensors



SINGLE PRESSURE SENSOR WITH DUAL ELECTRODES FOR RECORDING PRESSURE WHILE STIMULATING WITH OR RECORDING FROM THE ELECTRODES. Available in 5F size



Transducer Control Units are available for interfacing with most recorders or display systems.

[illegible] ium [illegible]ent from cheating themselves.

Most salt substitutes have an unpleasant metallic aftertaste. Not Adolph's. It really seasons like salt. It's granulated, too. Comes in a shaker bottle. So it looks and sprinkles like salt. The flavor won't fade in cooking, either. And it contains mono-potassium glutamate to enhance the natural flavor of food.

Adolph's Salt Substitute contains less than 1 mg. of sodium per teaspoon, and it's a valuable source of supplemental potassium.

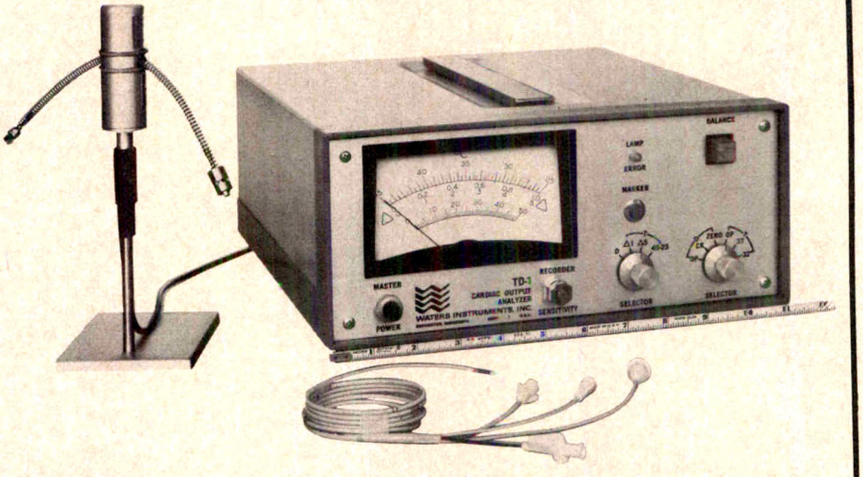
It's sold at food stores in two varieties—

Regular: Potassium chloride, glutamic acid, mono-potassium glutamate, silicon dioxide, tartaric acid, potassium iodide .01%.

Seasoned: Potassium chloride, sugar, spices, mono-potassium glutamate, glutamic acid, silicon dioxide, tartaric acid, vegetable oil.

For free physician's samples, write to Adolph's Ltd., P.O. Box 828, Dept. SM, Burbank, California, 91503.

Now... Thermal Dilution Capability with a Dichromatic Densitometer



The Waters TD-1 Cardiac Output Analyzer measures cardiac output via thermal dilution as well as dye dilution. This dual capability allows for the determination of cardiac output at frequent intervals over long periods and, in addition, provides accurate dye dilution measurements.

The Waters Dichromatic Densitometer has always been in a class by itself, because it not only reads the primary dye pattern but also considers artifacts and neutralizes their impact on measurement readings.

The addition of thermal dilution capability makes the Waters TD-1 the most accurate, versatile and advanced indicator dilution instrument available.

See the Waters TD-1 at the American College of Cardiology Convention in New York February 11-14 Booth 154

HEMODYNAMICS OF ANGINA PECTORIS* — PATIENTS RESTING AND EXERCISING, BEFORE AND AFTER ISORDIL® SUBLINGUAL
(isosorbide dinitrate)

BEFORE MEDICATION		AFTER 5 mg. ISORDIL SUBLINGUAL (isosorbide dinitrate)
	PULMONARY ARTERY (MEAN PRESSURE)		TOTAL PULMONARY RESISTANCE		CARDIAC INDEX		BRACHIAL ARTERY (MEAN PRESSURE)		TOTAL SYSTEMIC RESISTANCE	
IN ANGINA PECTORIS*

- to abort or terminate acute anginal attacks
- to reduce the frequency and severity of anginal episodes often caused by unavoidable everyday stress

ISORDIL® SUBLINGUAL
(ISOSORBIDE DINITRATE)

SUBLINGUAL TABLETS: 2.5 mg. and 5 mg.

***Indications:** Based on a review of this drug by the National Academy of Sciences—National Research Council and/or other information, FDA has classified the indication as follows:
"Probably" effective: When taken by the sublingual route, Isordil Sublingual is indicated for the treatment of acute anginal attacks and for prophylaxis in situations likely to provoke such attacks.
Final classification of the less-than-effective indications requires further investigation.

Contraindication: Idiosyncrasy to this drug.

Warnings: Data supporting the use of nitrites during the early days of the acute phase of myocardial infarction (the period during which clinical and laboratory findings are unstable) are insufficient to establish safety.

Precautions: Tolerance to this drug and cross-tolerance to other nitrites and nitrates may occur.

Adverse Reactions: Cutaneous vasodilation with flushing. Headache is common and may be severe and persistent. Transient episodes of dizziness and weakness as well as other signs of cerebral ischemia associated with postural hypotension may occasionally develop. This drug can act as a physiological antagonist to norepinephrine, acetylcholine, histamine, and many other agents. An occasional individual exhibits marked sensitivity to the hypotensive effects of nitrite, and severe responses (nausea, vomiting, weakness, restlessness, pallor, perspiration and collapse) can occur even with the usual therapeutic dose. Alcohol may enhance this effect. Drug rash and/or exfoliative dermatitis may occasionally occur.

Consult direction circular before prescribing.

May we send you reprints, detailed information and/or professional samples?

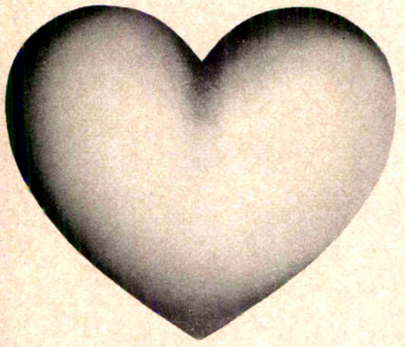
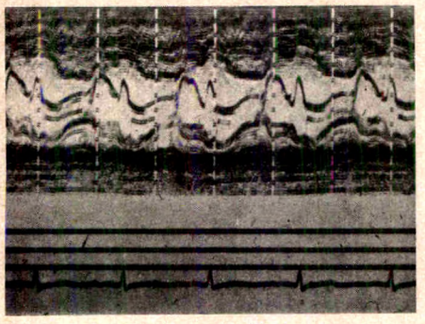
Ultrasound. Who needs it?





Heart scan on Echoview™ X showing prolapsing mitral valve. Photo courtesy Dr. Fred Winsberg, Montreal General Hospital, Montreal, Quebec.

You do. And your patients do. For ultrasound is opening new vistas in diagnostic visualization. In fact, it's the fastest-growing of the more important imaging technics. (We know because we also make the other major types—both radioisotope and x-ray imaging systems.)

But why Picker ultrasound? A fair question to which there are several good and valid answers.

1. Picker has been the pioneer and leader since we introduced ultrasound equipment in this country a decade ago.
2. Picker equipment has stood the test of time. Picker continues in its leadership role by innovative design and thorough field testing. In fact, more ultrasound scans are made with Picker equipment than with all other scanners combined.
3. Picker's new cardiac unit extends the breadth of our equipment line to encompass virtually every ultrasound requirement.
4. Picker systems are modularized and upgradable. And being American-made, that means you get all the improvements first since systems responsibility is right here.
5. Picker puts the clincher on with the largest field technical-service force in the industry. You get right-now Picker service by Picker personnel. No third parties are involved.

For a sound diagnosis, rely on Picker ultrasound. It's an ultrasound buying decision, too.

See your local Picker representative. Or contact Picker Corporation, 595 Miner Road, Cleveland, OH 44143.

For the prevention of the gripping pain of angina*
Peritrate® SA
Sustained Action (pentaerythritol tetranitrate) 80 mg
A logical choice for the "new" patient with angina pectoris.
*This drug has been evaluated as possibly effective for this indication.
See brief summary on following page.

Peritrate® SA

Sustained Action
(pentaerythritol tetranitrate) 80 mg

Description: Peritrate (pentaerythritol tetranitrate) is a nitric acid ester of a tetrahydric alcohol (pentaerythritol).

Indications: Based on a review of this drug by the National Academy of Sciences—National Research Council and/or other information, FDA has classified the indications as follows:

"Possibly" effective: Peritrate (pentaerythritol tetranitrate) is indicated for the relief of angina pectoris (pain associated with coronary artery disease). It is not intended to abort the acute anginal episode but is widely regarded as useful in the prophylactic treatment of angina pectoris.

Final classification of the less-than-effective indications requires further investigation.

Contraindications: Peritrate SA Sustained Action (pentaerythritol tetranitrate) 80 mg is contraindicated in patients who have a history of sensitivity to the drug.

Warning: Data supporting the use of Peritrate (pentaerythritol tetranitrate) during the early days of the acute phase of myocardial infarction (the period during which clinical and laboratory findings are unstable) are insufficient to establish safety. This drug can act as a physiological antagonist to norepinephrine, acetylcholine, histamine, and many other agents.

Precautions: Should be used with caution in patients who have glaucoma. Tolerance to this drug, and cross-tolerance to other nitrites and nitrates, may occur.

Adverse Reactions: Side effects reported to date have been predominantly related to rash (which requires discontinuation of medication) and headache and gastrointestinal distress, which are usually mild and transient with continuation of medication. In some cases severe persistent headaches may occur. In addition, the following adverse reactions to nitrates such as pentaerythritol tetranitrate have been reported in the literature: (a) Cutaneous vasodilatation with flushing. (b) Transient episodes of dizziness and weakness, as well as other signs of cerebral ischemia associated with postural hypotension, may occasionally develop. (c) An occasional individual exhibits marked sensitivity to the hypotensive effects of nitrite and severe responses (nausea, vomiting, weakness, restlessness, pallor, perspiration and collapse) can occur, even with the usual therapeutic doses. Alcohol may enhance this effect.

Dosage: Peritrate SA Sustained Action (pentaerythritol tetranitrate) 80 mg (b.i.d. on an empty stomach), 1 tablet immediately on arising and 1 tablet 12 hours later.

Supplied: Peritrate SA Sustained Action (pentaerythritol tetranitrate) 80 mg, bottles of 100 and 1000 tablets.

Additional Dosage Forms: Peritrate (pentaerythritol tetranitrate) 10 mg and 20 mg tablets in bottles of 100 and 1000.

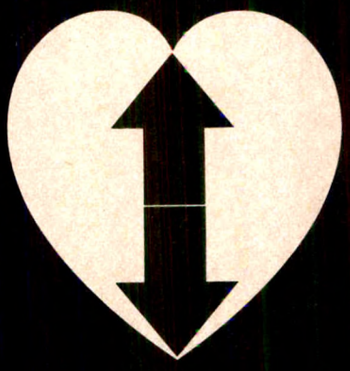
Concerned about over or under digitalization?



Then speak to your laboratory—they can now help you monitor digoxin and digitoxin blood levels.

Clearly the digitalis glycosides have been a mixed blessing. Their potential for good is inevitably coupled with the possibility of harmful effects due to inadequately low or toxically high blood levels. And then, as if the narrow margin of safety weren't enough, we also began to realize that there are variations in bioavailability of these glycosides. From glycoside to glycoside. From company to company. From one route of administration to another. From dosage form to dosage form. Sometimes even from lot to lot.

Yet, despite these multiple uncertainties, no really practical tool existed for monitoring digitalis glycoside blood levels. The result, according to some observers, can be serious. One worker stated that perhaps 20 to 25% of all digitalized patients are actually overdigitalized to the point of toxicity and that this situation had reached epidemic proportions.[1] Another reported that the mortality rate from overdigitalization ranges from 3% to 21%.[2]

And in the same study, 11% of the digitalized patients previously thought to be on adequate daily maintenance therapy were actually shown to be *underdigitalized.* One recent report indicated that while an oral digoxin solution was completely absorbed, a digoxin tablet was only 75% absorbed.[3]

Those are the problems. Now the news here is this: new radioimmunoassay techniques have been developed for monitoring digoxin and digitoxin blood levels. These are perfectly practical methods that offer exceptional sensitivity and specificity. So, if you're concerned about the problems of overdigitalization and underdigitalization, speak to your laboratory about the availability of these new radioimmunoassays. They can help minimize a serious problem. Perhaps you'll also be interested to know that we supply radioimmunoassay kits for renin activity and vitamin B_{12} determinations. These, too, are characterized by unusual sensitivity, specificity and precision. Once again, speak to your laboratory. For further information, write Schwarz/Mann, Mountain View Avenue, Orangeburg, New York 10962.

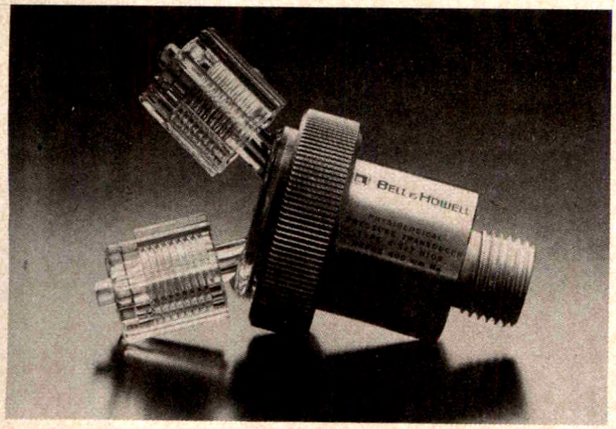
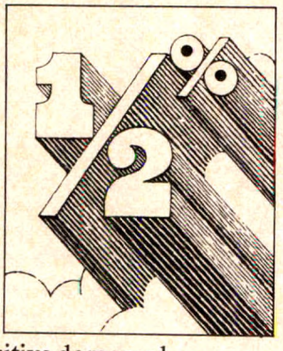
OUR BLOOD PRESSURE TRANSDUCER AND ITS CREDENTIALS.



The Bell & Howell Type 4-327 Physiological Blood Pressure Transducer Measures arterial and venous blood pressure. Specifically designed for use in hospital cath labs, ICUs and CCUs.

HOW ACCURATE? HOW GOOD?



It's the most accurate instrument available. *Twice* as accurate as any other make. Accurate down to ½ % as a matter of fact.

The Bell & Howell 4-327 transducer features a sensor design that has a four-active-arm Wheatstone bridge element with excellent calibration stability. Its advanced design includes a positive dome seal, stable output as saline fluid temperatures change, and a removable catch for quick interchangeability.

SPECIAL FEATURES:

Construction is rugged but its finish is that of a precision instrument. It has a positive seal using silicone rubber gaskets and is autoclaveable with/without connectors. Also, it has an overpressure stop to prevent damage up to 10 times the rated full scale pressure range and excellent frequency response for accurate monitoring of the heart pulse characteristic.

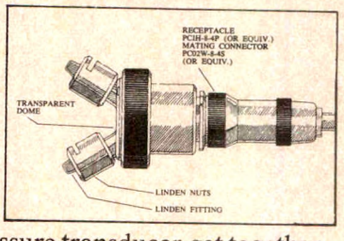
The Bell & Howell 4-327 is not affected by position. Not harmed by mechanical shock. And not shaken by vibration or microphonic transients. It's been a proven performer for 8 years.

THE PRESSURE IS ON US.

Our 4-327s are available on a moment's notice. We maintain an inventory which allows us to guarantee shipment within 24 hours of your order. That goes for new orders as well as repeat orders. New customers as well as old customers. Which means the world's most accurate blood pressure transducer is probably also the world's fastest, from our inventory into your hands.

Need service? Our delivery philosophy extends to our service policy. When you need us you can get us.

GET TOGETHER WITH THE 4-327.



Our transducers are our best representatives. But they can't answer a phone. However, if you call collect, (213) 796-9381 we'll see to it that you and our 4-327 blood pressure transducer get together.

WE'RE REWRITING THE BOOK.

It's true. We *are* rewriting the book, the Bell & Howell Transducer Handbook. To be published soon, it will contain important information on the use of the 4-327. If you would like a preview of this information, send for your free copy of the 4-327 Instruction Manual. Write: Handbook Editor, Bell & Howell, CEC/Instruments Division, 360 Sierra Madre Villa, Pasadena, California 91109.

The Gordon/DonMichael Esophageal Obturator Airway*

A new resuscitation concept, the Esophageal Obturator Airway developed by Dr. Archer S. Gordon and Dr. T. A. Don Michael* offers an effective but simpler method than endotracheal intubation for establishing a patent airway during resuscitation procedures. The Esophageal Obturator Airway is introduced into the esophagus rather than the trachea, and has the following advantages:

- Does not require use of a laryngoscope or other instrumentation.
- Does not require visualization of the larynx or esophagus.
- Does not require any interruption of CPR.

When the airway is inserted and the mask is seated on the face, the obturator tip and inflatable cuff lie in the esophagus below the bifurcation of the trachea. The tip and inflated cuff occlude the esophagus and:

- Prevent gastric distension during resuscitation.
- Prevent regurgitation which leads to aspiration of gastric contents.

Mouth-to-mask, bag-valve-mask, or mechanical ventilation at the mask orifice inflates the lungs via the multiple openings in the portion of the airway which lies in the pharynx.

Contraindications: 1. children; 2. conscious or semi-conscious patients; 3. cases of caustic poisoning; 4. patients with known esophageal disease; 5. rescuers without adequate manikin and/or clinical training and practice.

CLINICAL CARDIOLOGY MONOGRAPHS

J. Willis Hurst, M.D. and Dean T. Mason, M.D.
Series Consultants

SHOCK IN MYOCARDIAL INFARCTION

Edited by Rolf M. Gunnar, M.D. Concentrating on all the aspects of the clinical syndrome confronting the physician, some of the topics covered are: The Coronary Arteries and Myocardium in Acute Myocardial Infarction and Shock; Functional Basis of the Hemodynamic Spectrum; Physiologic Monitoring; Pharmacologic Agents in Support of the Circulation; Mechanical Cardiac Assistance in Shock; Surgical Treatment.

March 1974, 272 pp., 58 illus., abt. $16.00 £7.50 ISBN 0-8089-0815-4

ADVANCES IN CARDIOVASCULAR SURGERY

Edited by John W. Kirklin, M.D. Encompassing the enormous progress made in congenital, valvular and ischemic heart disease — this monograph details the indications for, the techniques of repair, the methods of support, and the results of cardiac surgery. Recent advances in complex congenital malformations and primary definitive intracardiac operations for infants are also discussed.

December 1973, 292 pp., 51 illus., $15.75 £7.40 ISBN 0-8089-0707-2

NONINVASIVE CARDIOLOGY

Edited by Arnold M. Weissler, M.D. This book provides a critical review of recent research into the physiologic basis and clinical application of noninvasive methods. Primary attention has been focused on the procedures which lend themselves to the assessment of the contractile performance of the heart.

November 1973, 384 pp., 215 illus., $19.00 £8.95 ISBN 0-8089-0815-4

CARDIAC PACING

Edited by Philip Samet, M.D. This volume covers both the basic aspects of cardiac pacing — such as the anatomy and pathology of the conduction system, physiologic aspects of pacing — and special problems such as techniques of permanent pacer implantation, pacer therapy of tachycardias, pacer induced arrhythmias, and problems in sensing in demand pacing.

July 1973, 448 pp., 168 illus., $21.00 £9.85 ISBN 0-8089-0800-6

MYOCARDIAL DISEASES

Edited by Noble O. Fowler, M.D. This volume presents a vivid and up-to-date view of the various myocardial diseases through the writings of experts in their special areas of interest. Special emphasis is placed on clinical recognition, possible etiologic background, treatment, and areas of need for further investigation.

June 1973, 392 pp., 115 illus., $18.50 £8.70 ISBN 0-8089-0799-9

ADVANCES IN ELECTROCARDIOGRAPHY

Edited by Robert C. Schlant, M.D. and J. Willis Hurst, M.D. "The distinguished editors of this symposium, both of them household names in cardiology, have very successfully recruited top-level contributors to report the most significant basic and clinical advances in electrocardiography. . . . The authors are to be congratulated on the breadth and depth of coverage and on the general level of 'readability' in highly technical areas." — J.A.M.A.

June 1972, 480 pp., 314 illus., $24.75 £11.60 ISBN 0-8089-0755-7

HYPERTENSION: Mechanisms and Management

The 26th Hahnemann Symposium

Edited by Gaddo Onesti, M.D. and Kwan E. Kim, M.D. The material presented is based on solid facts and conclusive data now available through long-term follow-up treatment programs. Much new information is the result of observations made on the role of the renin-aldosterone system and electrolyte metabolism in blood pressure regulation.

September 1973, 848 pp., illus., $39.00 £18.35 ISBN 0-8089-0790-5

CARDIAC ARRHYTHMIAS

The 25th Hahnemann Symposium

Edited by Leonard S. Dreifus, M.D. and William Likoff, M.D. Bringing all recent advances into sharp focus, the authors integrate basic electrophysiologic knowledge with useful clinical information. The conduction and mechanisms of the Wolff-Parkinson-White syndrome are elucidated and the subject of cardiac pacing is explored.

March 1973, 704 pp., 376 illus., $29.75 £13.95 ISBN 0-8089-0759-X

New from 3M
Littmann® ECG Trimmer
BRAND

Also ask about LITTMANN Brand ECG Gel-Pads. No cleanup. Less chance of cross contamination. Excellent electrical contact. See if you don't agree: 3M has found "the better way."

Now, all the advantages of LITTMANN Brand ECG Mounts are yours in a compact cutting device for trimming electrocardiogram leads. The new LITTMANN ECG Trimmer. With three blades for cutting uniform lead segments of specified sizes. When used with LITTMANN ECG Mounts you get professional-appearing permanent records barely thicker than a single sheet of paper. Saving filing space. Permitting photo copying of a single sheet. Providing faster, more efficient interpretation.

The ECG Trimmer from 3M—newest member of the LITTMANN ECG Mounting System. Contact your surgical supply dealer or 3M Representative today.

Pronestyl® Capsules/Injection
(Procainamide Hydrochloride)

Contraindications: In patients with myasthenia gravis and where a hypersensitivity to procainamide and related drugs exists. Should not be given to patients with complete atrioventricular heart block. Contraindicated in cases of high-degree A-V block unless an electrical pacemaker is operative.

Administration: Oral administration is preferred. When parenteral therapy is necessary, intramuscular administration is the method of choice. Intravenous use should be limited to extreme emergencies, be administered as a dilute infusion, and the patient be monitored electrocardiographically whenever practicable throughout the infusion. The intravenous dose should not exceed 1 g. Administer at a rate not exceeding 25 to 50 mg. per minute.

Should procainamide therapy be continued for any appreciable period, electrocardiograms should be made occasionally to determine its further need.

Precautions: Evidence of untoward myocardial response should be carefully watched for in all patients. In the presence of myocardial damage with atrial fibrillation or flutter, the ventricular rate may increase suddenly as the atrial rate is slowed; adequate digitalization reduces but does not abolish this danger. Ventricular tachysystole is particularly hazardous.

The dislodgement of mural thrombi producing an embolic episode may occur in correcting atrial fibrillation due to the forceful contractions of the atrium.

Extreme caution is required in attempting to adjust the heart rate when ventricular tachycardia has occurred during an occlusive coronary episode or where the use of procainamide may result in additional depression of conduction and ventricular asystole or fibrillation as in A-V block, bundle branch block, or severe digitalis intoxication.

Parenteral administration should be monitored electrocardiographically whenever practicable. Parenteral administration should be discontinued at once if electrocardiograms give evidence of impending heart block. This complication should be kept in mind when treating ventricular arrhythmias (especially parenterally) in patients with severe organic heart disease and ventricular tachycardia who may also have complete heart block. Since asystole may result if the ventricular rate is significantly slowed without attainment of regular atrioventricular conduction, procainamide should be stopped and the patient re-evaluated.

In the presence of both liver and kidney damage, normal dosage may produce symptoms of overdosage—principally ventricular tachycardia and severe hypotension.

A syndrome resembling lupus erythematosus has been reported with maintenance procainamide therapy. Common symptoms are polyarthralgia, arthritis and pleuritic pain. Fever, myalgia, skin lesions, pleural effusion and pericarditis may also occur. Rare cases of thrombocytopenia or Coombs-positive hemolytic anemia, possibly related to this syndrome, have been reported. Measure anti-nuclear antibody titers at regular intervals in patients on procainamide for extended periods of time or in whom symptoms suggestive of lupus-like reaction appear; discontinue drug in event of rising titer or clinical symptoms of LE. Steroid therapy may be effective if discontinuation of procainamide does not cause remission of symptoms. If the syndrome develops in a patient with recurrent life-threatening arrhythmias not otherwise controllable, steroid-suppressive therapy may be used concomitantly with procainamide.

Adverse Reactions: Because procainamide is a peripheral vasodilator, it may produce a hypotensive response, sometimes precipitous when given intravenously. Blood pressure should be measured almost continuously during the infusion which should be temporarily discontinued if the fall exceeds 15 mm. Hg. The hypotensive response is less likely to occur from intramuscular injection and is rare following oral administration. Serious disturbances of cardiac rhythm such as ventricular asystole or fibrillation are also more common with I.V. administration.

Large oral doses may sometimes produce anorexia, nausea, urticaria, and/or pruritus.

Reactions consisting of fever and chills; soreness of mouth, throat, or gums; and symptoms of upper respiratory tract infection have been reported. Agranulocytosis has been occasionally reported following prolonged use of the drug, and deaths have occurred. Therefore, routine blood counts are advisable during maintenance therapy. If any of the above symptoms should occur and leukocyte counts indicate cellular depression, procainamide therapy should be discontinued and appropriate treatment should be instituted immediately. Diarrhea, weakness, mental depression, giddiness, psychosis with hallucinations, hypersensitivity reactions such as angioneurotic edema and maculopapular rash, and bitter taste have been reported.

The package insert should be read carefully to become familiar with the recommended oral and parenteral dosage for the indicated conditions.

How Supplied: Pronestyl Capsules (Procainamide Hydrochloride Capsules U.S.P.) providing 250 mg. and 500 mg. are available in bottles of 100 and 1000 and Unimatic* Single Dose packaging in cartons of 100. Capsules providing 375 mg. are available in bottles of 100. Pronestyl Injection (Procainamide Hydrochloride Injection U.S.P.) providing a 10% sterile aqueous solution (100 mg./cc.) with 0.9% (w/v) benzyl alcohol is available in 10 cc. vials.

(Procainamide Hydrochloride)

for premature ventricular contractions

SQUIBB®

'The Priceless Ingredient of every product is the honor and integrity of its maker.'™

See opposite page for brief summary.

"The drug of choice for oral replacement of potassium is potassium chloride solution."

AMA Drug Evaluations 1971, First Edition, Chicago, American Medical Association, p. 121.

Kay Ciel® Elixir is potassium chloride... tastes good too!

COMPOSITION: Each 15 cc. (one tablespoonful) contains potassium chloride 1.5 Gm., supplying 20 mEq. of elemental potassium, in a cherry-flavored, palatable base, alcohol 4%. Contains no sugar.
INDICATIONS: Treatment of potassium deficiency occurring especially during thiazide diuretic or corticosteroid therapy, digitalis intoxication, low dietary intake of potassium or as a result of excessive vomiting and diarrhea.
CONTRAINDICATIONS: Impaired renal function, untreated Addison's Disease, dehydration, heat cramps, and hyperkalemia.
PRECAUTIONS: Potassium chloride should be administered with caution and adjusted to the requirements of the individual patient, since the amount of deficiency and corresponding daily dose is often not known. Excessive or even therapeutic dosages may result in potassium intoxication. Patients should be frequently checked and periodic ECG and/or plasma potassium levels made. High plasma concentrations of potassium ion may cause cardiac depression, arrhythmias or arrest. Use with caution in patients with cardiac disease. In hypokalemic states, attention should be directed toward the correction of the frequently associated hypochloremic alkalosis.
SIDE EFFECTS: Vomiting, nausea, abdominal discomfort and diarrhea may occur. Symptoms and signs of potassium intoxication include listlessness, mental confusion, paresthesia of the extremities, weakness of the legs, flaccid paralysis, fall in blood pressure, cardiac arrhythmias, and heart block. When hyperkalemia exists, it should be promptly treated with the discontinuance of potassium administration or other steps to lower serum levels if indicated, since sudden shift in plasma levels may induce potentially dangerous cardiac arrhythmias.
DOSAGE AND ADMINISTRATION: Adults, one tablespoonful (15 cc.) diluted in one glass of water, twice daily after the morning and evening meal. Larger doses may be indicated according to the individual patient's requirements but should be administered under close supervision due to the possibility of potassium intoxication. Patients should be cautioned to follow directions explicitly in regard to dilution of Kay Ciel Elixir to prevent gastrointestinal injury.
HOW SUPPLIED: One pint and one gallon bottles.

Cooper Laboratories, Inc., Wayne, N.J. 07470/Ste. Therese, P.Q., Canada

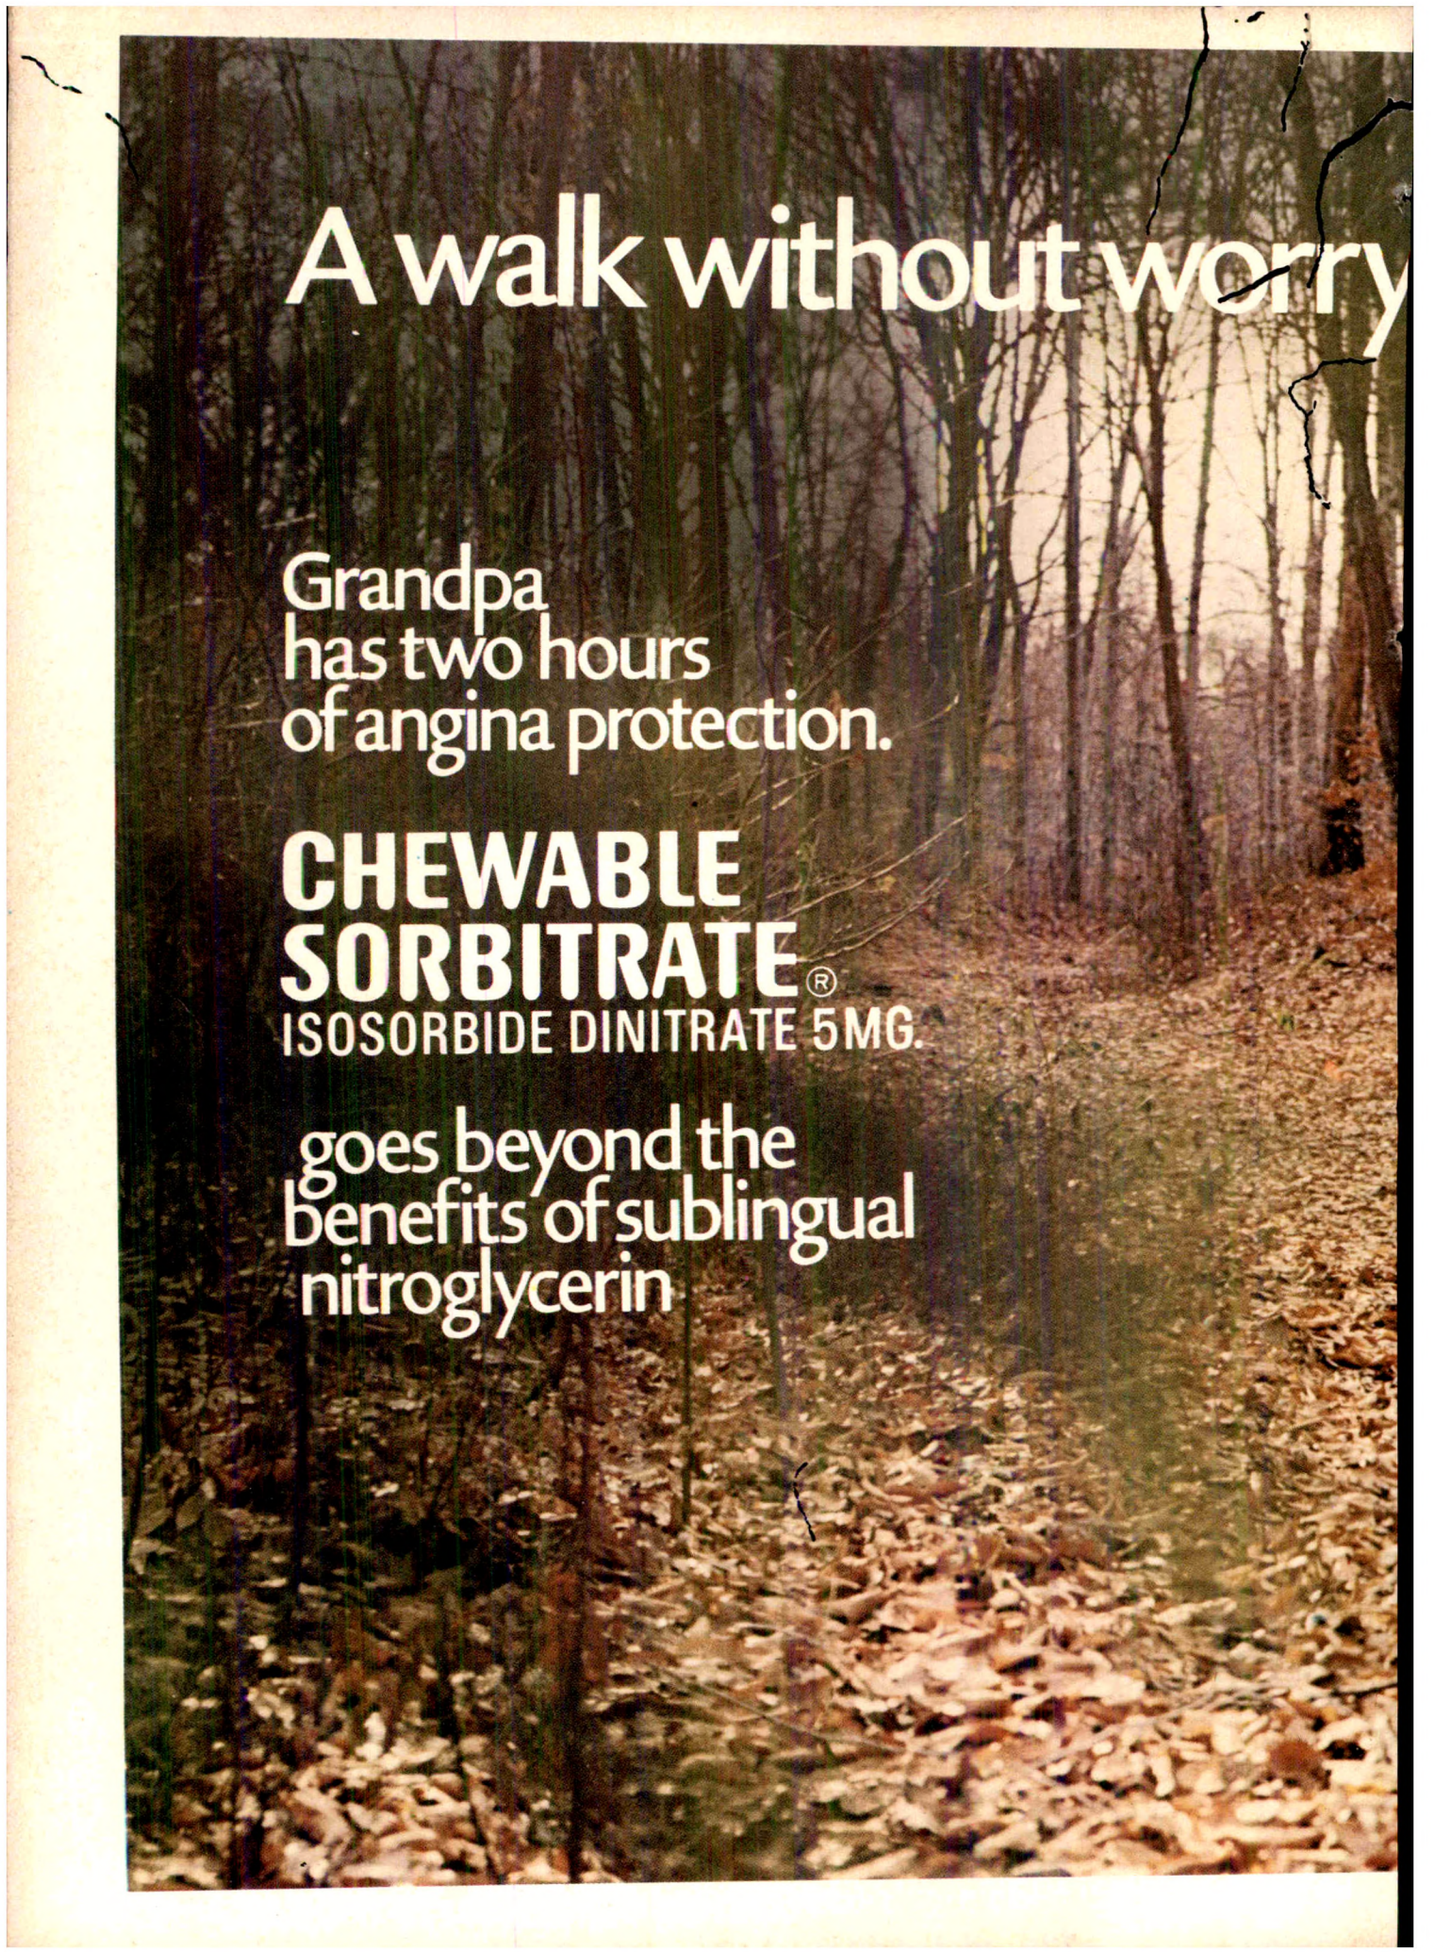
A YORKE MEDICAL JOURNAL

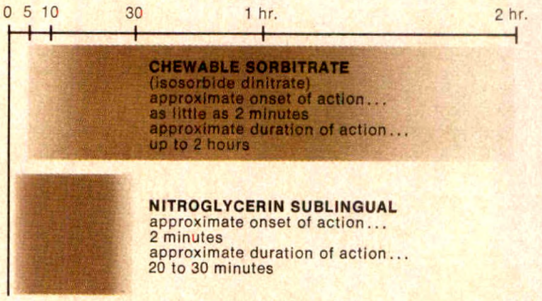
UNIVERSITY COLLEGE OF MEDICINE LIBRARY G. U.



A walk without worry
Grandpa
has two hours
of angina protection.
CHEWABLE
SORBITRATE®
ISOSORBIDE DINITRATE 5MG.
goes beyond the
benefits of sublingual
nitroglycerin

For up to two hours of protection, your angina patient needs *more* than sublingual nitroglycerin. And Chewable Sorbitrate provides more.

☐ Acts almost as fast as nitroglycerin...lasts about 4 times as long.



☐ More stable in air than sublingual nitroglycerin: it can be stored or carried with no significant loss of potency.

☐ And when indicated: Sorbitrate® (isosorbide dinitrate) Sublingual 5 mg. and 2.5 mg.

SUMMARY OF PRESCRIBING INFORMATION

Mode of action: The mechanism of action of SORBITRATE (isosorbide dinitrate) is unknown, although the basic pharmacologic action is to relax smooth muscle. Isosorbide dinitrate reduces in number and severity the incidence of angina pectoris attacks, with concomitant reduction in nitroglycerin intake.

Indications: Sublingual and Chewable: For the prevention and treatment of angina pectoris.

Oral: For the relief of angina pectoris. It is not intended to abort the acute anginal episode. SORBITRATE WITH PHENOBARBITAL is indicated for patients in whom the angina pectoris is accompanied by anxiety or its related symptoms.

Contraindications: A history of sensitivity to the drug.

Warnings: Data supporting the use of nitrates during the early days of the acute phase of myocardial infarction are insufficient to establish safety. Phenobarbital may be habit forming.

Precautions: Should be used with caution in patients who have glaucoma. Tolerance and cross tolerance to other nitrates may occur.

Adverse Reactions: Headache which may be severe and persistent. Lowering the dose and using analgesics will help control the headaches which usually diminish or disappear as therapy is continued.

Adverse reactions seen occasionally: Cutaneous vasodilation with flushing; transient dizziness and weakness as well as other signs of cerebral ischemia associated with postural hypotension; individual marked sensitivity to the hypotensive effects of nitrates wherein severe responses can occur even with the usual therapeutic dose (alcohol may enhance this effect); drug rash and/or exfoliative dermatitis.

This drug can act as a physiological antagonist to norepinephrine, acetylcholine, histamine and other agents.

Dosage and Administration: Route: Sublingual, oral and chewable tablets.

Individual Dose: To minimize hypotensive responses, which may occasionally be severe with chewable doses as low as 5 mg., the smallest effective dose should be employed. Chewable tablets are generally given in doses of 5 mg. Sublingually or orally, 5 to 10 mg. is the range commonly used although doses of up to 30 mg. have frequently been employed.

Dosage Schedule: Smallest effective dose necessary for the prevention and treatment of pain of an anginal attack. Sublingual SORBITRATE may be taken p.r.n. or at 4 to 6 hour intervals; Oral SORBITRATE may be taken 3 to 4 times daily. CHEWABLE SORBITRATE may be taken for prompt relief of anginal pain 3 or 4 times daily. Although the onset and duration of effect of coronary nitrates may vary, following are the generally reported ranges of these values for SORBITRATE:

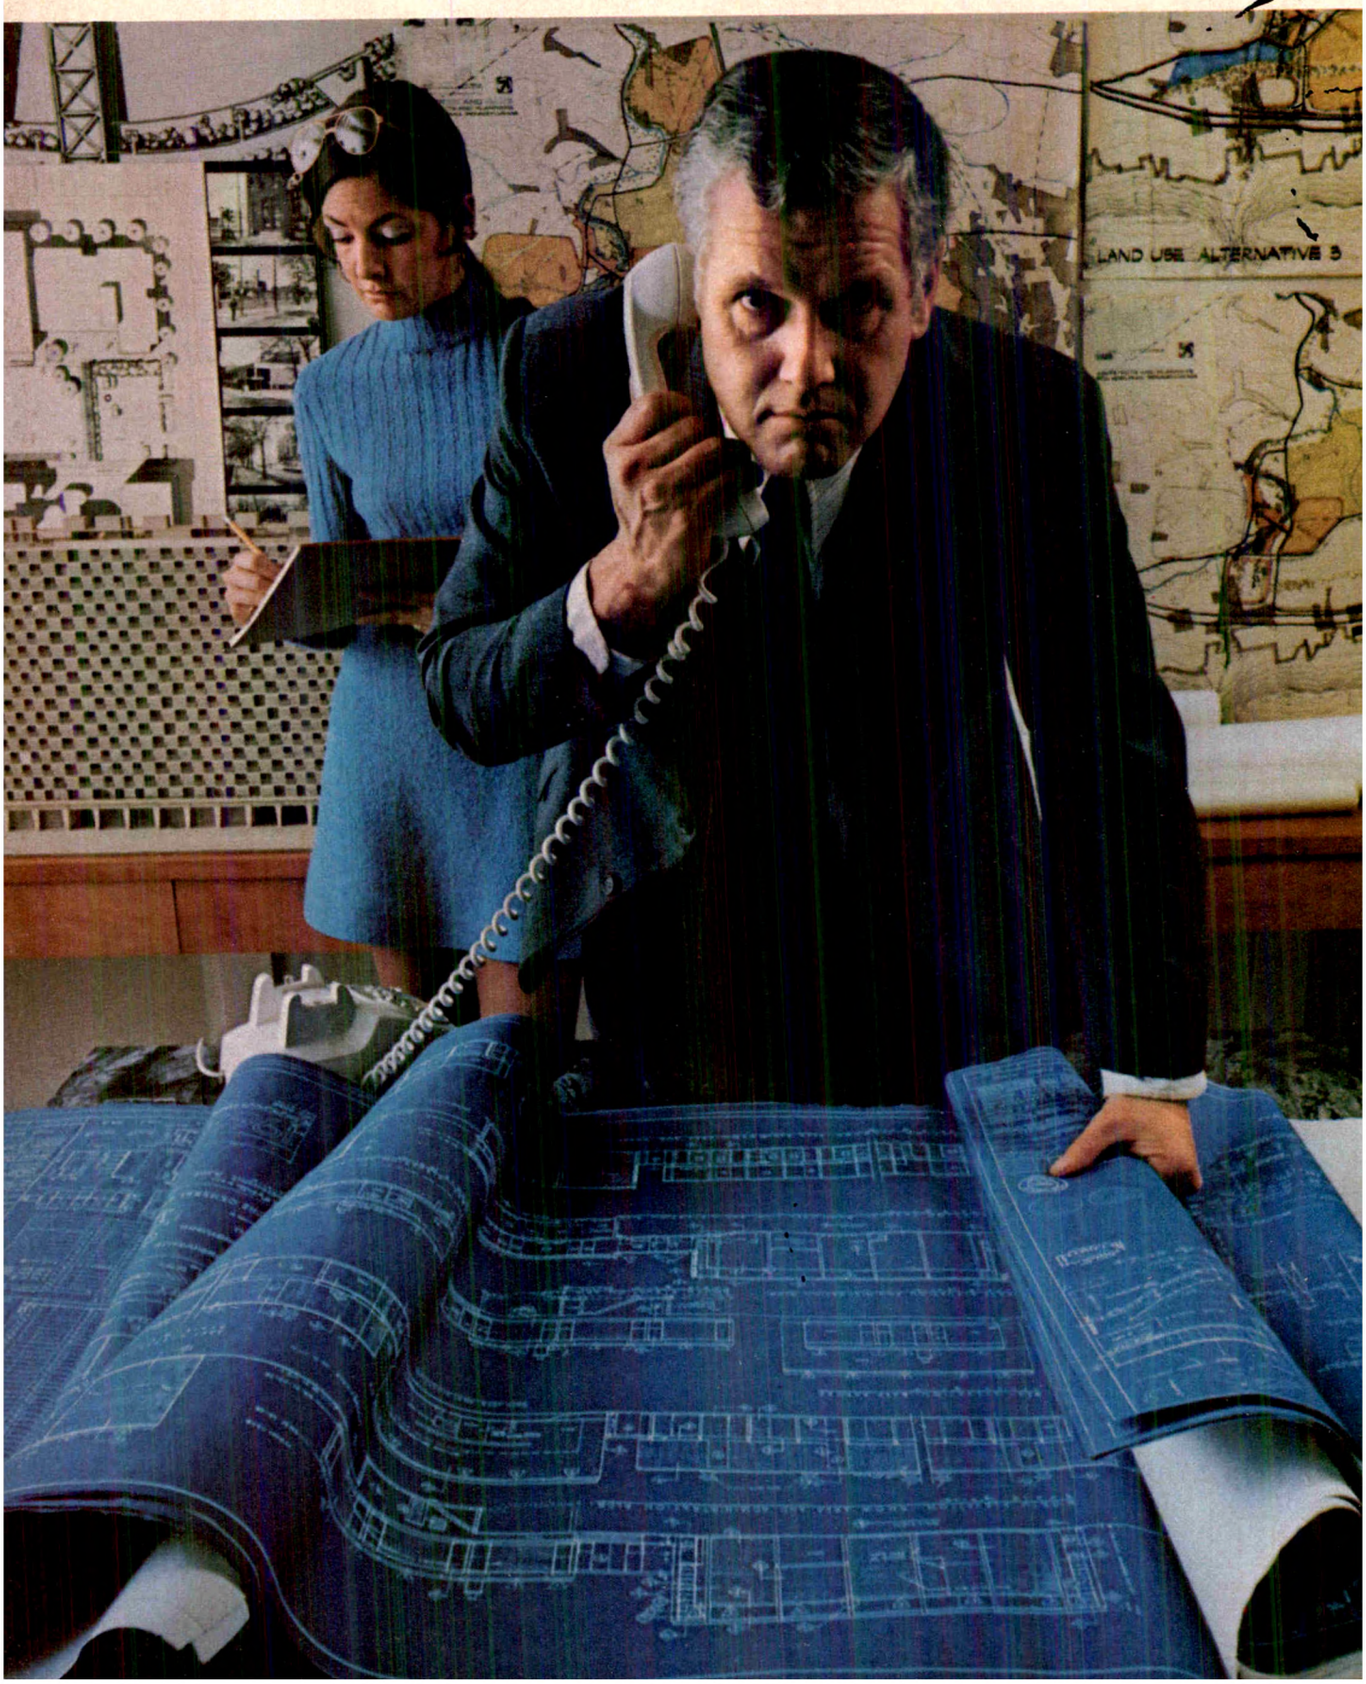
Onset of Effect: Sublingual and Chewable: 2 to 5 minutes. Oral: 15 to 30 minutes.

Duration of Effect: Sublingual and Chewable: 1 to 2 hours. Oral: Estimated to be 4 to 6 hours.

It is recommended that the oral dosage be taken on an empty stomach.

STUART PHARMACEUTICALS | Div of ICI America Inc.
WILMINGTON, DEL. 19899

HE HAS THE DRIVE OF A FULLBACK— BUT THE BLOOD PRESSURE OF AN EARLY HYPERTENSIVE



IS HE A "POTASSIUM WASTER" AS WELL?

Bartels et al.[1] found that 28 of 65 hypertensive patients treated with chlorothiazide developed hypokalemia despite, in 12 cases, the concurrent administration of 2 or 3 grams of KCl daily. In 10 patients, hypokalemia persisted for up to 10 weeks in spite of remedial measures. They concluded: **"The long-term use of drugs which may cause potassium depletion must be carefully considered in these patients who may be potential potassium wasters."**

Hypokalemia is usually associated with a considerable reduction of total body potassium.[2] By prescribing 'Dyazide', you can protect patients against hypokalemia, because 'Dyazide' contains DYRENIUM® (brand of triamterene), the unique potassium-sparing agent which acts *independently* of aldosterone secretion. Thus, 'Dyrenium' works from the *first dose* and throughout therapy at constant dosage levels. And the combination in 'Dyazide' lowers blood pressure as effectively as plain thiazides.

TO BRING HIS BLOOD PRESSURE DOWN TO KEEP HIS POTASSIUM LEVEL UP

DYAZIDE®

Trademark

Each capsule contains 50 mg. of Dyrenium® (brand of triamterene) and 25 mg. of hydrochlorothiazide.

The Dyrenium (triamterene, SK&F) component of 'Dyazide' conserves potassium. Therefore, dietary potassium supplements or potassium salts should not be used with 'Dyazide' unless hypokalemia develops or dietary intake of potassium is markedly impaired.

'Dyazide' can occasionally cause hyperkalemia. Accordingly, serum potassium and BUN should be checked during therapy, particularly in patients with suspected or confirmed renal insufficiency (e.g., elderly or diabetic patients). If hyperkalemia develops, 'Dyazide' should be withdrawn and a thiazide alone substituted.

Use 'Dyazide' with caution during pregnancy or in women who might bear children. Its potential benefits should be weighed against possible hazards to the fetus.

See next page for indications and brief prescribing information.

1. Bartels, C. C., et al.: Chlorothiazide—A Survey of Its Effects in Hypertensive Patients, J.A.M.A. 170:1796 (Aug. 8) 1959.

2. Edmonds, C.J., and Jasani, B.: Total-Body Potassium in Hypertensive Patients During Prolonged Diuretic Therapy, Lancet 2:8 (July 1) 1972.

DYAZIDE®

Trademark

Each capsule contains 50 mg. of Dyrenium® (brand of triamterene) and 25 mg. of hydrochlorothiazide.

TO BRING BLOOD PRESSURE DOWN TO KEEP POTASSIUM LEVELS UP

Before prescribing, see complete prescribing information in SK&F literature or *PDR*.

Indications: Edema associated with congestive heart failure, cirrhosis of the liver, the nephrotic syndrome; steroid-induced and idiopathic edema; edema resistant to other diuretic therapy. Also, mild to moderate hypertension.

Contraindications: Pre-existing elevated serum potassium. Hypersensitivity to either component. Continued use in progressive renal or hepatic dysfunction or developing hyperkalemia.

Warnings: Do not use dietary potassium supplements or potassium salts unless hypokalemia develops or dietary potassium intake is markedly impaired. Enteric-coated potassium salts may cause small bowel stenosis with or without ulceration. Hyperkalemia (>5.4 mEq/L) has been reported in 4% of patients under 60 years, in 12% of patients over 60 years, and in less than 8% of patients overall. Rarely, cases have been associated with cardiac irregularities. Accordingly, **check serum potassium during therapy, particularly in patients with suspected or confirmed renal insufficiency (e.g., elderly or diabetics). If hyperkalemia develops, substitute a thiazide alone. If spironolactone is used concomitantly with 'Dyazide', check serum potassium frequently**—both can cause potassium retention and sometimes hyperkalemia. Two deaths have been reported in patients on such combined therapy (in one, recommended dosage was exceeded; in the other, serum electrolytes were not properly monitored). Observe patients on 'Dyazide' regularly for possible blood dyscrasias, liver damage or other idiosyncratic reactions. Blood dyscrasias have been reported in patients receiving Dyrenium (triamterene, SK&F). Rarely, leukopenia, thrombocytopenia, agranulocytosis, and aplastic anemia have been reported with the thiazides. Watch for signs of impending coma in acutely ill cirrhotics. Thiazides are reported to cross the placental barrier and appear in breast milk. This may result in fetal or neonatal hyperbilirubinemia, thrombocytopenia, altered carbohydrate metabolism and possibly other adverse reactions that have occurred in the adult. When used during pregnancy or in women who might bear children, weigh potential benefits against possible hazards to fetus.

Precautions: Do periodic serum electrolyte and BUN determinations. Do periodic hematologic studies in cirrhotics with splenomegaly. Antihypertensive effects may be enhanced in postsympathectomy patients. The following may occur: hyperuricemia and gout, reversible nitrogen retention, decreasing alkali reserve with possible metabolic acidosis, hyperglycemia and glycosuria (diabetic insulin requirements may be altered), digitalis intoxication (in hypokalemia). Use cautiously in surgical patients. Concomitant use with antihypertensive agents may result in an additive hypotensive effect.

Adverse Reactions: Muscle cramps, weakness, dizziness, headache, dry mouth; anaphylaxis; rash, urticaria, photosensitivity, purpura, other dermatological conditions; nausea and vomiting (may indicate electrolyte imbalance), diarrhea, constipation, other gastrointestinal disturbances. Rarely, necrotizing vasculitis, paresthesias, icterus, pancreatitis, and xanthopsia have occurred with thiazides alone.

Supplied: Bottles of 100 capsules.

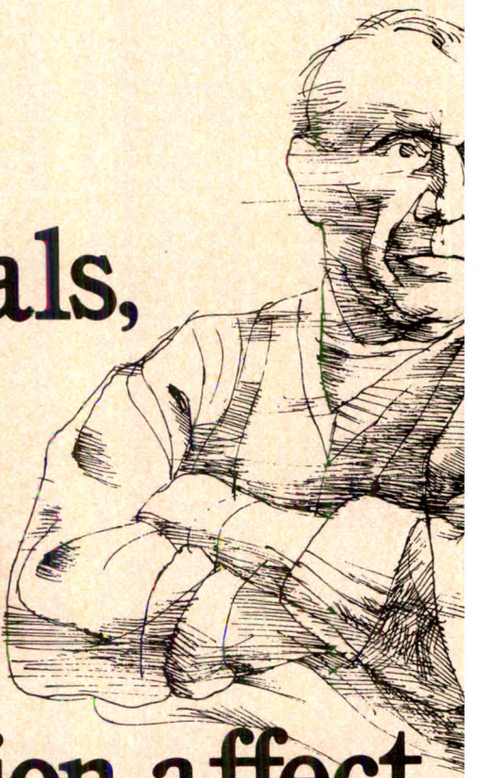
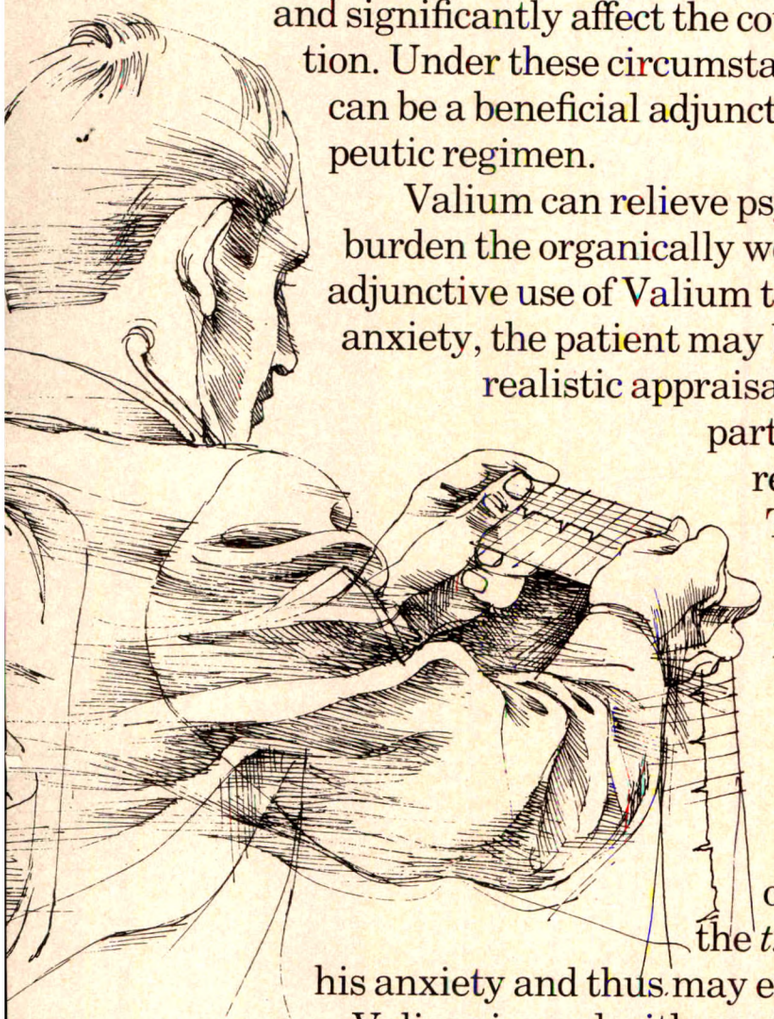
Development of fibrous scar and healing of infarcted area.



will psychic tension affect the patient's rehabilitation?

ROCHE

After the MI patient's acute episode has been successfully managed, a program of rehabilitation is begun. At times the overly tense cardiac patient may present a special problem. Although you continue to encourage a positive outlook through counseling and enlistment of support from the patient's family, psychic tension may remain, and significantly affect the course of rehabilitation. Under these circumstances, Valium (diazepam) can be a beneficial adjunct to the patient's therapeutic regimen.



Valium can relieve psychic tension that may burden the organically weak heart. As a result of adjunctive use of Valium to relieve unwarranted anxiety, the patient may be able to arrive at a more realistic appraisal of his situation and participate more fully with his rehabilitation program. Therapy should normally be continued until the patient's anxiety has been reduced to tolerable levels.

Since the cardiac patient may be particularly prone to tension and anxiety at bedtime, the addition of an *h.s.* dose of Valium to the *t.i.d.* schedule can relieve his anxiety and thus may encourage sleep.

Valium is used with most classes of primary medications such as cardiac glycosides, diuretics, vasodilators, anticholinergics and antacids. The most commonly reported side effects have been drowsiness, fatigue and ataxia. Patients taking Valium should be cautioned against driving or operating dangerous machinery.

Valium®(diazepam)
2-mg, 5-mg, 10-mg tablets

when you consider it essential to keep the heart patient calm

Please turn page for a summary of product information.

When you consider it essential to keep the heart patient calm

- Valium (diazepam) can relieve psychic tension and anxiety that may burden the organically weak heart and interfere with the patient's course of rehabilitation.
- Valium works promptly in most patients. Significant improvement is usually noted during the first few days of therapy, although some patients may require more time to respond.
- Adjustments in dosage can alter clinical response. With appropriate titration, a regimen can be tailored to the patient's individual needs.
- Valium has a wide margin of safety in the usual oral dosage range and generally does not significantly affect respiration or pulse.

Valium® (diazepam)
2-mg, 5-mg, 10-mg tablets

Before prescribing, please consult complete product information, a summary of which follows:

Indications: Tension and anxiety states, somatic complaints which are concomitants of emotional factors; psychoneurotic states manifested by tension, anxiety, apprehension, fatigue, depressive symptoms or agitation; symptomatic relief of acute agitation, tremor, delirium tremens and hallucinosis due to acute alcohol withdrawal; adjunctively in skeletal muscle spasm due to reflex spasm to local pathology, spasticity caused by upper motor neuron disorders, athetosis, stiff-man syndrome, convulsive disorders (not for sole therapy).

Contraindicated: Known hypersensitivity to the drug. Children under 6 months of age. Acute narrow angle glaucoma; may be used in patients with open angle glaucoma who are receiving appropriate therapy.

Warnings: Not of value in psychotic patients. Caution against hazardous occupations requiring complete mental alertness. When used adjunctively in convulsive disorders, possibility of increase in frequency and/or severity of grand mal seizures may require increased dosage of standard anticonvulsant medication; abrupt withdrawal may be associated with temporary increase in frequency and/or severity of seizures. Advise against simultaneous ingestion of alcohol and other CNS depressants. Withdrawal symptoms (similar to those with barbiturates and alcohol) have occurred following abrupt discontinuance (convulsions, tremor, abdominal and muscle cramps, vomiting and sweating). Keep addiction-prone individuals under careful surveillance because of their predisposition to habituation and dependence. In pregnancy, lactation or women of childbearing age, weigh potential benefit against possible hazard.

Precautions: If combined with other psychotropics or anticonvulsants, consider carefully pharmacology of agents employed; drugs such as phenothiazines, narcotics, barbiturates, MAO inhibitors and other antidepressants may potentiate its action. Usual precautions indicated in patients severely depressed, or with latent depression, or with suicidal tendencies. Observe usual precautions in impaired renal or hepatic function. Limit dosage to smallest effective amount in elderly and debilitated to preclude ataxia or oversedation.

Side Effects: Drowsiness, confusion, diplopia, hypotension, changes in libido, nausea, fatigue, depression, dysarthria, jaundice, skin rash, ataxia, constipation, headache, incontinence, changes in salivation, slurred speech, tremor, vertigo, urinary retention, blurred vision. Paradoxical reactions such as acute hyperexcited states, anxiety, hallucinations, increased muscle spasticity, insomnia, rage, sleep disturbances, stimulation have been reported; should these occur, discontinue drug. Isolated reports of neutropenia, jaundice; periodic blood counts and liver function tests advisable during long-term therapy.

Dosage: Individualize for maximum beneficial effect. *Adults:* Tension, anxiety and psychoneurotic states, 2 to 10 mg b.i.d. to q.i.d.; alcoholism, 10 mg t.i.d. or q.i.d. in first 24 hours, then 5 mg t.i.d. or q.i.d. as needed; adjunctively in skeletal muscle spasm, 2 to 10 mg t.i.d. or q.i.d.; adjunctively in convulsive disorders, 2 to 10 mg b.i.d. to q.i.d. *Geriatric or debilitated patients:* 2 to 2½ mg, 1 or 2 times daily initially, increasing as needed and tolerated. (See Precautions.) *Children:* 1 to 2½ mg t.i.d. or q.i.d. initially, increasing as needed and tolerated (not for use under 6 months).

Supplied: Valium® (diazepam) Tablets, 2 mg, 5 mg and 10 mg; bottles of 100 and 500. All strengths also available in Tel-E-Dose® packages of 1000.

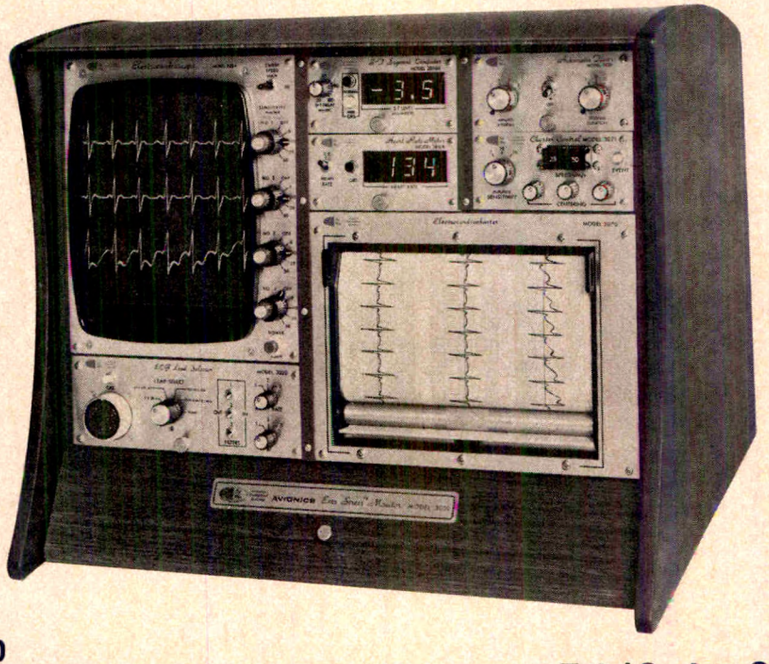
The "Ultimate" in exercise stress testing

Now, get more complete ECG data with this advanced *3-channel* monitoring system and its unique ST-segment computer



Model 3000 ExerStress™ ECG Monitor

- Large, 4-channel oscilloscope display
- 3-channel ECG recorder designed to AHA recommendations
- ST-segment computer/digital display
- Digital heart rate meter
- Automatic ECG writer programmer
- Full patient input isolation protection
- Standard 12-leads, Frank leads, and CM leads
- Outputs available for trend recording of heart rate and ST-segment
- Clean artifact-free traces

Total System Components

- Full line of finest quality treadmills
- Automatic blood pressure during stress test
- Graphic write-out of heart rate, ST-segment, and time
- Telemetry systems
- DC Defibrillators
- Accurate minute-by-minute update of O_2, CO_2, RQ, and volume data during stress test

For more information, return the coupon below.

Please send complete product information on the Model 3000 ☐, Avionics treadmills ☐, the other stress test components ☐,

CONTENTS

CLINICAL STUDIES

195 **Natural History of Severe Proximal Coronary Artery Disease as Documented by Coronary Cineangiography**

JOEL S. WEBSTER, CARL MOBERG and GUSTAVO RINCON

Average yearly mortality rates in 469 patients with 80 to 100 percent occlusive lesions in the proximal coronary tree diagnosed by selective angiography were 4 percent in patients with isolated disease of the left anterior descending artery and 2.3 percent in those with isolated disease of the right coronary artery. Patients with double and triple vessel disease had, respectively, 41.5 and 63 percent 6 year mortality rates. Survival appeared to be related to the number of vessels involved. Patients with severe cardiomegaly, heart failure or left ventricular dysfunction were excluded from the study.

201 **Unstable Angina—Prospective and Randomized Study of Its Evolution, With and Without Surgery. Preliminary Report.**

CARLOS A. BERTOLASI, JORGE E. TRONGÉ, CÉSAR A. CARRENO, JORGE JALON and MARCELO RUDA VEGA

Unstable angina includes three major categories: (1) intermediate syndrome, (2) progressive angina, and (3) postinfarction angina. In this prospective and randomized study of 142 patients with unstable angina, the natural history of the patients in each group differed. Patients with an intermediate syndrome treated surgically had a significantly reduced mortality and the survivors were clinically better than medically treated subjects.

209 **Right Ventricular Infarction. Clinical and Hemodynamic Features**

JAY N. COHN, NABIL H. GUIHA, MARTIN I. BRODER and CONSTANTINOS J. LIMAS

The diagnosis of right ventricular infarction should be considered in any patient with an acute diaphragmatic wall infarction and evidence of systemic venous engorgement. Six such patients with hemodynamic evidence of right ventricular failure disproportionate to left ventricular failure, an unusual finding in patients with acute myocardial infarction, are described. Shock in three patients was successfully treated by plasma volume expansion to increase right-sided pressure or by the administration of sodium nitroprusside to reduce left-sided filling pressure.

215 **Electrocardiographic and Serum Enzyme Changes of Myocardial Infarction After Coronary Artery Bypass Surgery**

MALCOLM R. ROSE, EPHRAIM GLASSMAN, O. WAYNE ISOM and FRANK C. SPENCER

Postoperative myocardial infarction (new Q waves) occurred in 10 percent of 50 patients after coronary artery bypass surgery, in 20 percent of 15 patients after aortic valve replacement, and in none of 12 patients after mitral valve surgery. Myocardial infarction after coronary artery bypass surgery is more likely in patients with at least three vessel disease, but appears to be unrelated to pump time or aortic cross-clamping. Serum enzyme values correlated well with electrocardiographic evidence of infarction.

To convert to normal sinus rhythm, and maintain...and maintain...and maintain...

CARDIOQUIN tablets

(quinidine polygalacturonate)

Low B.I.D. or T.I.D. dosage in most cases

Greater G.I. tolerance

Full quinidine cardiodynamics

***From case records on file with the Medical Department, The Purdue Frederick Company.**

BRIEF SUMMARY—INDICATIONS: CARDIOQUIN Tablets (quinidine polygalacturonate) are indicated in the treatment of: premature atrial and ventricular contractions; paroxysmal atrial tachycardia; paroxysmal AV junctional rhythm; atrial flutter; paroxysmal atrial fibrillation; established atrial fibrillation when therapy is appropriate; paroxysmal ventricular tachycardia when not associated with complete heartblock; maintenance therapy after electrical conversion of atrial fibrillation and/or flutter. CONTRAINDICATIONS: Aberrant impulses and abnormal rhythms due to escape mechanisms should not be treated with quinidine. WARNING: In the treatment of atrial flutter reversion to sinus rhythm may be preceded by a progressive reduction in the degree of AV block to a 1:1 ratio and resulting extremely rapid ventricular rate. COMPOSITION: Each CARDIOQUIN Tablet (quinidine polygalacturonate 275 mg.) is equivalent in quinidine content to 3 grains quinidine sulfate. DOSAGE AND ADMINISTRATION: Dosage must be adjusted to individual needs, both for conversion and maintenance. An initial dose of 1 to 3 tablets may be used to terminate arrhythmias, and may be repeated in 3-4 hours. If normal sinus rhythm is not restored after 3 or 4 equal doses, the dose may be increased by ½ to 1 tablet (137.5 to 275 mg.) and administered three to four times before any further dosage increase. For maintenance, one tablet may be used two to three times a day; generally one tablet morning and night will be adequate. SUPPLIED: Uncoated, scored tablets in bottles of 50.

221 New Q Waves After Coronary Artery Bypass Surgery for Angina Pectoris

JAIME ESPINOZA, JANET LIPSKI, ROBERT LITWAK, EPHRAIM DONOSO and SIMON DACK

Postoperative electrocardiograms in 44 patients with angina pectoris who underwent single or multiple coronary artery bypass procedures and, in 7 cases, additional surgery demonstrated new Q waves in 30 percent of the patients who underwent bypass procedures alone. The prevalence of new Q waves was greater in those who had two or three vessel disease demonstrated by coronary arteriography before operation and in those who had three coronary bypasses. The postoperative clinical course and mortality rates were not affected.

225 Correlation of Serum Magnesium Levels and Cardiac Digitalis Intoxication

GEORGE A. BELLER, WILLIAM B. HOOD, Jr., THOMAS W. SMITH, WALTER H. ABELMANN and WARREN E. C. WACKER

Hypomagnesemia occurred in 21 percent of patients with and 10 percent of those without digitalis toxicity. Hypermagnesemia was significantly greater in patients with digitalis toxicity (18 percent) than in those without toxicity (5 percent), probably the result of the greater prevalence of abnormal renal function in the former group. Further investigation of the value of giving magnesium to hypomagnesemic patients with digitalis toxicity is indicated.

230 Influence of Exercise on Arrhythmias Induced by Digitalis-Diuretic Therapy in Patients with Atrial Fibrillation

ALDEN S. GOOCH, GANGAIAH NATARAJAN and HARRY GOLDBERG

In 20 ambulatory patients with atrial fibrillation low-level treadmill exercise testing provided a simple method of provoking latent cardiac irritability in patients with suspected digitalis and diuretic toxicity. Arrhythmias suggesting digitalis toxicity were junctional tachycardia with or without exit block, frequent ventricular beats and bigeminy. Serial exercise testing after withdrawal of the drugs demonstrated devolution of the arrhythmias.

EXPERIMENTAL STUDIES

238 Effect of Procainamide on Fibrillation Threshold of Normal and Ischemic Ventricles

MYUNG S. YOON, JAOK HAN, BRIJ G. GOEL and PAULA CREAMER

In these dog experiments procainamide at therapeutic blood levels increased the mean fibrillation threshold 88 percent in normal ventricles and only 63 percent in dogs with acute coronary occlusion. Procainamide did not completely revert the decreased fibrillation threshold to normal values during acute myocardial ischemia, thus indicating that it is inferior to lidocaine in reducing the vulnerability of the ischemic myocardium to ventricular fibrillation.

243 Ventricular Defibrillation in the Dog Using Implanted and Partially Implanted Electrode Systems

JOHN C. SCHUDER, HARRY STOECKLE, JERRY H. GOLD, JOE A. WEST and JAMES A. HOLLAND

Ventricular defibrillation in large anesthetized dogs can be better achieved at any given percent success level with significantly less energy in systems involving a right atrium-superior vena cava electrode (catheter-internal disk or catheter-external disk systems).

Contents

248 **Accelerated Cardiac Escape Rhythms Caused by Ouabain Intoxication**

DOUGLAS P. ZIPES, EMANUEL ARBEL, RUSSEL F. KNOPE and GORDON K. MOE

Ectopic activity associated with early ouabain toxicity in anesthetized dogs appears to be caused by frequency-related transient depolarizations rather than "true" phase 4 depolarization or reentry.

254 **Predominant Right Ventricular Dysfunction After Right Ventricular Destruction in the Dog**

NABIL H. GUIHA, CONSTANTINOS J. LIMAS and JAY N. COHN

Damage of the right ventricle in dogs produces predominant right ventricular dysfunction but does not precipitate profound dysfunction with a low output state so long as intravascular volume is adequately expanded and pulmonary vascular resistance is not increased. An increase in cardiac output can be attained either by volume expansion or by reduction in left atrial pressure.

METHODS

259 **Complications of Percutaneous Femoral Arterial Catheterization. Prospective Evaluation with the Doppler Ultrasonic Velocity Detector**

ROBERT W. BARNES, JOHN L. PETERSEN, RICHARD B. KRUGMIRE, Jr. and D. EUGENE STRANDNESS, Jr.

The rate of complications was 14 percent in 160 percutaneous femoral arterial catheterizations in 142 adult patients at two hospitals. These complications included one accidental dissection of the iliac artery and 22 arterial thromboemboli. The location of thromboemboli was related to the duration of use of an indwelling arterial catheter. The use of a Doppler ultrasonic velocity detector before and after each procedure proved simple, rapid and effective for assessing limb hemodynamics.

264 **New Instrument for Transvenous Cardiac Biopsy**

PHILIP K. CAVES, WERNER P. SCHULZ, EUGENE DONG, Jr., EDWARD B. STINSON and NORMAN E. SHUMWAY

With newly developed forceps serial percutaneous transvenous endomyocardial biopsies have been routinely performed in new heart transplant recipients and in patients with primary cardiomyopathy. One hundred and sixty-three biopsy specimens have been obtained from 19 transplanted human hearts during 85 biopsy procedures.

PROGRESS REPORTS

271 Principles and Pitfalls in Establishing Normal Electrocardiographic Limits

ERNST SIMONSON

Three main prerequisites for establishing valid normal electrocardiographic limits include (1) adequate sample size, (2) a sample representative of the average healthy population, and (3) adequate statistical evaluation. Many studies of normal electrocardiographic values fall short of these standards, particularly that for adequate sample size.

DIAGNOSTIC SHELF

277 Echocardiographic Manifestations of Discrete Subaortic Stenosis

RICHARD H. DAVIS, HARVEY FEIGENBAUM, SONIA CHANG, LEE L. KONECKE and JAMES C. DILLON

Echocardiographic patterns suggestive, if not specific, for discrete membranous subaortic stenosis as found in three verified cases include: early systolic closure of aortic valve, persistent valve closure throughout the remainder of systole, coarse fluttering of the leaflets, and absence of asymmetric septal hypertrophy.

281 Echocardiographic Diagnosis of Left Atrial Myxoma

ENRIQUE C. MARTINEZ, THOMAS D. GILES and GEORGE E. BURCH

Echocardiography easily led to the correct diagnosis and ruled out mitral stenosis in a patient in whom cardiac catheterization missed the presence of left atrial myxoma. The motion of the tumor produces a characteristic wavy appearance of interrupted echo traces representing echoes from the tumor mass. The echocardiogram is extremely useful in diagnosing obstructive lesions of the mitral valve orifice.

286 Delayed Systolic Peak of the Femoral Pulse from Kinking of the Aortic Arch

KYUHYUN WANG, DONALD HARRINGTON and FREDARICK L. GOBEL

Indirect pulse tracings taken simultaneously from the femoral and the right radial arteries revealed a delayed femoral pulse due to a longer systolic build-up time in the femoral artery than in the radial artery. This finding led to the diagnosis of kinking of the aortic arch in an asymptomatic 38 year old man.

CASE REPORTS

291 Demonstration of Dual Atrioventricular Nodal Pathways in Man

KENNETH M. ROSEN, ASHWIN MEHTA and ROBERT A. MILLER

The demonstration of two ranges of A–H intervals as well as dual atrioventricular nodal effective and functional refractory periods in a child after repair of a ventricular septal defect provides supporting evidence for the presence of dual atrioventricular nodal pathways.

Continued on page A-19

The patient with cardiac arrhythmia may need medication most when he's least likely to take it...

while he's sleeping.

Quinaglute® Dura-Tabs® (quinidine gluconate) "a pharmacologic pacemaker":

- produces sustained serum quinidine levels, thus providing a convenient 8 or 12 hour dosage schedule
- usually insures uninterrupted therapeutic quinidine gluconate levels during sleep
- avoids peaks and valleys in plasma levels during which time the arrhythmias may recur
- maintains normal sinus rhythm following conversion by other techniques
- well tolerated to enhance patient cooperation — few G.I. disturbances

Contraindications: Quinaglute Dura-Tabs are contraindicated in patients with partial A-V or complete heart block, or intraventricular conduction defects, especially those exhibiting a marked grade of QRS widening; in patients manifesting idiosyncrasy or sensitivity to quinidine (e.g. febrile reactions, skin eruptions, thrombocytopenia, etc.), in patients with renal disease resulting in significant azotemia, or those developing cardiotoxic effects such as conduction defects; ventricular premature beats, ventricular tachycardia or flutter while on the drug. It may be contraindicated in certain patients who have marked cardiac enlargement, particularly with congestive failure, poor renal function, and especially renal tubular acidosis.

Precautions: The precautions to be observed include all those applicable to quinidine. A preliminary test dose of a single tablet of quinidine sulfate should be administered to determine if the patient has an idiosyncrasy to quinidine. Hypersensitivity to quinidine, although rare, should constantly be considered; especially during the first weeks of therapy.

Signs of idiosyncrasy include febrile reactions, skin eruptions, thrombocytopenic purpura, and respiratory embarrassment. Extreme caution should be exercised in using the drug in patients with severe heart disease and congestive heart failure, with digitalis intoxication, or renal insufficiency. It should be administered cautiously, if at all, to senile patients. Hospitalization for close clinical observations, electrocardiographic monitoring, and possibly plasma quinidine levels, is indicated when large doses are used, or with patients who present an increased risk.

As with all quinidine preparations, the titrating of the exact quinidine dosage will vary with each individual patient. With the dosage regimen of 2 tablets every 8 hours, higher blood levels than necessary for maintenance of normal sinus rhythm could be reached, whereas with 1 tablet every 12 hours, the blood levels may be too low to maintain normal sinus rhythm.

As with other quinidine products, Quinaglute Dura-Tabs should not be used during pregnancy.

Adverse Reactions: The patient should be advised to report immediately to the physician any symptoms of cinchonism (including tinnitus, decreased auditory acuity, vertigo, blurred vision, color perception disturbances, photophobia, diplopia, night blindness, scotomata, reduced visual fields, mydriasis and respiratory distress).

Where such symptoms develop, or if evidence of hypotension appears, the drug should be discontinued. Gastrointestinal disturbances have only rarely been reported. If they occur, they may be minimized by administering the drug with food. If they persist, dosage should be decreased.

Dosage: For the prevention of premature atrial, nodal or ventricular contractions, the dose usually ranges from 1 to 2 tablets every 8 or 12 hours.

Before prescribing or administering, please refer to QUINAGLUTE full product information.

295 **Pacemaker-Induced Cardiovascular Failure. Hemodynamic and Angiographic Observations**

JOHN M. HAAS and GAIL B. STRAIT

Severe acúte mitral regurgitation with decreased effective stroke volume and cardiac output as a result of loss of atrial contribution to ventricular filling and stroke volume were documented in a 71 year old woman after implantation of a permanent transvenous right ventricular pacemaker. These detrimental effects necessitated removal of the pacemaker.

300 **Double Opening Sound Related to Dysfunction in a Caged Disc Mitral Valve Prosthesis**

EARL C. HARRISON, E. JOHN ROSCHKE, MASAYOSHI MATSUNO and JOHN W. ALLEN

This case report illustrates the value of phonocardiography in detecting the dysfunction of mitral caged disc prostheses. An extra opening click present before embolization disappeared coincidentally with the occlusion of the left femoral artery by a grooved embolic fragment presumed to arise from the Kay-Shiley caged disc mitral valve prosthesis.

304 **Multiple Coronary Arteriosystemic Fistulas**

KOTA REDDY, MOHINDER GUPTA and ROBERT I. HAMBY

In a 58 year old man with angina pectoris and no heart murmur, selective coronary angiography disclosed multiple coronary arteriosystemic fistulas involving all three major coronary arteries which communicated through Thebesian vessels with the left ventricle. The normal pulse pressure and absence of left ventricular hypertrophy suggest that there was no hemodynamically significant volume overload on the left ventricle.

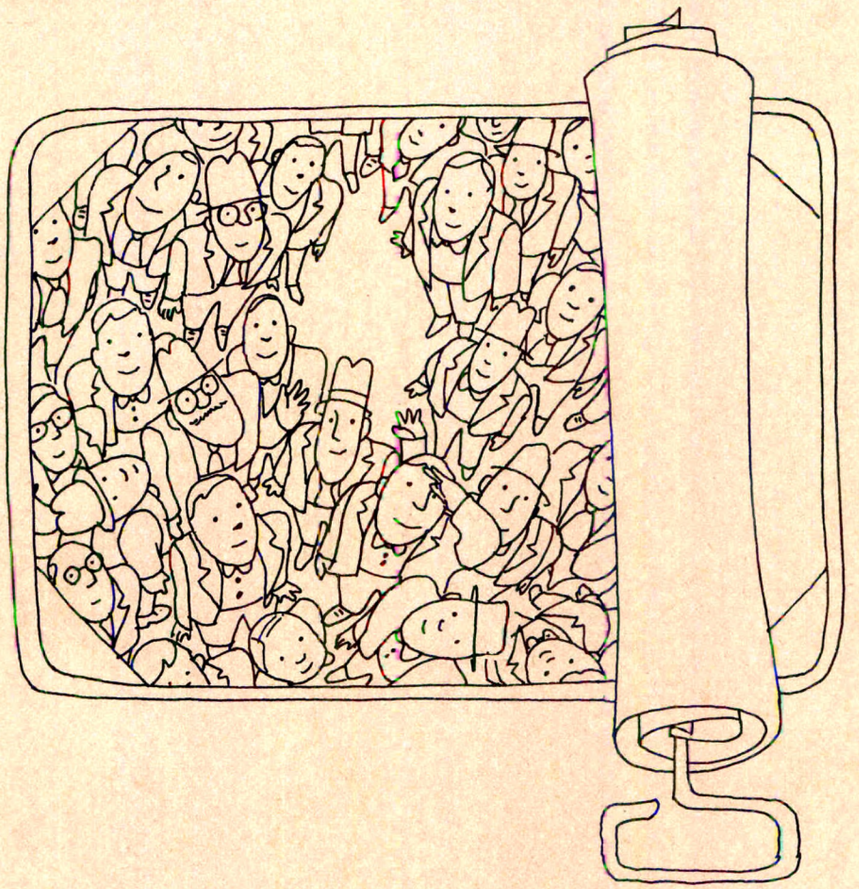
The sardine syndrome:



The cure:

You can see lots of look-alike work-alike patient monitoring systems, these days.

You can also see a system that's different because it's made by a different kind of company:

B-D Electrodyne.

B-D Electrodyne *pioneered* the patient monitoring system. Like the fellow says, we know the territory.

B-D Electrodyne has a fully staffed Quality Control Department and a full time Director of Safety, Efficacy and Reliability. Their job? To represent you, by fine-tooth-combing our equipment. If they say it doesn't ship . . . it doesn't ship.

We also have field offices. Each is staffed with factory-trained monitoring system service men. Each is fully equipped with repair shop, inventory of spare parts and units, around-the-clock answering service.

B-D Electrodyne. We're not like all the others. You'll like that. Why not let us tell you more? B-D ELECTRODYNE, Division of Becton, Dickinson and Company, Sharon, Mass. 02067. (617) 828-9080.

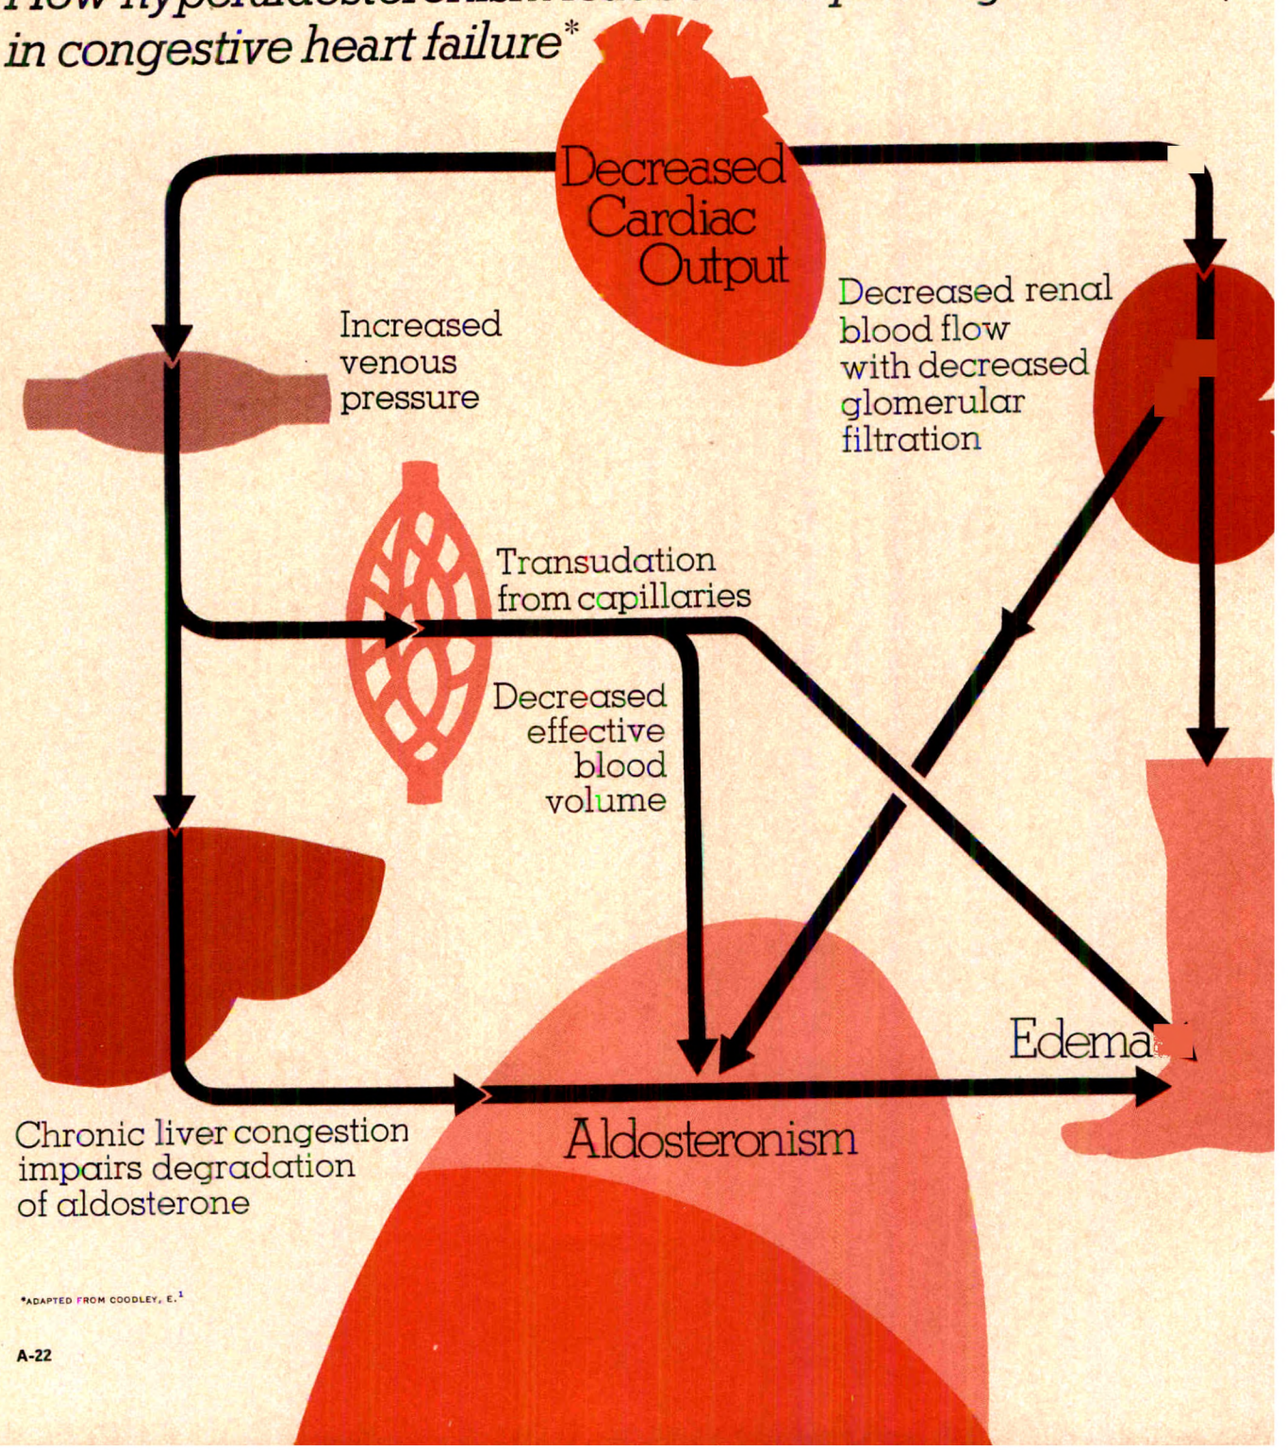
B-D AND ELECTRODYNE ARE TRADEMARKS OF BECTON, DICKINSON AND COMPANY.

In congestive heart failure...

secondary aldosteronism

*How hyperaldosteronism leads to and prolongs edema in congestive heart failure**



*ADAPTED FROM COODLEY, E.[1]

is a primary factor

To "switch off" the aldosterone factor in congestive heart failure

Aldactone®

brand of

spironolactone 25-mg. tablets

the only specific aldosterone antagonist... basic in all diuretic therapy

Three ways to use Aldactone in congestive heart failure

1. As the only diuretic

- Often sufficient alone.
- Produces gradual, sustained diuresis by blocking aldosterone action in the distal renal tubule.
- Avoids potassium loss.

2. As the basic daily diuretic with an "add-on" alternate-day-diuretic ("A.D.D." schedule)

- Can be administered daily as basic therapy with the additional agent (furosemide or ethacrynic acid) given every second or third day.
- Aldactone plus "A.D.D." schedule minimizes potassium deficiency and potentiates effect of "add-on" diuretic.[2]
- Avoids acute volume depletion and aldosterone rebound.[2]

3. As a daily diuretic in combination with a daily dose of a thiazide

- Permits daily additive diuretic effect while maintaining potassium balance.

Indications—Essential hypertension; edema or ascites of congestive heart failure, cirrhosis of the liver and the nephrotic syndrome; idiopathic edema. Some patients with malignant effusions may benefit from Aldactone (spironolactone), particularly when given with a thiazide diuretic.

Contraindications—Acute renal insufficiency, rapidly progressing impairment of renal function, anuria and hyperkalemia.

Warnings—Potassium supplementation may cause hyperkalemia and is not indicated unless a glucocorticoid is also given. Discontinue potassium supplementation if hyperkalemia develops. **Usage of any drug in women of childbearing age requires that the potential benefits of the drug be weighed against its possible hazards to the mother and fetus.**

Precautions—Patients should be checked carefully since electrolyte imbalance may occur. Although usually insignificant, hyperkalemia may be serious when renal impairment exists; deaths have occurred. Hyponatremia, manifested by dryness of the mouth, thirst, lethargy and drowsiness, together with a low serum sodium may be caused or aggravated, especially when Aldactone is combined with other diuretics. Elevation of BUN may occur, especially when pretreatment hyperazotemia exists. Mild acidosis may occur. Reduce the dosage of other antihypertensive drugs, particularly the ganglionic blocking agents, by at least 50 percent when adding Aldactone since it may potentiate their action.

Adverse Reactions—Drowsiness, lethargy, headache, diarrhea and other gastrointestinal symptoms, maculopapular or erythematous cutaneous eruptions, urticaria, mental confusion, drug fever, ataxia, gynecomastia, inability to achieve or maintain erection, mild androgenic effects, including hirsutism, irregular menses and deepening voice. Adverse reactions are infrequent and usually reversible.

Dosage and Administration—For **essential hypertension** in **adults** the daily dosage is 50 to 100 mg. in divided doses. Aldactone may be combined with a thiazide diuretic if necessary. Continue treatment for two weeks or longer since an adequate response may not occur sooner. Adjust subsequent dosage according to response of patient.

For edema, ascites or **effusions** in **adults** initial daily dosage is 100 mg. in divided doses. Continue medication for at least five days to determine diuretic response; add a thiazide or organic mercurial if adequate diuretic response has not occurred. Aldactone dosage should not be changed when other therapy is added. A daily dosage of Aldactone considerably greater than 75 mg. may be given if necessary.

A glucocorticoid, such as 15 to 20 mg. of prednisone daily, may be desirable for patients with extremely resistant edema which does not respond adequately to Aldactone and a conventional diuretic. Observe the usual precautions applicable to glucocorticoid therapy; supplemental potassium will usually be necessary. Such patients frequently have an associated hyponatremia—restriction of fluid intake to 1 liter per day or administration of mannitol or urea may be necessary (these measures are contraindicated in patients with uremia or severely impaired renal function). Mannitol is contraindicated in patients with congestive heart failure, and urea is contraindicated with a history or signs of hepatic coma unless the patient is receiving antibiotics orally to "sterilize" the gastrointestinal tract.

Glucocorticoids should probably be given first to patients with nephrosis since Aldactone, although useful for diuresis, will not directly affect the basic pathologic process.

For **children** the daily dosage should provide 1.5 mg. of Aldactone per pound of body weight.

Vitatron Medical add 50 % to pacemaker longevity

A specially designed new battery now considerably increases the reliability of Vitatron Medical's completely analysable pacemakers by giving them 50% more longevity. Development of this HgO-Zn energizer was a joint-venture of Vitatron Medical and one of the world's leading battery manufacturers.
Battery failure rate is no more than 0.05%/1000h.

Other important features contributing to the longevity and reliability of Vitatron Medical's new generation of fully analysable pacemakers are

- small dimensions and light weight
- easy connection
- interference protection
- no loss of battery charge on stock
- complete program of permanent stimulation electrodes with the unique intracardial electrode MIP 2000 provided with heartwall fixation facilities
- TRIPLEXTERN multimode external pacemaker
- completely automized analyzer for pacemakers in action.

The Four Horsemen of Stroke...

HYPERTENSION

HEART DISEASE

DIABETES

ELEVATED CHOLESTEROL

You have your own therapeutic regimen to reduce these risk factors—the "Big Four" accelerators of stroke.

...and TIA's-the Prophetic Fifth Horseman

Transient Ischemic Attacks (TIA's) are another signal of impending stroke that is particularly ominous. In fact, 33% of patients with TIA's will develop a severe neurological deficit within 5 years.*

For such patients, PAVABID® (papaverine HCl) vasodilatation helps to preserve cerebral circulation. By reducing arterial tone, Pavabid therapy helps block vasospasm that can result in neurological damage.

*Meyer, J. S., and Gilroy, J.: *Medical Neurology*

PAVABID®
(papaverine HCl, 150 mg.) Plateau CAPS®

Pavabid® Plateau CAPS® (Papaverine HCl, 150 mg.)—Each capsule contains papaverine hydrochloride, 150 mg. in a special base for prolonged therapeutic effect. *Indications:* ischemia associated with arterial spasm and myocardial ischemia complicated by arrhythmias. *Dosage:* One capsule every 12 hours. In difficult cases, administration may be increased to one capsule every 8 hours, or two capsules every 12 hours. *Precaution:* Use with caution in patients with glaucoma. Hepatic hypersensitivity has been reported with gastrointestinal symptoms, jaundice, eosinophilia and altered liver function tests. Discontinue medication if these occur. *Side effects:* Infrequently reported side effects of papaverine include nausea, abdominal distress, anorexia, constipation, malaise, drowsiness, vertigo, sweating and headache, diarrhea and skin rash.

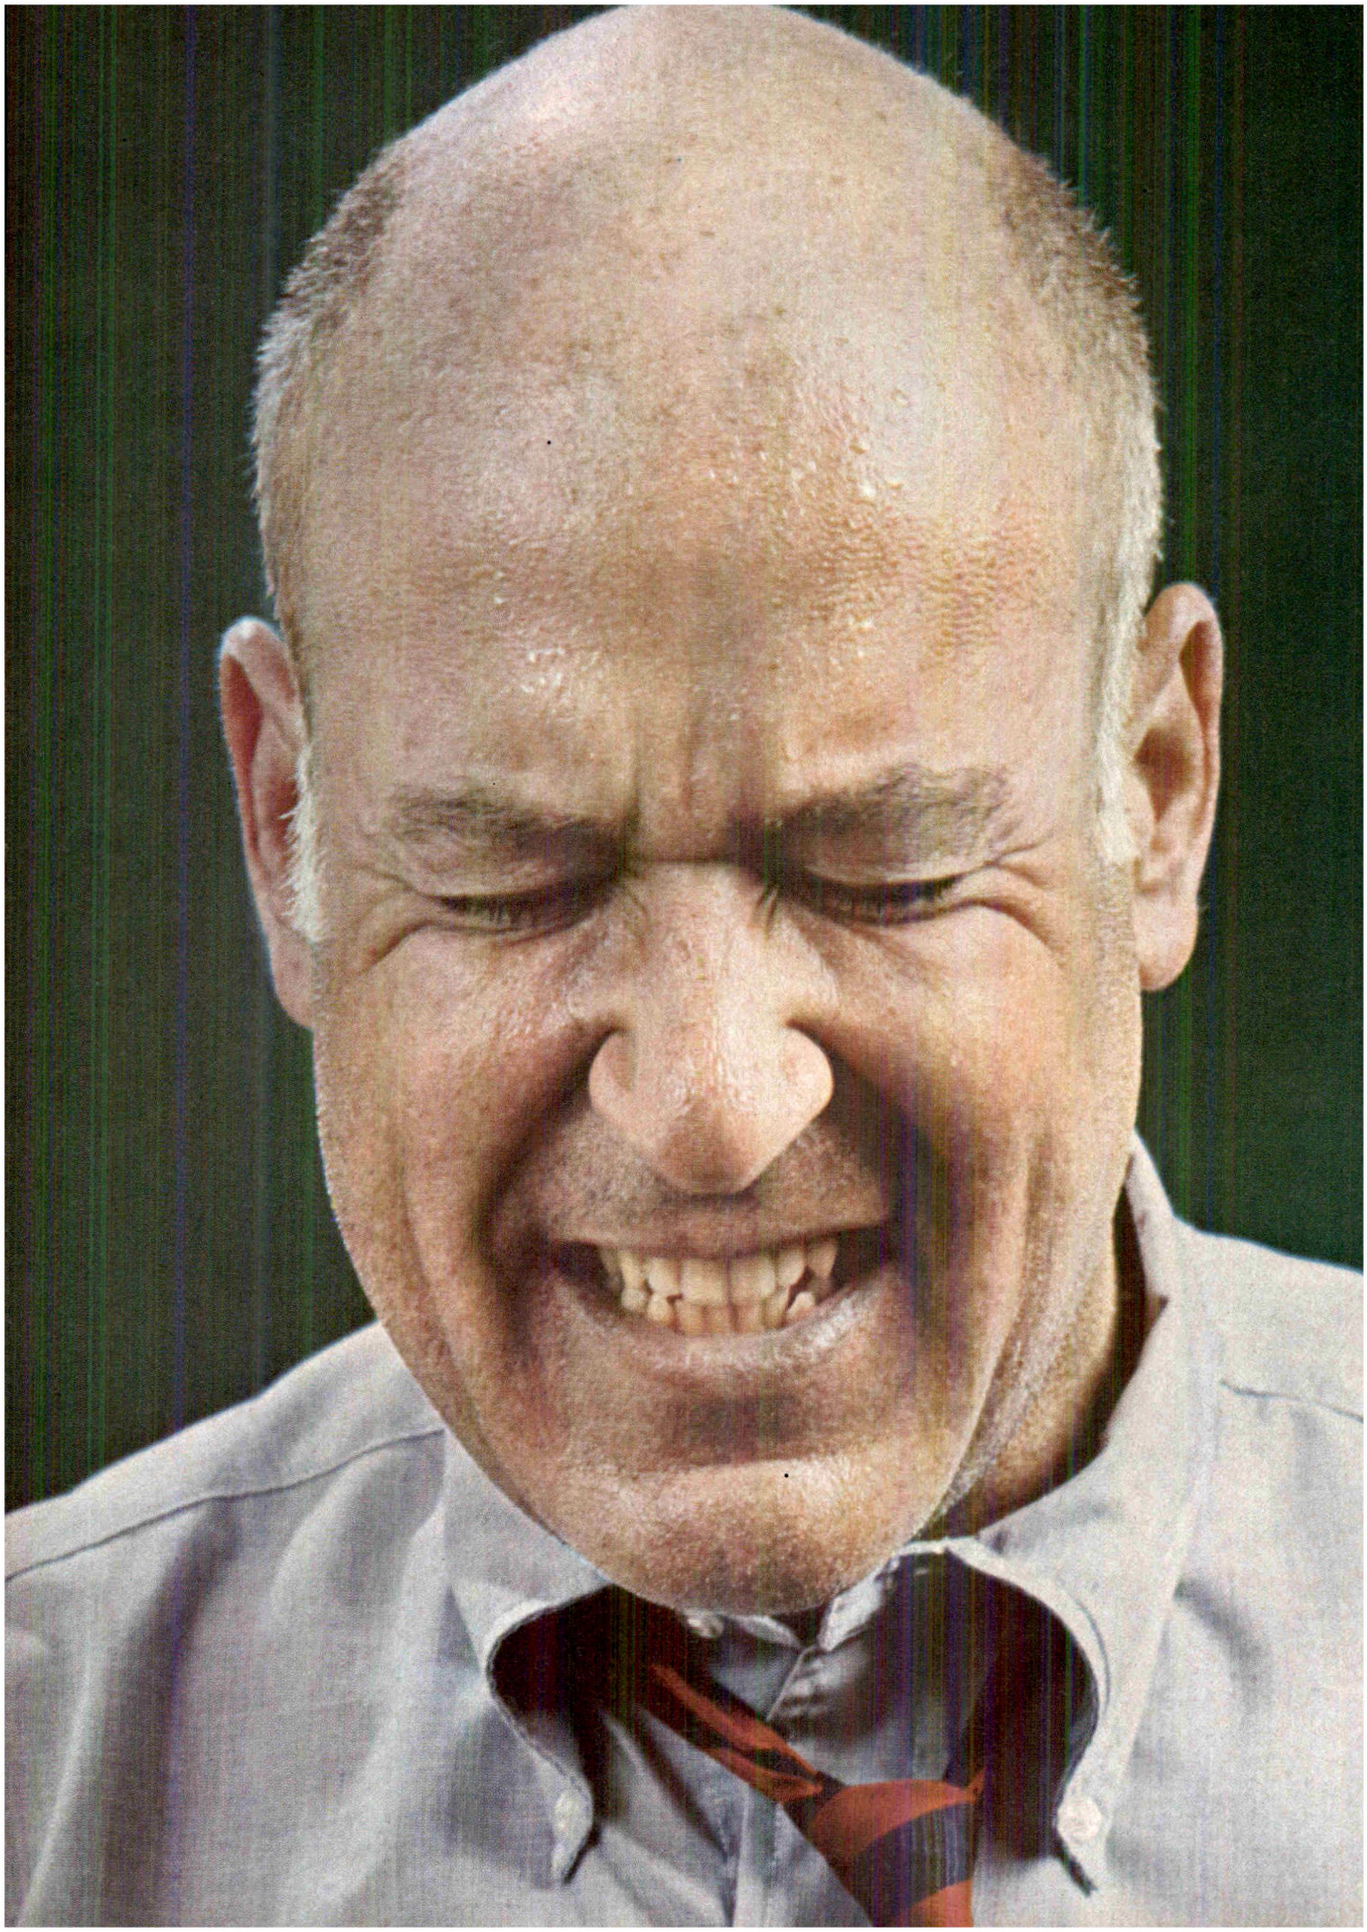
PHARMACEUTICAL DIVISION
MARION



A new approach in the management of angina pectoris...

Inderal®

Brand of

propranolol hydrochloride

For patients unresponsive to conventional measures

When conventional methods such as weight control, rest, cessation of smoking, use of sublingual nitroglycerin, and avoidance of precipitating circumstances prove to be inadequate, a new mechanism for the management of moderate to severe angina pectoris is provided by INDERAL—the first beta-adrenergic blocking agent in clinical cardiologic use. INDERAL should not be used in patients with angina which occurs only with considerable effort or with precipitating factors that occur infrequently.

Distinctive mode of action: works to decrease myocardial oxygen demand, prevent oxygen deficit in responsive patients

When physical or psychological stress increases beta-adrenergic stimulation of the heart, oxygen demand may exceed capacity for oxygen delivery in a coronary circulation compromised by atherosclerosis. The result is anginal pain.

INDERAL—through its beta-adrenergic blocking action—provides a unique approach. By specifically competing with catecholamines for available myocardial beta-receptor sites, INDERAL can reduce sympathetically induced increases in heart rate, systolic blood pressure and velocity of contraction during exercise or stress—and thus decrease the oxygen requirements of the heart. On the other hand, propranolol may increase oxygen requirements by increasing left ventricular fiber length, end diastolic pressure, and systolic ejection period.

If the net physiologic effect of beta-adrenergic blockade in angina is advantageous, it would be expected to manifest itself during exercise by delayed onset of pain due to the decreased oxygen requirement.

USE OF INDERAL®/ANGINA PECTORIS CONTINUED ON NEXT PAGE

(See last two pages of advertisement for prescribing information.)

Inderal®
(propranolol hydrochloride)
for moderate to severe angina pectoris

Wide clinical experience

The use of INDERAL (propranolol hydrochloride) in angina pectoris has been the subject of numerous published papers, including 33 on controlled clinical trials (28 double-blind) involving 746 patients,[1-33] and 27 on other studies covering 774 patients. The results of these studies support INDERAL's usefulness in reducing incidence of pain and increasing exercise tolerance in patients with angina pectoris. Proof of effectiveness has been demonstrated both *clinically* and by *objective laboratory measurements*.[1-29,31-33]

Decrease in frequency of anginal attacks and reduced need for nitroglycerin shown in controlled clinical studies

Thirty of the above papers reported on the effect of INDERAL on incidence of anginal pain and consumption of nitroglycerin. INDERAL was found to be effective in reducing the incidence of anginal pain and the consumption of nitroglycerin in 29 of these 30 controlled clinical trials.[1-29] Of the 29 studies reporting effectiveness with INDERAL, results were deemed statistically significant in 19,[1-19] not statistically significant in 2,[20,21] and the statistical significance was not given in 8 studies.[22-29] One study[30] reported that propranolol was not effective.

In 24† of these clinical studies, it was possible to determine the proportion of patients responding to treatment. The results showed that approximately three-quarters of the patients had less pain and used less nitroglycerin when taking INDERAL than on placebo.

Improvement in exercise tolerance demonstrated by objective laboratory measurements

Seventeen of the controlled trials dealt with the effect of oral INDERAL on exercise tolerance. Of these, INDERAL was found to be effective in 14,[2,8,10,12,13,15,16,18,22,23,25,27,28,32] and not effective in three.[3,29,30] Of the fourteen studies reporting effectiveness with INDERAL, the improvement was statistically significant in eight,[2,8,10,12,15,16,18,32] and significance was not given in six.[13,22,23,25,27,28]

For example in a double-blind study, the effect of INDERAL (propranolol hydrochloride) on exercise tolerance was examined by Gianelly and associates. In a double-blind crossover study of 19 patients, the effects of INDERAL on exercise tolerance were assessed and correlated with cardiovascular physiologic effects.[8] Nineteen patients (18 male and 1 female) with a typical history of angina and a positive Master test, ranging in age from 38 to 65 years, received for 4 weeks either placebo or 160 mg. INDERAL daily in 4 divided doses. During the study, exercise tolerance was assessed using a treadmill which was adjusted for speed and incline so that each patient would experience chest pain within one to five minutes. Measurements were made at the end point of each test (pain, fatigue, or dyspnea). From this study and a subsequent study,[31] the investigators concluded that in responsive patients INDERAL, by reducing cardiac work, tends to bring into balance myocardial oxygen supply and need, and increases exercise tolerance.

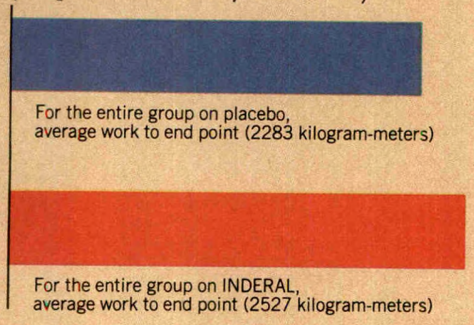
Side effects, including bradycardia, nocturnal dyspnea, mildly blurred vision, diarrhea and postural hypotension, occurred in 5 patients, but did not require permanent discontinuation of the drug.

†1-9, 11-15, 17, 18, 20-24, 26, 27, 30

With 160 mg. INDERAL (propranolol hydrochloride) daily—increase in exercise tolerance with treadmill test (kilogram-meters)

160 mg. INDERAL daily increased exercise tolerance by 22% in 14 of 18 patients who completed exercise to an end point of pain, fatigue or dyspnea. For the total group, the average increase in exercise tolerance on INDERAL 160 mg. daily was 11%. Incomplete data on one patient reduced the number to 18 for this aspect of the study.

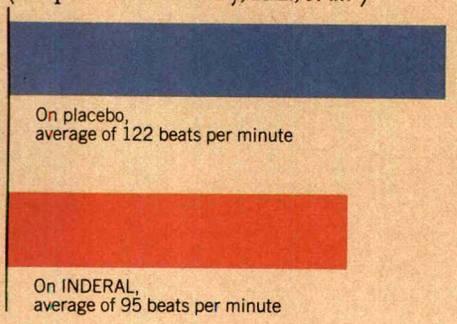
(Adapted from Gianelly, R.E., *et al.*[8])



With 160 mg. INDERAL daily—reduction of heart rate on exercise

160 mg. INDERAL daily reduced heart rate in all 19 subjects at end point of standard exercise procedure.

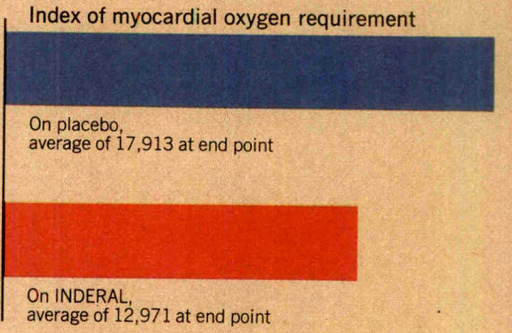
(Adapted from Gianelly, R.E., *et al.*[8])



With 160 mg. INDERAL (propranolol hydrochloride) daily—reduction of myocardial oxygen requirement on exercise (by the treadmill test)

Index of myocardial oxygen requirement at end of exercise, as measured by the product of systolic blood pressure and heart rate, "was consistently reduced by propranolol..." in 19 patients taking 160 mg. INDERAL daily.

(Adapted from Gianelly, R.E., *et al.*[8])



It is important that the dosage be titrated and individualized for maximum effect

Starting with 10-20 mg. 3 or 4 times daily, before meals and at bedtime, dosage should be gradually increased at three to seven day intervals until optimum response is obtained. Although individual patients may respond at any dosage level, the average optimum dosage appears to be 160 mg. per day. Higher doses may be required; however, the value and safety of dosage exceeding 320 mg. per day have not been established.

If treatment is to be discontinued, it is recommended that withdrawal be gradual over a two-week period. (See PRECAUTIONS.)

Special caution should be observed in patients with heart block or a history of congestive heart failure. (See CONTRAINDICATIONS AND WARNINGS.)

Good medical practice dictates that INDERAL should not be continued unless there is reduced pain or increased work capacity. Treatment should be carefully monitored.

INDERAL will not interfere with the cardiac action of sublingual nitroglycerin, or cardiotonic agents such as digitalis.

BRIEF SUMMARY

(For full prescribing information, see package circular.)

Inderal®

Brand of

propranolol hydrochloride

A beta-adrenergic blocking agent

BEFORE USING INDERAL (PROPRANOLOL HYDROCHLORIDE), THE PHYSICIAN SHOULD BE THOROUGHLY FAMILIAR WITH THE BASIC CONCEPT OF ADRENERGIC RECEPTORS (ALPHA AND BETA), AND THE PHARMACOLOGY OF THIS DRUG.

ACTIONS: INDERAL is a beta-adrenergic receptor blocking drug, possessing no other autonomic nervous system activity. It specifically competes with beta-adrenergic receptor stimulating agents for available beta receptor sites. When access to beta receptor sites is blocked by INDERAL (propranolol hydrochloride), the chronotropic, inotropic, and vasodilator responses to beta-adrenergic stimulation are decreased proportionately.

In dosages greater than required for beta blockade, INDERAL also exerts a quinidine-like or anesthetic-like membrane action which affects the cardiac action potential and depresses cardiac function.

Propranolol is almost completely absorbed from the gastrointestinal tract, but a portion is immediately bound by the liver. Peak effect occurs in one to one and one-half hours. The biologic half-life is approximately two to three hours. There is no simple correlation between dose or plasma level and therapeutic effect, and the dose-sensitivity range as observed in clinical practice is wide. The principal reason for this is that sympathetic tone varies widely between individuals. Since there is no reliable test to estimate sympathetic tone or to determine whether total beta blockade has been achieved, proper dosage requires titration.

Beta receptor blockade is useful in conditions in which, because of pathologic or functional changes, sympathetic activity is excessive or inappropriate and detrimental to the patient. But there are also situations in which sympathetic stimulation is vital. For example, in patients with severely damaged hearts, adequate ventricular function is maintained by virtue of sympathetic drive which should be preserved. In the presence of AV block, beta blockade may prevent the necessary facilitating effect of sympathetic activity on conduction. Beta blockade results in bronchial constriction by interfering with adrenergic bronchodilator activity which should be preserved in patients subject to bronchospasm.

The proper objective of beta blockade therapy is to decrease adverse sympathetic stimulation but not to the degree that may impair necessary sympathetic support or vital functional balances.

Propranolol exerts its antiarrhythmic effects in concentrations associated with beta-adrenergic blockade and this appears to be its principal antiarrhythmic mechanism of action. The membrane effect also plays a role, particularly, some authorities believe, in digitalis-induced arrhythmias. Beta-adrenergic blockade is of unique importance in the management of arrhythmias due to increased levels of circulating catecholamines or enhanced sensitivity of the heart to catecholamines (arrhythmias

associated with pheochromocytoma, thyrotoxicosis, exercise).

Propranolol may reduce the oxygen requirement of the heart at any given level of effort by blocking catecholamine-induced increases in heart rate, systolic blood pressure, and the velocity and extent of myocardial contraction. On the other hand, propranolol may increase oxygen requirements by increasing left ventricular fiber length, end-diastolic pressure, and systolic ejection period.

If the net physiologic effect of beta-adrenergic blockade in angina is advantageous, it would be expected to manifest itself during exercise by delayed onset of pain due to decreased oxygen requirement.

INDICATIONS: *Angina Pectoris Due to Coronary Atherosclerosis.* The initial treatment of angina pectoris involves weight control, rest, cessation of smoking, use of sublingual nitroglycerin, and avoidance of precipitating circumstances. INDERAL (propranolol hydrochloride) is indicated in selected patients with moderate to severe angina pectoris who have not responded to these conventional measures. Propranolol should not be used in patients with angina which occurs only with considerable effort or with infrequent precipitating factors.

INDERAL exerts both favorable and unfavorable effects, the preponderance of which may be beneficial. (See ACTIONS Section.) INDERAL should not be continued unless there is reduced pain or increased work capacity.

Because of the potential for adverse results, treatment should be carefully monitored. The patient should also be reevaluated periodically since the dosage requirement and the need to continue INDERAL may be altered by clinical exacerbations or remissions. (See DOSAGE AND ADMINISTRATION.)

Additional studies of the effects of INDERAL in angina pectoris patients are in progress to better evaluate and define the proper role of INDERAL in this condition.

CONTRAINDICATIONS: INDERAL is contraindicated in: 1) bronchial asthma; 2) allergic rhinitis during the pollen season; 3) sinus bradycardia and greater than first degree block; 4) cardiogenic shock; 5) right ventricular failure secondary to pulmonary hypertension; 6) congestive heart failure (see WARNINGS) unless the failure is secondary to a tachyarrhythmia treatable with INDERAL; 7) in patients on adrenergic-augmenting psychotropic drugs (including MAO inhibitors), and during the two week withdrawal period from such drugs.

WARNINGS: CARDIAC FAILURE: Sympathetic stimulation is a vital component supporting circulatory function in congestive heart failure, and inhibition with beta-blockade always carries the potential hazard of further depressing myocardial contractility and precipitating cardiac failure. INDERAL acts selectively without abolishing the inotropic action of digitalis on the heart muscle (*i.e.* that of supporting the strength of myocardial contractions). However, the inotropic action of digitalis may be reduced by INDERAL's opposite inotropic effect. The effect of INDERAL and digitalis are additive in depressing AV conduction.

IN PATIENTS WITHOUT A HISTORY OF CARDIAC FAILURE, continued depression of the myocardium over a period of time can, in some cases, lead to cardiac failure. In rare instances, this has been observed during INDERAL therapy. Therefore, at the first sign or symptom of impending cardiac failure, patients should be fully digitalized, and the response observed closely: (a) if cardiac failure continues, INDERAL therapy must be immediately withdrawn; (b) if tachyarrhythmia is being controlled, patients should be maintained on combined dosage and the patient closely followed until threat of cardiac failure is over.

IN PATIENTS WITH THYROTOXICOSIS, possible deleterious effects from long term use have not been adequately appraised. Special consideration should be given to propranolol's potential for aggravating congestive heart failure. Propranolol may mask the clinical signs of continuing hyperthyroidism or complications and give a false impression of improvement. Propranolol does not distort thyroid function tests.

IN PATIENTS WITH WOLFF-PARKINSON-WHITE SYNDROME, several cases have been reported in which, after propranolol, the tachycardia was replaced by a severe bradycardia requiring a demand pacemaker. In one case this resulted after an initial dose of 5 mg. propranolol.

IN PATIENTS DURING ANESTHESIA with agents that require catecholamine release for maintenance of adequate cardiac function, beta blockade will impair the desired inotropic effect. Therefore, INDERAL (propranolol hydrochloride) should be titrated carefully when administered for arrhythmias occurring during anesthesia.

IN PATIENTS UNDERGOING MAJOR SURGERY, beta blockade impairs the ability of the heart to respond to reflex stimuli. For this reason, with the exception of pheochromocytoma, INDERAL should be withdrawn 48 hours prior to surgery, at which time all chemical and physiologic effects are gone according to available evidence. However, in case of emergency surgery, since INDERAL is a competitive inhibitor of beta receptor agonists, its effects can be reversed by administration of such agents, *e.g.* isoproterenol or levarterenol. However, such patients may be subject to protracted severe hypotension. Difficulty in restarting and maintaining the heart beat has also been reported.

IN PATIENTS PRONE TO NONALLERGIC BRONCHOSPASM (*e.g.* CHRONIC BRONCHITIS, EMPHYSEMA), INDERAL should be administered with caution since it may block bronchodilation produced by endogenous and exogenous catecholamine stimulation of beta receptors.

DIABETICS AND PATIENTS SUBJECT TO HYPOGLYCEMIA: Because of its beta-adrenergic blocking activity, INDERAL may prevent the appearance of premonitory signs and symptoms (pulse rate and pressure changes) of acute hypoglycemia. Especially important with labile diabetics.

USE IN PREGNANCY: The safe use of INDERAL in human pregnancy has not been established. Use of any drug in pregnancy or women of childbearing potential requires that the possible risk to mother and/or fetus be weighed against the expected therapeutic benefit.

PRECAUTIONS: Patients receiving catecholamine depleting drugs such as reserpine should be closely observed if INDERAL is administered. The added catecholamine blocking action of this drug may then produce an excessive reduction of the resting sympathetic nervous activity. Occasionally, the pharmacologic activity of INDERAL may produce hypotension and/or marked bradycardia resulting in vertigo, syncopal attacks, or orthostatic hypotension.

In chronically treated patients, dosage should be gradually reduced over a two week period when it is anticipated that the administration of INDERAL will be discontinued. There have been a few reports of myocardial infarction occurring within 2-3 days of propranolol hydrochloride discontinuation in angina pectoris patients, but an association has not yet been established.

As with any new drug given over prolonged periods, laboratory parameters should be observed at regular intervals. The drug should be used with caution in patients with impaired renal or hepatic function.

ADVERSE REACTIONS: *Cardiovascular:* bradycardia; congestive heart failure; intensification of AV block; hypotension; paresthesia of hands; arterial insufficiency, usually of the Raynaud type; thrombocytopenic purpura

Central Nervous System: lightheadedness; mental depression manifested by insomnia, lassitude, weakness, fatigue; reversible mental depression progressing to catatonia; visual disturbances; hallucinations; an acute reversible syndrome characterized by disorientation for time and place, short term memory loss, emotional lability, slightly clouded sensorium, and decreased performance on neuropsychometrics

Gastrointestinal: nausea, vomiting, epigastric distress, abdominal cramping, diarrhea, constipation

Allergic: pharyngitis and agranulocytosis, erythematous rash, fever combined with aching and sore throat, laryngospasm and respiratory distress

Respiratory: bronchospasm

Hematologic: agranulocytosis, non-thrombocytopenic purpura, thrombocytopenic purpura

Miscellaneous: reversible alopecia

Clinical Laboratory Test Findings: Elevated blood urea levels in patients with severe heart disease, elevated serum transaminase, alkaline phosphatase, lactate dehydrogenase

DOSAGE AND ADMINISTRATION: The oral route of administration is preferred.

ORAL

Angina Pectoris—Dosage must be individualized. Starting with 10-20 mg. three or four times daily, before meals and at bedtime, dosage should be gradually increased at three to seven day intervals until optimum response is obtained. Although individual patients may respond at any dosage level, the average optimum dosage appears to be 160 mg. per day. The value and safety of dosage exceeding 320 mg. per day have not been established.

If treatment is to be discontinued, it is recommended that withdrawal be gradual over a two week period. (See PRECAUTIONS.)

PEDIATRIC DOSAGE

At this time the data on the use of the drug in this age group are too limited to permit adequate directions for use.

OVERDOSAGE OR EXAGGERATED RESPONSE

IN THE EVENT OF OVERDOSAGE OR EXAGGERATED RESPONSE, THE FOLLOWING MEASURES SHOULD BE EMPLOYED:

BRADYCARDIA—ADMINISTER ATROPINE (0.25 to 1.0 mg.): IF THERE IS NO RESPONSE TO VAGAL BLOCKADE, ADMINISTER ISOPROTERENOL CAUTIOUSLY

CARDIAC FAILURE—DIGITALIZATION AND DIURETICS

HYPOTENSION—VASOPRESSORS, *e.g.* LEVARTERENOL OR EPINEPHRINE (THERE IS EVIDENCE THAT EPINEPHRINE IS THE DRUG OF CHOICE.)

BRONCHOSPASM—ADMINISTER ISOPROTERENOL AND AMINOPHYLLINE

HOW SUPPLIED

INDERAL®
(propranolol hydrochloride)

TABLETS

No. 461—Each tablet contains 10 mg. of propranolol hydrochloride, in bottles of 100 and 1,000.

No. 464—Each tablet contains 40 mg. of propranolol hydrochloride, in bottles of 100 and 1,000.

INJECTABLE

No. 3265—Each cc. contains 1 mg. of propranolol hydrochloride in Water for Injection. The pH is adjusted with citric acid. Supplied as: 1 cc. ampuls in boxes of 10.

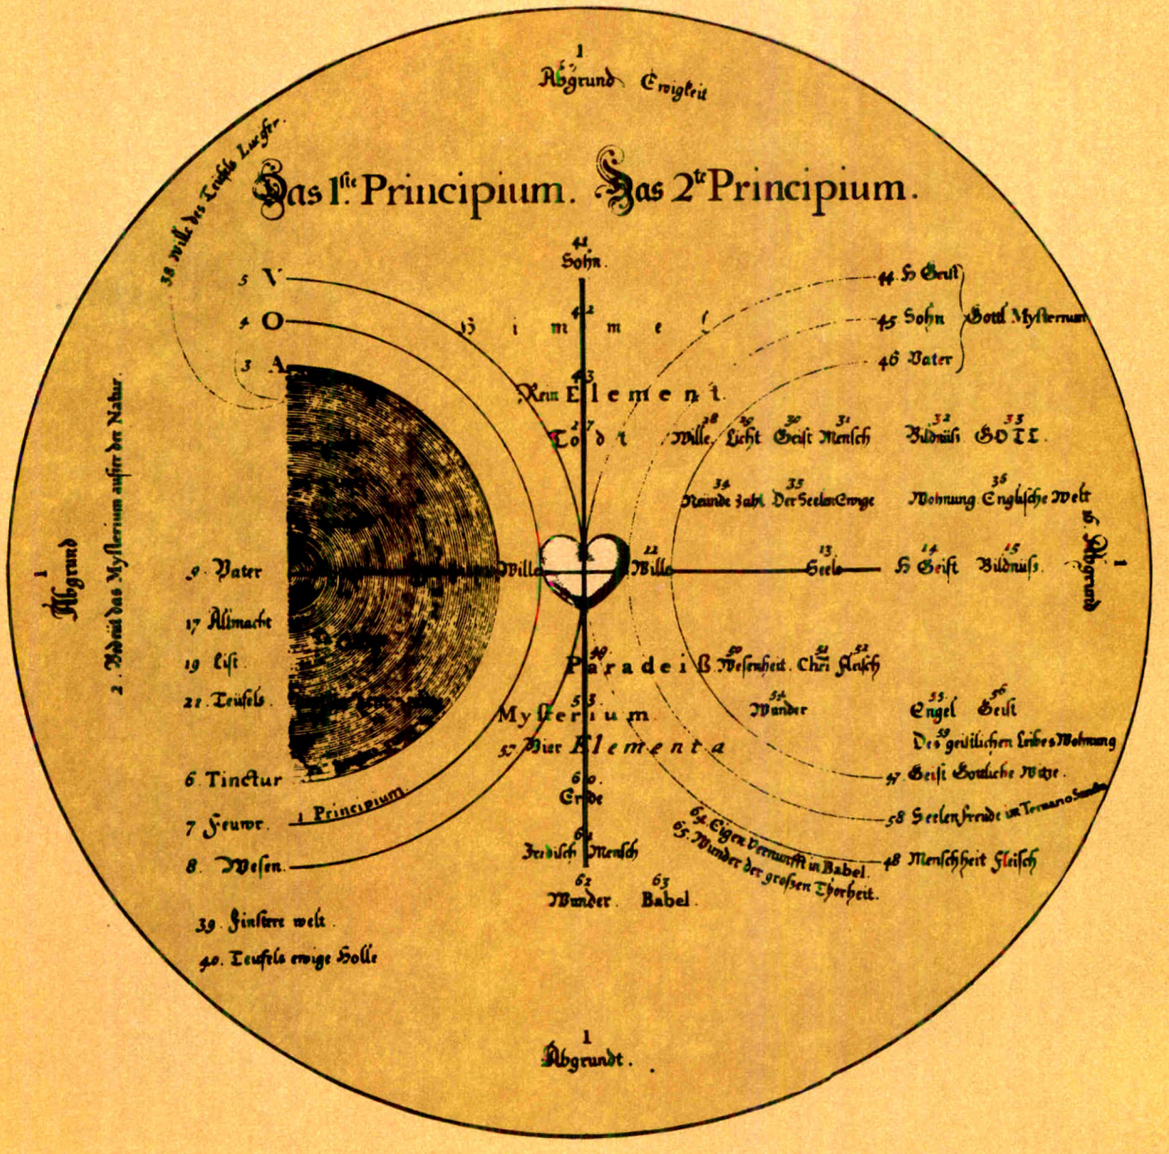
NEW YORK, N.Y. 10017

INDERAL® (propranolol hydrochloride) is available in the United States by arrangement with Imperial Chemical Industries Ltd. 7355

Die Philosophische Kugel oder das Wunder-Auge der Ewigkeit.



The art of antianginal therapy

For centuries, treating the heart's ills has been the subtlest of arts. Even today, evaluating a drug for chronic angina pectoris involves the art of medicine as well as its science.

Persantine — over a decade of use

During more than a decade of clinical experience, compounding both science and art, Persantine has often been found useful in the long-term management of chronic angina pectoris.* It may:

eliminate or reduce the frequency of anginal attacks

improve exercise tolerance

reduce nitroglycerin requirements

Persantine — give enough — long enough

The recommended dosage: 50 mg. t.i.d. at least one hour before meals. *Give enough, long enough* — several weeks or longer of continuous therapy may be needed to see response.

Persantine® Tablets of 25 mg.
dipyridamole

the non-nitrate
coronary vasodilator

*INDICATIONS – Based on a review of this drug by the National Academy of Science-National Research Council and/or other information, FDA has classified the indication as follows:

"Possibly" effective: For long-term therapy of chronic angina pectoris. Prolonged therapy may reduce the frequency or eliminate anginal episodes, improve exercise tolerance, and reduce nitroglycerin requirements. The drug is not intended to abort the acute anginal attack.

Final classification of the less-than-effective indications requires further investigation.

CONTRAINDICATIONS – No specific contraindications are known.

PRECAUTIONS – Since excessive doses can produce peripheral vasodilation, the drug should be used cautiously in patients with hypotension.

ADVERSE REACTIONS – Adverse reactions are minimal and transient at recommended dosages. Instances of headache, dizziness, nausea, flushing, weakness or syncope, mild gastrointestinal distress and skin rash have been noted during therapy. Rare cases of what appeared to be an aggravation of angina pectoris have been reported, usually at the initiation of therapy. On those uncommon occasions when adverse reactions have been persistent or intolerable, withdrawal of medication has been followed promptly by cessation of undesirable symptoms.

DOSAGE AND ADMINISTRATION – The recommended dosage is 50 mg. (2 tablets) three times a day, taken at least one hour before meals. In some cases higher doses may be necessary but a significantly increased incidence of side effects is associated with increased dosage. Clinical response may not be evident before the second or third month of continuous therapy.

For complete details, please see the full prescribing information.

The Philosophical Sphere
The philosophical sphere, according to Jakob Böhme. The "true psychology" or forty questions about the soul (1620).

"The heart set in the angle of the cross means the basis or center of the Divinity . . . that we may learn to distinguish the Divinity from nature, and that Christians may learn to understand the rebirth, how God in Christ, out of his crucified heart, resurrected us."

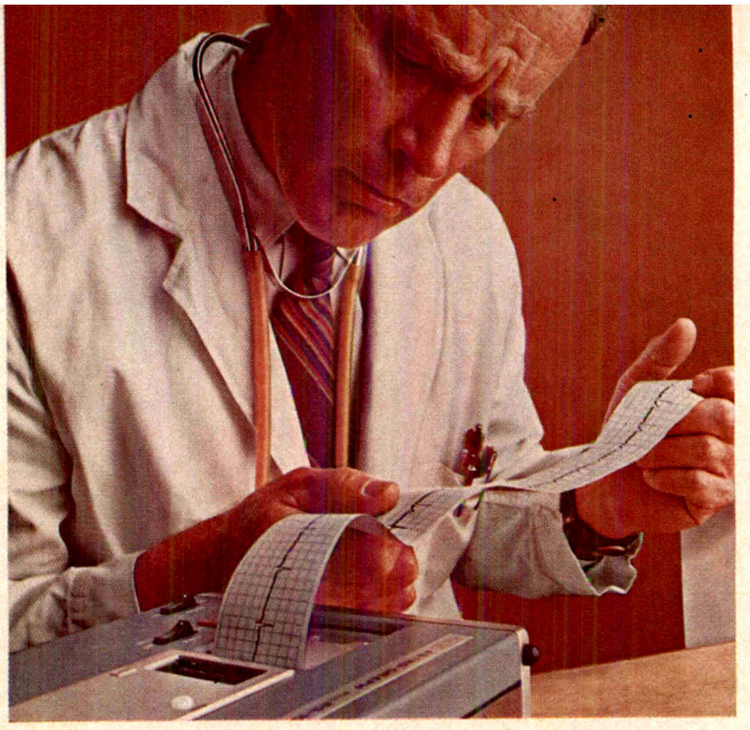
When cardiac complaints occur in the absence of organic findings, underlying anxiety may be one factor



The influence of anxiety on heart function

Excessive anxiety is one of a combination of factors that may trigger a series of maladaptive functional reactions which can generate further anxiety. Often involved in this vicious circle are some cardiac arrhythmias, paroxysmal supraventricular tachycardia and premature systoles. When these symptoms resemble those associated with actual organic disease, the overanxious patient needs reassurance that they have no

---

Before prescribing, please consult complete product information, a summary of which follows:

Indications: Relief of anxiety and tension occurring alone or accompanying various disease states.

Contraindications: Patients with known hypersensitivity to the drug.

Warnings: Caution patients about possible combined effects with alcohol and other CNS depressants. As with all CNS-acting drugs, caution patients against hazardous occupations requiring complete mental alertness (*e.g.*, operating machinery, driving). Though physical and psychological dependence have rarely been reported on recommended doses, use caution in administering to addiction-prone individuals or those who might increase dosage; withdrawal symptoms (including convulsions), following discontinuation of the drug and similar to those seen with barbiturates, have been reported. Use of any drug in pregnancy, lactation, or in women of childbearing age requires that its potential benefits be weighed against its possible hazards.

Precautions: In the elderly and debilitated, and in children over six, limit to smallest effective dosage (initially 10 mg or less per day) to preclude ataxia or oversedation, increasing gradually as needed and tolerated. Not recommended in children under six. Though generally not recommended, if combination therapy with other psychotropics seems indicated, carefully consider individual pharmacologic effects, particularly in use of potentiating drugs such as MAO inhibitors and phenothiazines. Observe usual precautions

organic basis and that reduction of excessive anxiety and emotional overreaction would be medically beneficial.

The benefits of antianxiety therapy

Antianxiety medication, when used to complement counseling and reassurance, should be both effective and comparatively free from undesirable side effects. More than 13 years of extensive clinical experience has demonstrated that Librium (chlordiazepoxide HCl) fulfills these requirements with a high degree of consistency. Because of its wide margin of safety, Librium may generally be administered for extended periods, at the physician's discretion, without diminution of effect or need for increase in dosage. (See summary of prescribing information.) If cardiovascular drugs are necessary, Librium is used concomitantly whenever anxiety is a clinically significant factor. (See Precautions.) Librium should be discontinued when anxiety has been reduced to appropriate levels.

For relief of excessive anxiety adjunctive

Librium® 10 mg
(chlordiazepoxide HCl)
1 or 2 capsules t.i.d./q.i.d.

ROCHE
Roche Laboratories
Division of Hoffmann-La Roche Inc.
Nutley, N.J. 07110

---

in presence of impaired renal or hepatic function. Paradoxical reactions (*e.g.*, excitement, stimulation and acute rage) have been reported in psychiatric patients and hyperactive aggressive children. Employ usual precautions in treatment of anxiety states with evidence of impending depression; suicidal tendencies may be present and protective measures necessary. Variable effects on blood coagulation have been reported very rarely in patients receiving the drug and oral anticoagulants; causal relationship has not been established clinically.

Adverse Reactions: Drowsiness, ataxia and confusion may occur, especially in the elderly and debilitated. These are reversible in most instances by proper dosage adjustment, but are also occasionally observed at the lower dosage ranges. In a few instances syncope has been reported. Also encountered are isolated instances of skin eruptions, edema, minor menstrual irregularities, nausea and constipation, extrapyramidal symptoms, increased and decreased libido—all infrequent and generally controlled with dosage reduction; changes in EEG patterns (low-voltage fast activity) may appear during and after treatment; blood dyscrasias (including agranulocytosis), jaundice and hepatic dysfunction have been reported occasionally, making periodic blood counts and liver function tests advisable during protracted therapy.

Supplied: Librium® Capsules containing 5 mg, 10 mg or 25 mg chlordiazepoxide HCl. Libritabs® Tablets containing 5 mg, 10 mg or 25 mg chlordiazepoxide.

ENERGY: How the new Medtronic

For complete product information, contact your local Medtronic Representative or Medtronic Corporate Headquarters:

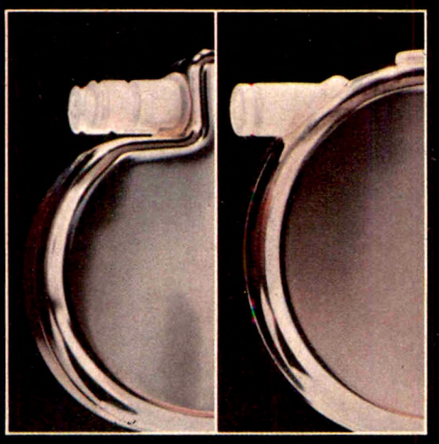
Medtronic, Inc.
3055 Old Highway Eight
Minneapolis, Minn. 55418
Telephone 612/781-6061

pacemakers conserve it.

The concept of Energy Conservation is based on one simple fact: lessen the drain on a power source and you extend its life.

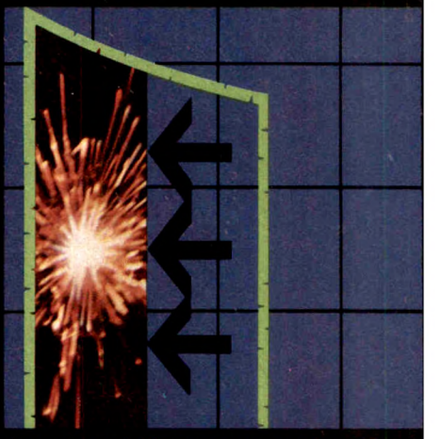
In the new Medtronic pacemakers, pulse width has been reduced to reduce the energy expenditure per pulse.

Less energy expended means longer projected life. It's that simple.



Model 5944—Bipolar Demand Pulse Generator

Model 5945—Unipolar Demand Pulse Generator



As pulse width narrows, projected life of the pulse generator is extended.

Another significant improvement combines the idea of energy compensation with a redundant cell depletion indicator. It works this way: when depletion of the first cell occurs, the new Medtronic pulse generators show a decrease in rate similar to most other pulse generators. But, they also automatically increase pulse width when depletion occurs. This increase in pulse width compensates for the decrease in voltage, thus providing a margin of safety above threshold while also serving as a positive cell depletion indicator.

By now she should

Rheumatic fever prevention and the noncompliant patient.

Patients on oral penicillin for prevention of recurrent rheumatic fever usually don't ignore their daily dosage regimen deliberately. But since patients are only human, doses *are* missed occasionally—through simple lapse of memory, lack of time or insufficient drug on hand.

Prolonged penicillin blood levels to obviate need for daily dosage.

A single injection of benzathine penicillin G (1.2 million units) once a month provides continuous prophylaxis in most patients. Which is why it's recommended as the method of choice* to prevent streptococcal infection and possible recurrence of rheumatic fever.

A method of choice in treatment of strep pharyngitis, too.*

In therapy of mild to moderate Group A streptococcal pharyngitis without bacteremia, just one injection of 600,000 to 900,000 units usually maintains penicillin serum concentrations in children for the 10 days necessary to eradicate the infecting organisms.† In adults, 1.2 million units are required.

*Rheumatic Fever Committee of the Council on Rheumatic Fever and Congenital Heart Disease of the American Heart Association.

have taken all of them.

Indications: In treatment of infections due to penicillin G-sensitive microorganisms susceptible to the low and very prolonged serum levels common to this dosage form. Therapy should be guided by bacteriological studies (including sensitivity tests) and clinical response.

The following infections usually respond to adequate dosage of IM benzathine penicillin G.

Streptococcal infections (Group A—without bacteremia). Mild to moderate upper respiratory infections (e.g., pharyngitis).

Venereal infections —Syphilis, yaws, bejel, and pinta.

Medical Conditions in which Benzathine Penicillin G Therapy is indicated as Prophylaxis:

Rheumatic fever and/or chorea —Prophylaxis with benzathine penicillin G has proven effective in preventing recurrence of these conditions. It has also been used as followup prophylactic therapy for rheumatic heart disease and acute glomerulonephritis.

FOR DEEP INTRAMUSCULAR INJECTION ONLY.

Contraindications: Previous hypersensitivity reaction to any penicillin.

Warnings: Serious and occasionally fatal hypersensitivity (anaphylactoid) reactions have been reported. Anaphylaxis is more frequent following parenteral therapy but has occurred with oral penicillins. These reactions are more apt to occur in individuals with history of sensitivity to multiple allergens. Severe hypersensitivity reactions with cephalosporins have been well documented in patients with history of penicillin hypersensitivity. Before penicillin therapy, carefully inquire into previous hypersensitivity to penicillins, cephalosporins and other allergens. If allergic reaction occurs, discontinue drug and treat with usual agents, e.g., pressor amines, antihistamines and corticosteroids.

Precautions: Use cautiously in individuals with histories of significant allergies and/or asthma.

Carefully avoid intravenous or intraarterial use or injection into or near major peripheral nerves or blood vessels, since such injection may produce neurovascular damage.

†In streptococcal infections, therapy must be sufficient to eliminate the organism, otherwise the sequelae of streptococcal disease may occur. Take cultures following completion of treatment to determine whether streptococci have been eradicated.

Prolonged use of antibiotics may promote overgrowth of non-susceptible organisms including fungi. Take appropriate measures if superinfection occurs.

Adverse Reactions: Hypersensitivity reactions reported are skin eruptions (maculopapular to exfoliative dermatitis), urticaria and other serum sickness reactions, laryngeal edema and anaphylaxis. Fever and eosinophilia may frequently be only reaction observed. Hemolytic anemia, leucopenia, thrombocytopenia, neuropathy and nephropathy are infrequent and usually associated with high parenteral doses.

As with other antisyphilitics, Jarisch-Herxheimer reaction has been reported.

Composition: (units benzathine penicillin G as active ingredient): 300,000 units per cc.—10-cc. multi-dose vial. Each cc. also contains sodium citrate buffer, approximately 6 mg. lecithin, 3 mg. povidone, 1 mg. carboxymethylcellulose, 0.5 mg. sorbitan monopalmitate, 0.5 mg. polyoxyethylene sorbitan monopalmitate, 1.2 mg. methylparaben and 0.14 mg. propylparaben.

600,000 units in 1-cc. TUBEX® (sterile cartridge-needle unit) Wyeth, packages of 10.

1,200,000 units in 2-cc. TUBEX, packages of 10, and in 2-cc. single-dose disposable syringe.

2,400,000 units in 4-cc. single-dose disposable syringe.

Each TUBEX or disposable syringe also contains sodium citrate buffer and, as w/v, approximately 0.5% lecithin, 0.4% carboxymethylcellulose, 0.4% povidone, 0.09% methylparaben and 0.01% propylparaben.

Physicians Ask Us, "Who Is ESB Medcor?"

Two years ago, ESB Incorporated and Medcor, Inc. formed ESB Medcor, Inc. to bring to the medical profession a series of unique products for the field of cardiology.

ESB Incorporated, the world's largest battery company with expertise in electrical, electro-chemical and chemical products, is best known for its Ray-O-Vac, Exide and Willard brand products. Over a period of years, it has carried out research and development in cardiac pacing as well as monitoring the critical parameters of patients with pacers. While this does represent a marked departure from ESB's major thrust, it is apparent that much of ESB's technical expertise has direct application in the medical field.

Medcor, Inc., a new name in medical electronics, has brought together some of the finest and most experienced technical talent in the field of cardiac pacing. This group has developed a line of pacer related products, including a unique heart pacer which utilizes a 'fail-safe' battery system and minimum current drain circuit to achieve greater reliability and longer life.

ESB Medcor, Inc. unites the strengths of both companies, and offers a systems approach to the treatment of pacer patients through its advanced cardiac pacers and the Pacer-Check System.

For further information about ESB Medcor, Inc. write: P.O. Box 6699, Hollywood, Florida 33021. Or call: (305) 791-8310.

HEMODYNAMICS OF ANGINA PECTORIS* — PATIENTS RESTING AND EXERCISING, BEFORE AND AFTER ISORDIL® SUBLINGUAL
(isosorbide dinitrate)

BEFORE MEDICATION		AFTER 5 mg. ISORDIL SUBLINGUAL (isosorbide dinitrate)
	PULMONARY ARTERY (MEAN PRESSURE)		TOTAL PULMONARY RESISTANCE		CARDIAC INDEX		BRACHIAL ARTERY (MEAN PRESSURE)		TOTAL SYSTEMIC RESISTANCE	
IN ANGINA PECTORIS*

- to abort or terminate acute anginal attacks
- to reduce the frequency and severity of anginal episodes often caused by unavoidable everyday stress

ISORDIL® SUBLINGUAL
(ISOSORBIDE DINITRATE)

SUBLINGUAL TABLETS: 2.5 mg. and 5 mg.

***Indications:** Based on a review of this drug by the National Academy of Sciences—National Research Council and/or other information, FDA has classified the indication as follows:
"Probably" effective: When taken by the sublingual route, Isordil Sublingual is indicated for the treatment of acute anginal attacks and for prophylaxis in situations likely to provoke such attacks.
Final classification of the less-than-effective indications requires further investigation.

Contraindication: Idiosyncrasy to this drug.

Warnings: Data supporting the use of nitrites during the early days of the acute phase of myocardial infarction (the period during which clinical and laboratory findings are unstable) are insufficient to establish safety.

Precautions: Tolerance to this drug and cross-tolerance to other nitrites and nitrates may occur.

Adverse Reactions: Cutaneous vasodilation with flushing. Headache is common and may be severe and persistent. Transient episodes of dizziness and weakness as well as other signs of cerebral ischemia associated with postural hypotension may occasionally develop. This drug can act as a physiological antagonist to norepinephrine, acetylcholine, histamine, and many other agents. An occasional individual exhibits marked sensitivity to the hypotensive effects of nitrite, and severe responses (nausea, vomiting, weakness, restlessness, pallor, perspiration and collapse) can occur even with the usual therapeutic dose. Alcohol may enhance this effect. Drug rash and/or exfoliative dermatitis may occasionally occur.

Consult direction circular before prescribing.

Prescribe good-tasting

K^+LORVESS®

effervescent tablets

Each tablet contains 20 mEq. each of potassium and chloride supplied by potassium chloride 1.125 g., potassium bicarbonate 0.5 g., l-lysine hydrochloride 0.913 g.

1:1 ratio K^+ and Cl^- in solution

SIMPLE TO TAKE—Tablets dissolve in 3-4 oz. cold water

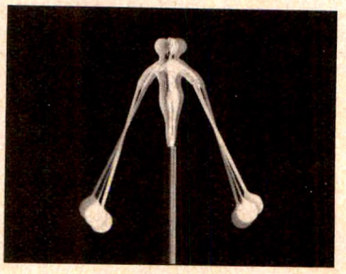
SPARKLING TASTE APPEAL—Fruitlike flavor

PATIENT ACCEPTANCE—Reduces chance of G.I. irritation. No added calories.

UNIT DOSE CONVENIENCE—Tablets individually foil-wrapped

KLORVESS offers what you and the patient like

Dorsey
LABORATORIES
Division of Sandoz-Wander, Inc.
Lincoln, Nebraska 68501



KLORVESS®
Effervescent Tablets

Description: Each dry effervescent tablet contains 20 mEq. each of potassium and chloride supplied by potassium chloride 1.125 g., potassium bicarbonate 0.5 g., l-lysine hydrochloride 0.913 g. Solution of the tablet in water provides the potassium and chloride available for oral ingestion as potassium chloride, potassium bicarbonate, potassium citrate, and l-lysine hydrochloride.

Indications: For prevention or correction of potassium depletion and hypokalemic alkalosis. Especially useful when thiazide diuretics or corticosteroids cause excessive excretory potassium losses.

Contraindications: Severe renal impairment with oliguria or azotemia, untreated Addison's disease, adynamia episodica hereditaria, acute dehydration, heat cramps, and hyperkalemia from any cause.

Precautions: In response to a rise in the concentration of body potassium, renal excretion of the ion is increased. With normal kidney function, it is difficult, therefore, to produce potassium intoxication by oral administration. However, potassium supplements must be administered with caution, since the amount of the deficiency or daily dosage is not accurately known. Frequent checks of the clinical status of the patient, and periodic ECG and/or serum potassium levels should be made. High serum concentrations of potassium ion may cause death through cardiac depression, arrhythmias or arrest. This drug should be used with caution in the presence of cardiac disease. Potassium supplements should be given cautiously to digitalized patients. To minimize the possibility of gastrointestinal irritation associated with the oral ingestion of concentrated potassium salt preparations, patients should be carefully directed to dissolve each tablet completely in the stated amount of water.

Adverse Reactions: Vomiting, diarrhea, nausea and abdominal discomfort may occur with the use of potassium salts. The symptoms and signs of potassium intoxication include paresthesias of the extremities, flaccid paralysis, listlessness, mental confusion, weakness and heaviness of the legs, fall in blood pressure, cardiac arrhythmias and heart block. Hyperkalemia may exhibit the following electrocardiographic abnormalities: disappearance of the P wave, widening and slurring of QRS complex, changes of the S-T segment, and tall, peaked T waves.

Dosage and Administration: Adults: 1 tablet (20 mEq. each of potassium and chloride) completely dissolved in 3 to 4 ounces of cold water 2 to 4 times daily depending upon the requirements of the patient. The approximate minimum adult daily requirement of potassium is 40 mEq. Deviations from this recommendation may be indicated, since no average total daily dose can be defined but must be governed by close observation for clinical effects.
NOTE: Klorvess should be taken with meals.

Overdosage: Potassium intoxication may result from overdosage of potassium or from therapeutic dosage in conditions stated under "Contraindications." Hyperkalemia, when detected, must be treated immediately because lethal levels can be reached in a few hours.

How Supplied: Klorvess Tablets (white, round) in boxes of 60 (2 Rx units of 30, NDC 43-100-87). Each tablet is individually foil wrapped.

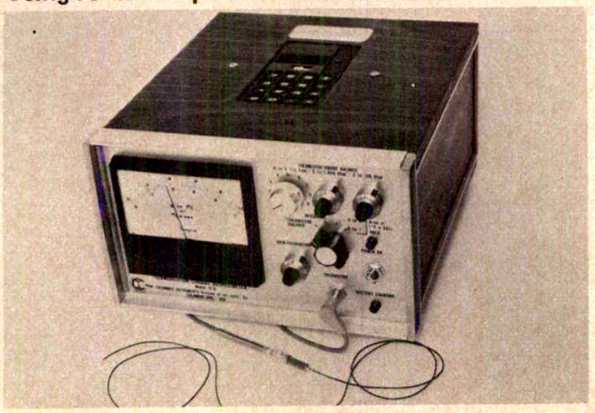
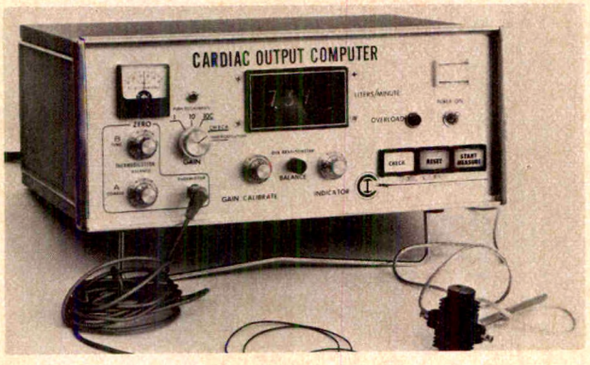
THERMODILUTION

Using room temperature indicator!



THERMODILUTION CARDIAC OUTPUT METER AND INTEGRATOR

- An intermediate instrument between the simple bridge and full scale computer.
- Battery operated—no shock hazards. Rechargeable.
- Will work with any thermistor catheter on the market; including Swan-Ganz balloon flow-directed catheter.
- Equipped with a recorder output.
- Provides information on the area under the dilution curve. (Extrapolates the dilution curve!)
- Price: $1,540.00



THERMO AND DYE DILUTION CARDIAC OUTPUT COMPUTER

- Equipped with Thermodilution and/or Dye Dilution Densitometer
- Easy calibration, automatic zeroing.
- Remote control by foot switch.
- Digital readout in L/min.
- Recorder outputs.

Pronestyl® Capsules/Injection

(Procainamide Hydrochloride)

Contraindications: In patients with myasthenia gravis and where a hypersensitivity to procainamide and related drugs exists. Should not be given to patients with complete atrioventricular heart block. Contraindicated in cases of high-degree A-V block unless an electrical pacemaker is operative.

Administration: Oral administration is preferred. When parenteral therapy is necessary, intramuscular administration is the method of choice. Intravenous use should be limited to extreme emergencies, be administered as a dilute infusion, and the patient be monitored electrocardiographically whenever practicable throughout the infusion. The intravenous dose should not exceed 1 g. Administer at a rate not exceeding 25 to 50 mg. per minute.

Should procainamide therapy be continued for any appreciable period, electrocardiograms should be made occasionally to determine its further need.

Precautions: Evidence of untoward myocardial response should be carefully watched for in all patients. In the presence of myocardial damage with atrial fibrillation or flutter, the ventricular rate may increase suddenly as the atrial rate is slowed; adequate digitalization reduces but does not abolish this danger. Ventricular tachysystole is particularly hazardous.

The dislodgement of mural thrombi producing an embolic episode may occur in correcting atrial fibrillation due to the forceful contractions of the atrium.

Extreme caution is required in attempting to adjust the heart rate when ventricular tachycardia has occurred during an occlusive coronary episode or where the use of procainamide may result in additional depression of conduction and ventricular asystole or fibrillation as in A-V block, bundle branch block, or severe digitalis intoxication.

Parenteral administration should be monitored electrocardiographically whenever practicable. Parenteral administration should be discontinued at once if electrocardiograms give evidence of impending heart block. This complication should be kept in mind when treating ventricular arrhythmias (especially parenterally) in patients with severe organic heart disease and ventricular tachycardia who may also have complete heart block. Since asystole may result if the ventricular rate is significantly slowed without attainment of regular atrioventricular conduction, procainamide should be stopped and the patient re-evaluated.

In the presence of both liver and kidney damage, normal dosage may produce symptoms of overdosage—principally ventricular tachycardia and severe hypotension.

A syndrome resembling lupus erythematosus has been reported with maintenance procainamide therapy. Common symptoms are polyarthralgia, arthritis and pleuritic pain. Fever, myalgia, skin lesions, pleural effusion and pericarditis may also occur. Rare cases of thrombocytopenia or Coombs-positive hemolytic anemia, possibly related to this syndrome, have been reported. Measure anti-nuclear antibody titers at regular intervals in patients on procainamide for extended periods of time or in whom symptoms suggestive of lupus-like reaction appear; discontinue drug in event of rising titer or clinical symptoms of LE. Steroid therapy may be effective if discontinuation of procainamide does not cause remission of symptoms. If the syndrome develops in a patient with recurrent life-threatening arrhythmias not otherwise controllable, steroid-suppressive therapy may be used concomitantly with procainamide.

Adverse Reactions: Because procainamide is a peripheral vasodilator, it may produce a hypotensive response, sometimes precipitous when given intravenously. Blood pressure should be measured almost continuously during the infusion which should be temporarily discontinued if the fall exceeds 15 mm. Hg. The hypotensive response is less likely to occur from intramuscular injection and is rare following oral administration. Serious disturbances of cardiac rhythm such as ventricular asystole or fibrillation are also more common with I.V. administration.

Large oral doses may sometimes produce anorexia, nausea, urticaria, and/or pruritus.

Reactions consisting of fever and chills; soreness of mouth, throat, or gums; and symptoms of upper respiratory tract infection have been reported. Agranulocytosis has been occasionally reported following prolonged use of the drug, and deaths have occurred. Therefore, routine blood counts are advisable during maintenance therapy. If any of the above symptoms should occur and leukocyte counts indicate cellular depression, procainamide therapy should be discontinued and appropriate treatment should be instituted immediately. Diarrhea, weakness, mental depression, giddiness, psychosis with hallucinations, hypersensitivity reactions such as angioneurotic edema and maculopapular rash, and bitter taste have been reported.

The package insert should be read carefully to become familiar with the recommended oral and parenteral dosage for the indicated conditions.

How Supplied: Pronestyl Capsules (Procainamide Hydrochloride Capsules U.S.P.) providing 250 mg. and 500 mg. are available in bottles of 100 and 1000 and Unimatic* Single Dose packaging in cartons of 100. Capsules providing 375 mg. are available in bottles of 100. Pronestyl Injection (Procainamide Hydrochloride Injection U.S.P.) providing a 10% sterile aqueous solution (100 mg./cc.) with 0.9% (w/v) benzyl alcohol is available in 10 cc. vials.

See opposite page for brief summary.

tolerance to exercise improved for angina patients

INDICATIONS: For the prophylaxis and long-term management of patients with frequent or recurrent anginal pain and reduced exercise tolerance associated with angina pectoris, rather than for the treatment of the acute attack of angina pectoris, since its onset of action is somewhat slower than that of nitroglycerin.

PRECAUTIONS: As with other effective nitrites, some fall in blood pressure may occur with large doses. Caution should be observed in patients with a history of recent cerebral hemorrhage, because of the vasodilatation which occurs in the area. Although therapy permits more normal activity, the patient should not be allowed to misinterpret freedom from anginal attacks as a signal to drop all restrictions.

SIDE EFFECTS: No serious side effects have been reported. As with nitroglycerin or other effective nitrites, temporary vascular headache may occur during the first few days of therapy. This can be controlled by temporary dosage reduction in order to allow adjustment of the cerebral hemodynamics to the initial marked cerebral vasodilatation. These headaches usually disappear within one week of continuous therapy but may be minimized by the administration of analgesics such as Empirin® Compound.

Mild gastrointestinal disturbances occur occasionally with larger doses and may be controlled by reducing the dose temporarily.

SUPPLIED: 10 mg. chewable tablets. Bottles of 100. Also 5, 10 and 15 mg. scored tablets in bottles of 100 10 mg. scored tablets also supplied in bottles of 1000.

Also available: Cardilate-P brand Erythrityl Tetranitrate with Phenobarbital (Warning: may be habit-forming).

Is Sublingual Nitroglycerin still the drug of choice for acute angina?

Most physicians agree that of the nitrates available for the relief of acute angina pectoris, sublingual nitroglycerin remains the drug of choice. However, nitroglycerin is an unstable compound that can migrate from tablet to tablet, from tablet to cotton packing, from tablet to air.

And your patient may end up with too little nitroglycerin—just when it's needed most. To help solve this problem, Parke-Davis has developed Nitrostat, a stabilized sublingual nitroglycerin.

Nitrostat offers these important benefits:

- Rapid relief of pain
- Predictable patient response
- Uniform potency from tablet to tablet
- Stable sublingual dosage
- Reliable in clinical confirmation of angina pectoris

So whenever you're confronted by a patient with acute angina, *think* nitroglycerin. But *write* Nitrostat.

NITROSTAT®... the dependable nitroglycerin
(nitroglycerin tablets, USP)

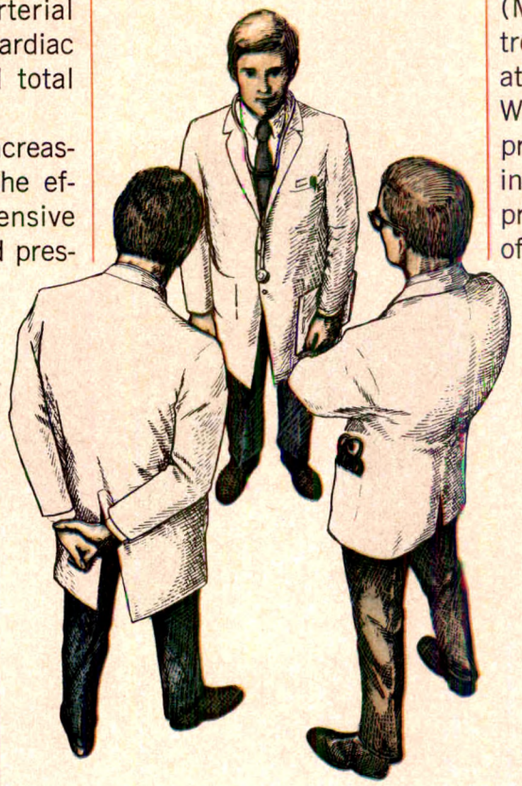
The more physicians consider the hemodynamics of lowering blood pressure...

Most physicians now agree on the importance of reducing blood pressure in the hypertensive patient. But high blood pressure exists, of course, only as part of a complete clinical picture. The hemodynamic profile of well-established essential hypertension is characterized by elevated arterial blood pressure, normal cardiac output, and increased total peripheral resistance.

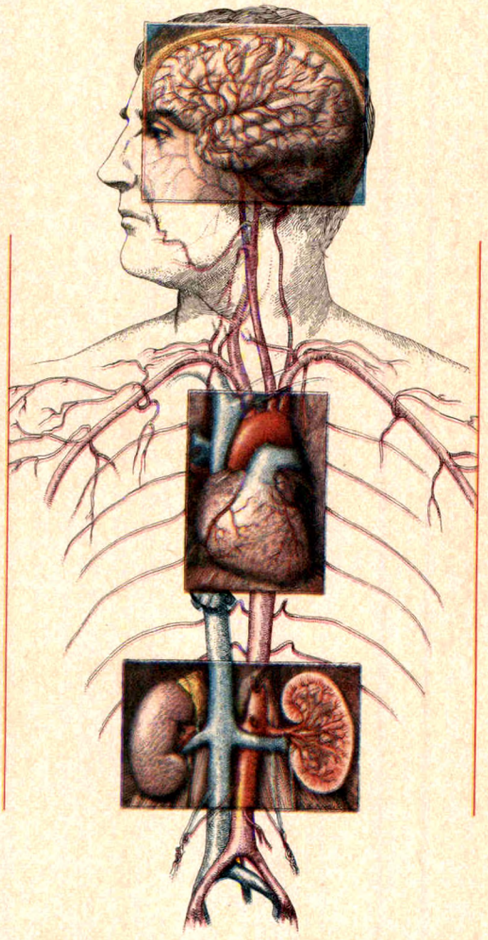
And so, physicians are increasingly concerned with the effects of an antihypertensive agent not only on blood pressure itself but also on the hemodynamic pattern—in short, with the total effect of the drug. *Does* it indeed help lower blood pressure effectively? *Is* peripheral resistance reduced? *Are* cardiac output and renal functions maintained? And, also, is there likely to be drug-induced postural hypotension serious enough to pose a threat to the patient's cerebrovascular status?



With this emphasis on overall drug performance has come a growing reliance on ALDOMET® (Methyldopa, MSD) in the treatment of sustained moderate hypertension.

With its unique hemodynamic profile, ALDOMET has drawn increasing attention and approval from physicians. First, of course, for its efficacy in

the more physicians rely on this unique antihypertensive



lowering blood pressure. But there are other considerations as well. Cardiac output is usually maintained with no cardiac acceleration; in some patients the heart rate is actually slowed. Peripheral resistance is apparently reduced. ALDOMET does not usually compromise existing renal function; it generally does not reduce renal blood flow, glomerular filtration rate, or filtration fraction. And ALDOMET usually does not cause symptomatic postural or exercise hypotension.

Some patients on continuous methyldopa therapy may develop a positive direct Coombs test. For more details, see the brief summary of prescribing information.

Contraindicated in active hepatic disease and known sensitivity to the drug. Not recommended in pheochromocytoma or pregnancy. It should be used with caution in patients with a history of liver disease or dysfunction. Discontinue the drug if fever, abnormal liver function, jaundice, or acquired hemolytic anemia occurs.

In most cases of sustained moderate hypertension

TABLETS, 250 mg

ALDOMET®
(METHYLDOPA | MSD)

smoothly lowers blood pressure

For a brief summary of prescribing information, please see following page.

In most cases of sustained moderate hypertension

TABLETS, 250 mg

ALDOMET®
(METHYLDOPA | MSD)

smoothly lowers blood pressure

Contraindications: Active hepatic disease, such as acute hepatitis and active cirrhosis; known sensitivity. Not recommended in pheochromocytoma. Unsuitable in mild or labile hypertension responsive to mild sedation or thiazide therapy. Use cautiously in patients with history of previous liver disease or dysfunction.

Warnings: Acquired hemolytic anemia has occurred rarely in association with therapy with methyldopa. Should clinical symptoms indicate the possibility of anemia, hemoglobin and/or hematocrit determinations should be performed. If anemia is present, appropriate laboratory studies should be done to determine if hemolysis is present. Evidence of hemolytic anemia is an indication for discontinuation of the drug. Discontinuation of methyldopa alone or the initiation of adrenocortical steroids usually results in a prompt remission of the anemia. Rarely, however, fatalities have occurred.

Some patients on continued therapy with methyldopa develop a positive direct Coombs test; incidence reported has averaged between 10% and 20%. It rarely occurs in first six months of therapy, and if not seen within twelve months, is unlikely to develop with continued administration. Positive Coombs test is dose-related; lowest incidence occurs in patients on 1 g methyldopa or less per day. Reversal of the positive Coombs test occurs within weeks to months after discontinuation of methyldopa. Prior knowledge of a positive Coombs reaction aids in evaluation of cross match for transfusions. Patients with positive Coombs tests at time of cross match may exhibit incompatible minor cross match. When this occurs, an indirect Coombs test should be performed. If negative, transfusion with blood otherwise compatible in the major cross match may be carried out. If positive, advisability of transfusion with blood compatible in major cross match should be determined by hematologist or expert in transfusion problems.

Fever has occurred within first three weeks of therapy, sometimes with eosinophilia or abnormalities in liver function tests, such as serum alkaline phosphatase, serum transaminases (SGOT, SGPT), bilirubin, cephalin cholesterol flocculation, prothrombin time, and bromsulphalein retention. Jaundice, with or without fever, may occur, with onset usually in the first two to three months of therapy. Rare cases of fatal hepatic necrosis have been reported. Liver biopsy in several patients with liver dysfunction has shown microscopic focal necrosis compatible with drug hypersensitivity. Rarely, reversible reduction in leukocyte count with primary effect on granulocytes has been seen; reversible agranulocytosis has been reported. Methyldopa may interfere with measurement of creatinine by alkaline picrate method and of uric acid by phosphotungstate method. When used with other antihypertensive drugs, potentiation of antihypertensive action may occur.

Usage in Pregnancy and Childbearing Age—Not recommended in pregnancy. In women of childbearing age, weigh potential benefits against possible fetal hazards.

Precautions: Perform periodic hepatic function tests and white cell and differential blood counts during first six to twelve weeks of therapy or in unexplained fever. Discontinue if fever, abnormalities in liver function tests, or jaundice appears. Since methyldopa causes fluorescence in urine samples at the same wavelengths as catecholamines, spuriously high levels of urinary catecholamines may be reported. This will interfere with the diagnosis of pheochromocytoma. Discontinue drug if involuntary choreoathetotic movements occur in patients with severe bilateral cerebrovascular disease. Anesthetics requirements may be reduced; hypotension occurring during anesthesia usually can be controlled with vasopressors. Hypertension may occur after dialysis because methyldopa is removed by this procedure.

Dosage should be limited initially to 500 mg daily when following previous antihypertensive agents other than thiazides. Do not exceed recommended daily dose of 3.0 g. Patients with impaired renal function may respond to smaller doses than patients with normal kidney function. Syncope in older patients has been related to increased sensitivity in those with advanced arteriosclerotic vascular disease; this may be avoided by lower doses. Tolerance occasionally seen either early or late, but more likely between second and third month after initiation of therapy; increased dosage or combined therapy with a thiazide frequently restores effective control.

Adverse Reactions: Sedation, usually transient, may be seen during initial therapy or when dosage is increased. Headache, asthenia, or weakness may be noted as early, transient symptoms. Symptoms associated with effective lowering of blood pressure, including dizziness, lightheadedness, and symptoms of cerebrovascular insufficiency, are seen occasionally. Angina pectoris may be aggravated. Symptoms of orthostatic and exercise hypotension may occur; if symptoms occur, reduce dosage. Bradycardia, nasal stuffiness, mild dryness of mouth, and gastrointestinal symptoms including distension, constipation, flatus, and diarrhea occur occasionally; these can be relieved by reducing dosage. Nausea and vomiting have been reported in only a few patients. Sore tongue or "black tongue," pancreatitis, and inflammation of salivary glands may occur.

Weight gain and edema occur infrequently; if edema progresses or signs of pulmonary congestion appear, discontinue drug. Rarely, urine exposed to air may darken due to breakdown of methyldopa or its metabolites. Other rare reactions include breast enlargement, lactation, impotence, decreased libido, skin rash, mild arthralgia, myalgia, paresthesias, parkinsonism, psychic disturbances including nightmares, reversible mild psychoses or depression, reversible thrombocytopenia, drug-related fever and abnormal liver function studies with jaundice and hepatocellular damage (see **Warnings** and **Precautions**), rise in BUN, and a single case of bilateral Bell's palsy.

Supplied: Tablets, containing 250 mg methyldopa each, in single-unit packages of 100 and bottles of 100 and 1000.

MSD
MERCK SHARP & DOHME

ADDENDUM

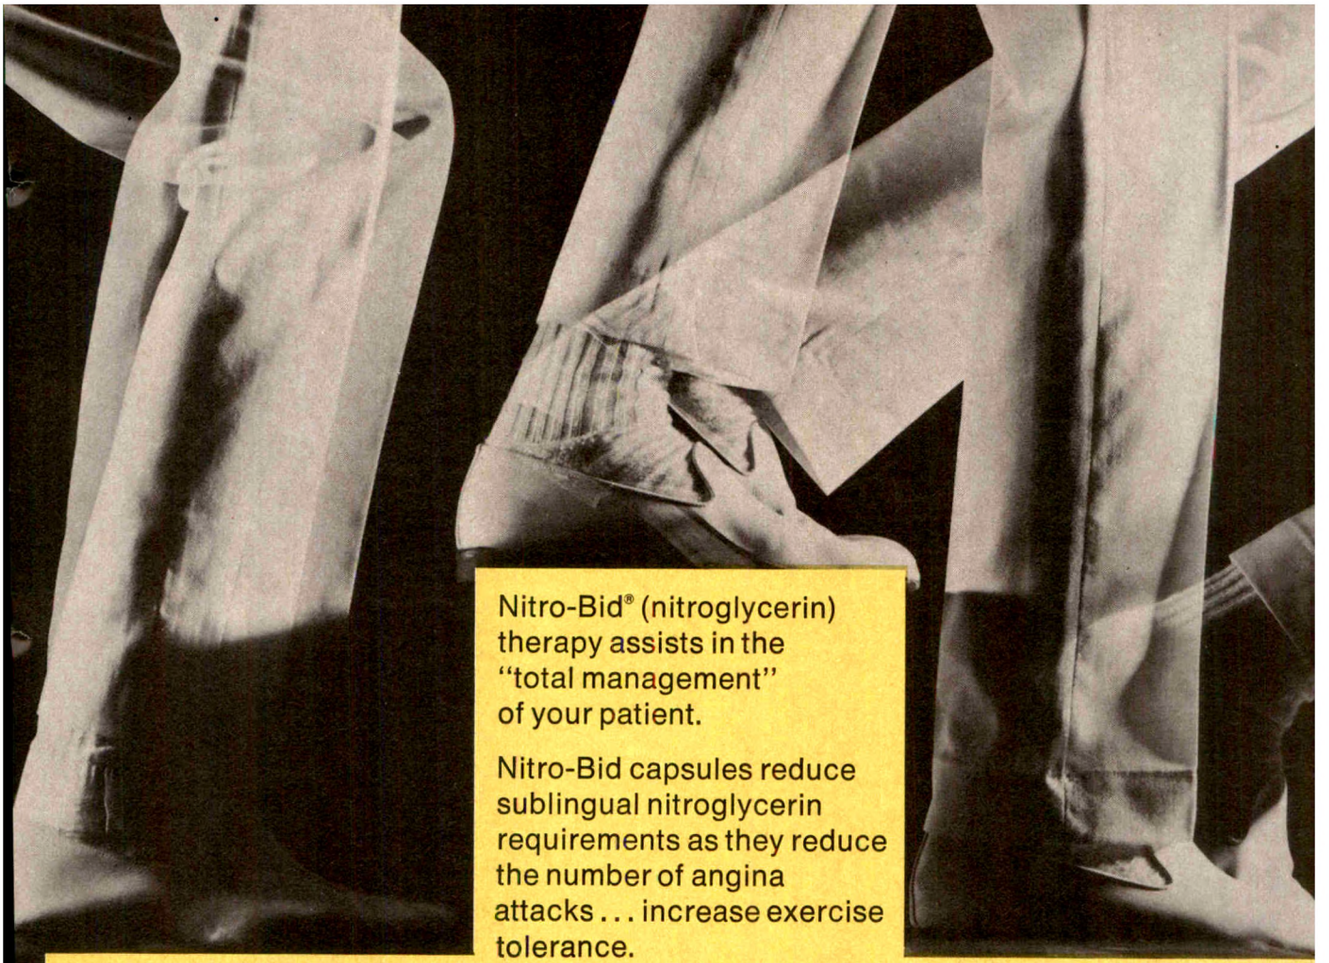
Let's make blood pressure "required reading" for all physicians.

With recent estimates that about 23 million Americans have high blood pressure—and that half of them are not even aware of it—detection of the problem in asymptomatic persons has become an issue of national importance.

Family physicians are being urged to take blood pressure readings as a matter of office routine, regardless of the presenting complaint or the reason for the visit. And because many people do not see a family physician for relatively long periods of time, some experts are suggesting that ophthalmologists, gynecologists, dermatologists, orthopedists, psychiatrists, dentists, school nurses, family planning counselors, and other health-care personnel make blood pressure reading a routine part of every examination or consultation.

Of course, a diagnosis of hypertension cannot be made on the basis of a single reading, but routine blood pressure readings can uncover potential trouble in a certain proportion of patients. And when trouble is suggested, further evaluation can be pursued more effectively.

Blood pressure—"required reading" for all physicians.



Nitro-Bid® (nitroglycerin) therapy assists in the "total management" of your patient.

Nitro-Bid capsules reduce sublingual nitroglycerin requirements as they reduce the number of angina attacks . . . increase exercise tolerance.

The Third Step in Angina.*

After the classic "2-Step" Test aids in a diagnosis of angina, sustained-release Nitro-Bid® (nitroglycerin) is a logical third step. Here's why.

In angina secondary to arteriosclerotic heart disease, sustained-release Nitro-Bid Plateau CAPS® provide a metered sequence of medication during the night to protect against nocturnal angina attack.

In titrating dosage, availability of different strengths "...is quite an asset..."[1]

Nitro-Bid 2.5 and Nitro-Bid 6.5 capsules afford two dosage strengths for convenience in increasing or decreasing dose to accommodate patient symptoms.

NITRO-BID® 2.5
(nitroglycerin 2.5 mg)
Plateau CAPS®

NITRO-BID® 6.5
(nitroglycerin 6.5 mg)
Plateau CAPS®

INDICATIONS

Based on a review of this drug by the National Academy of Sciences—National Research Council and/or other information, FDA has classified the indications as follows:

*"Possibly" effective:
For the management, prophylaxis or treatment of anginal attacks.

Final classification of the less-than-effective indications requires further investigation.

Contraindications: Recent myocardial infarction, severe anemia, glaucoma, increased intracranial pressure, idiosyncrasy.
Precautions: For ORAL, not sublingual, use. If blurring of vision or dryness of mouth occurs, discontinue drug. Tolerance may develop on long-term usage.
Adverse Reactions: Occasional transient headaches. Overdose may cause flushing, headaches, tachycardia, dizziness.
Dosage: One capsule two or three times daily at 8 to 12 hour intervals.
Reference: 1. Master, AM: The management of angina pectoris. *Modern Medicine* **38**:92-100 (Feb 23) 1970.

For the prevention of the gripping pain of angina*
Peritrate® SA
Sustained Action (pentaerythritol tetranitrate) 80 mg
A logical choice for the "new" patient with angina pectoris.
*This drug has been evaluated as possibly effective for this indication.
See brief summary on following page.

Peritrate® SA

Sustained Action
(pentaerythritol tetranitrate) 80 mg

Description: Peritrate (pentaerythritol tetranitrate) is a nitric acid ester of a tetrahydric alcohol (pentaerythritol).

Indications: Based on a review of this drug by the National Academy of Sciences—National Research Council and/or other information, FDA has classified the indications as follows:

"Possibly" effective: Peritrate (pentaerythritol tetranitrate) is indicated for the relief of angina pectoris (pain associated with coronary artery disease). It is not intended to abort the acute anginal episode but is widely regarded as useful in the prophylactic treatment of angina pectoris.

Final classification of the less-than-effective indications requires further investigation.

Contraindications: Peritrate SA Sustained Action (pentaerythritol tetranitrate) 80 mg is contraindicated in patients who have a history of sensitivity to the drug.

Warning: Data supporting the use of Peritrate (pentaerythritol tetranitrate) during the early days of the acute phase of myocardial infarction (the period during which clinical and laboratory findings are unstable) are insufficient to establish safety. This drug can act as a physiological antagonist to norepinephrine, acetylcholine, histamine, and many other agents.

Precautions: Should be used with caution in patients who have glaucoma. Tolerance to this drug, and cross-tolerance to other nitrites and nitrates, may occur.

Adverse Reactions: Side effects reported to date have been predominantly related to rash (which requires discontinuation of medication) and headache and gastrointestinal distress, which are usually mild and transient with continuation of medication. In some cases severe persistent headaches may occur. In addition, the following adverse reactions to nitrates such as pentaerythritol tetranitrate have been reported in the literature: (a) Cutaneous vasodilatation with flushing. (b) Transient episodes of dizziness and weakness, as well as other signs of cerebral ischemia associated with postural hypotension, may occasionally develop. (c) An occasional individual exhibits marked sensitivity to the hypotensive effects of nitrite and severe responses (nausea, vomiting, weakness, restlessness, pallor, perspiration and collapse) can occur, even with the usual therapeutic doses. Alcohol may enhance this effect.

Dosage: Peritrate SA Sustained Action (pentaerythritol tetranitrate) 80 mg (b.i.d. on an empty stomach), 1 tablet immediately on arising and 1 tablet 12 hours later.

Supplied: Peritrate SA Sustained Action (pentaerythritol tetranitrate) 80 mg, bottles of 100 and 1000 tablets.

Additional Dosage Forms: Peritrate (pentaerythritol tetranitrate) 10 mg and 20 mg tablets in bottles of 100 and 1000.

CLINICAL STUDIES

Natural History of Severe Proximal Coronary Artery Disease as Documented by Coronary Cineangiography

JOEL S. WEBSTER, MD*
CARL MOBERG, MD
GUSTAVO RINCON, MD

Cleveland, Ohio

Studying the natural history of patients with severe proximal coronary arterial lesions may assist evaluation of coronary revascularization surgery. We reviewed the mortality statistics of 469 patients with 80 to 100 percent occlusive lesions in the proximal coronary tree as diagnosed by selective angiography. Only patients with normal or moderately impaired left ventricular function were included in the study; patients with severe cardiomegaly, congestive heart failure or severe left ventricular impairment by left ventriculography were excluded. Follow-up periods ranged from 6 to 11 years for 178 patients with single vessel disease, 177 with double vessel disease and 114 with triple vessel disease. Patients with isolated disease of the left anterior descending artery had a 4 percent average yearly attrition rate or a 6 year mortality rate of 25.5 percent (17 of 69). Those with isolated disease of the right coronary artery demonstrated only a 2.3 percent yearly attrition rate or a 14 percent mortality rate in 6 years (11 of 77). Patients with double and triple vessel disease had, respectively, 41.5 and 63 percent 6 year mortality rates.

Survival was related to the number of vessels involved. Patients with single vessel disease of the left anterior descending artery had a significant annual mortality rate. The prognosis improved when good angiographic collateralization was present, particularly in single vessel disease with total occlusion. Functional disability, classified according to the New York Heart Association criteria, was related to mortality rates and proved a useful indicator in large patient groups. Prior myocardial infarction, location of the lesion above or below the major septal perforator in left anterior descending artery disease, and left main trunk lesions did not alter the prognosis significantly.

From the Department of Cardiovascular Disease and Cardiac Laboratory, The Cleveland Clinic Foundation and The Cleveland Clinic Educational Foundation, Cleveland, Ohio. Manuscript accepted October 17, 1973.

* Present address and address for reprints: Joel S. Webster, MD, Mercy Hospital, 2000 East Fifth St., Charlotte, N. C. 28204.

The purpose of our investigation was to determine survival and mortality rates in patients with severe proximal coronary arterial lesions documented by angiography. These patients received medical treat-

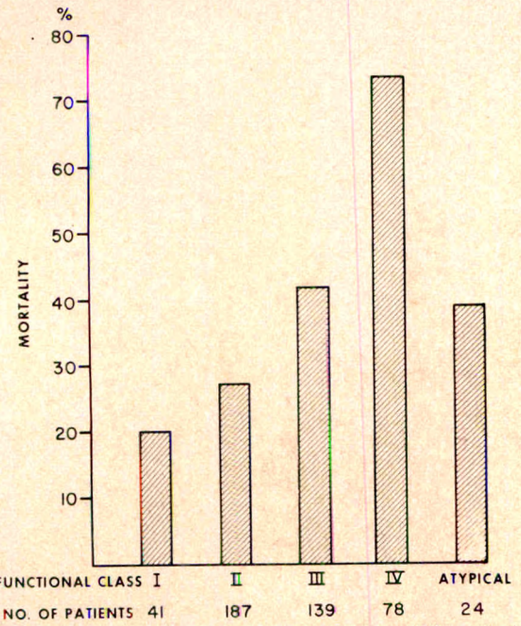

FIGURE 1. Functional class (New York Heart Association criteria) at time of cardiac catheterization related to 6 year mortality rates.

ment only. Patients with severe proximal lesions are often amenable to surgical intervention, and a study of their survival rates may help evaluate present and future surgical treatment for coronary artery disease.

Methods

Our angiographic criteria for case selection divided the series into three major groups: patients with single, double and triple vessel disease. Single vessel disease was defined as 80 to 100 percent occlusion of the right coronary, left anterior descending or left circumflex artery, and 50 percent or less reduction in lumen caliber in the other two vessels. Double vessel disease was considered 80 to 100 percent occlusion of two vessels with 50 percent or less obstruction in the third vessel. Triple vessel disease constituted 80 to 100 percent occlusive disease in all three major coronary arteries.

Ventriculography was not performed in 18 percent (88 of 469) of our patients in the early era of coronary arteriography but became a routine part of the examination by 1964. Patients with congestive heart failure, severe cardiomegaly or severe left ventricular impairment determined by left ventriculography were excluded, as were all patients with associated rheumatic or other cardiac disease. Only those with severe proximal lesions in dominant or major coronary arteries supplying the left ventricle were included in this study. Thus, a patient with a severe proximal lesion in a nondominant right coronary artery was excluded. Isolated left main trunk lesions were classified as double vessel disease of the left anterior descending and circumflex arteries. The Sones-Shirey cineangiographic technique was employed using selective injections in the right and left coronary arterial systems in multiple right and left anterior oblique views. Left ventricular angiography was usually performed in the right anterior oblique projection, and the left anterior oblique view was also obtained in patients with significant lesions of the left circumflex artery.

The completed follow-up study included 469 patients (424 men and 45 women) selected from 3,527 patients studied in the Cleveland Clinic Cardiac Laboratory between 1960 and 1965. During these years surgical treatment of coronary artery disease was in its infancy, and only a few patients underwent single internal mammary artery implantation for left anterior descending artery lesions. By present criteria, most of these 469 patients would be candidates for bypass graft surgery. Follow-up data were obtained by reviewing hospital and outpatient department records when available, and by letter or telephone communication with the referring physician and the patient or, when necessary, the patient's family. Of a total of 526 patients fulfilling the criteria, 469 (89.2 percent) were followed up for a minimum of 6 years (range 6 to 11 years).

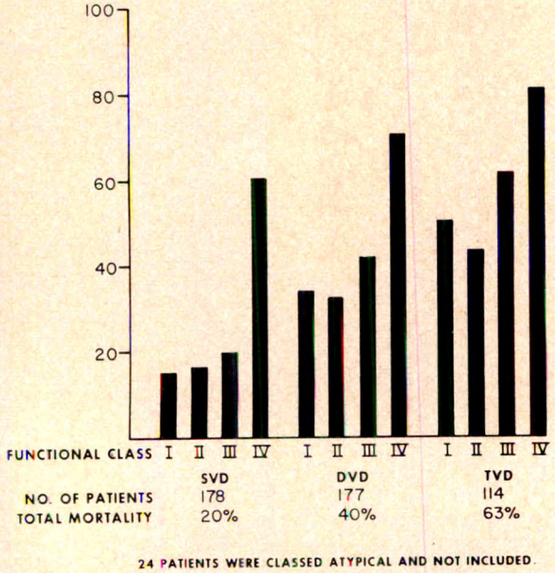

FIGURE 2. Six year observation of mortality related to functional class in patients with single (SVD), double (DVD) and triple (TVD) vessel disease. Percent mortality is on the ordinate.

Results

Our method of study resulted in different survival rates in each group. There was consistent agreement in assessment of the severity of the lesions by experienced interpreters using direct visual evaluation of the cineangiographic study. Opinion of even experienced observers is more variable when evaluating milder obstructive lesions. Finally, the simplicity of our criteria provided a basis for quick, easy communication and comprehension. Obviously, this is a clinical model used to evaluate survival statistics in a selected group of patients.

The 469 patients ranged in age from 28 to 69 years (median 49 years). The group can be characterized as white men aged 40 to 60 years with an average 2 year (range 2 months to 13 years) duration of symptoms before catheterization.

Relation between functional class, severity of disease and mortality: Patients were classified by functional capacity using the New York Heart Association criteria. The status of 24 patients was classified as atypical, characterized by bizarre chest pain or intermittent episodes of coronary insufficiency

with no symptoms between crises and no history of effort-related chest pain.

Figure 1 relates functional class to mortality. The majority of patients were in classes II and III. Mortality was related to the degree of functional disability; it was highest in patients with class IV angina. Figure 2 relates mortality to functional class and number of vessels involved. Patients with double and triple vessel disease, as anticipated, had the greatest functional disability and highest mortality rate. Relation of functional class to the presence of single, double and triple vessel disease (Fig. 3) demonstrated that 80 percent of class I patients had single vessel disease. Class II patients had predominantly single vessel disease and those in class III were equally divided among the three anatomic groups. Class IV patients usually had double or triple vessel disease. Thus, functional class is generally useful in predicting degrees of anatomic disease in large patient groups but, unfortunately, not in an individual patient. During the 6 year period of observation, the 288 survivors generally experienced an episodic course with exacerbations and remissions, and it was rare for a patient to remain asymptomatic. Thus, our subjects represent a broad spectrum of patients with symptomatic angina and all degrees of disability. Figure 4 summarizes the patients' functional status at the onset of the study and 6 years later according to the number of vessels involved.

Survival rates related to extent of coronary disease: One cannot assume all deaths were cardiac in origin but, in almost all cases, information received from the referring physician or the patient's family suggested that death was due to coronary artery disease. A survival curve for 1960 to 1965 for the American white male population aged 49 years and older reveals a 1 percent yearly attrition rate or a 6 1/2 percent total mortality rate in 6 years (U. S. Office of Vital Statistics). Thus, we can anticipate 30 deaths in 469 persons in the general white male population. By comparison, there were 181 deaths and a 6 year mortality rate of 38.3 percent in our series, a figure six times the anticipated death rate.

Figure 5 shows the life survival curves in patients with single, double and triple vessel disease; the calculated mortality rates were 20, 40 and 63 percent, respectively, for the three anatomic groups during the 6 year study period. Death occurred in 36 of 178 patients with single vessel disease, 73 of 177 with double vessel disease and 72 of 114 with triple vessel disease. Calculation of the average yearly attrition rate results in respective annual mortality rates of 3.3, 6.6 and 10 percent for the three groups.

Figure 6 shows the life survival curves for the 6 year study period in the subgroups with single vessel disease. There were 11 deaths in the 77 patients with right coronary artery disease (2.3 percent average yearly attrition rate). Patients with disease of the left anterior descending and left circumflex arteries experienced a considerably higher average annual mortality rate (4 percent for patients with left anterior descending artery disease and 4.2 percent for those with

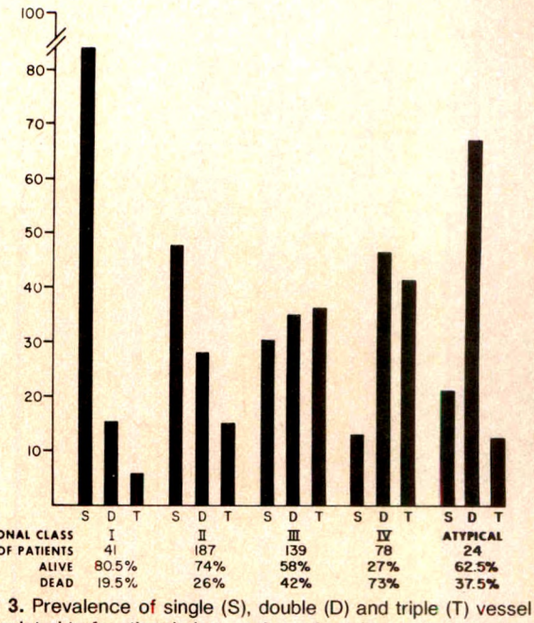

FIGURE 3. Prevalence of single (S), double (D) and triple (T) vessel disease related to functional class at time of cardiac catheterization, and 6 year mortality rate. Prevalence rate is on the ordinate.

left circumflex artery disease). Although the latter group was small, 8 of the 32 patients died, all over the age of 50 years. Patients with single vessel disease of the left anterior descending artery had a significant mortality rate at all ages.

There were three possible combinations or subgroups of patients with double vessel disease. Disease of the left anterior descending and right coronary arteries was the most common combination in our series, a finding consistent with the well known frequency of disease in the proximal left anterior descending and right coronary arterial systems. Mortal-

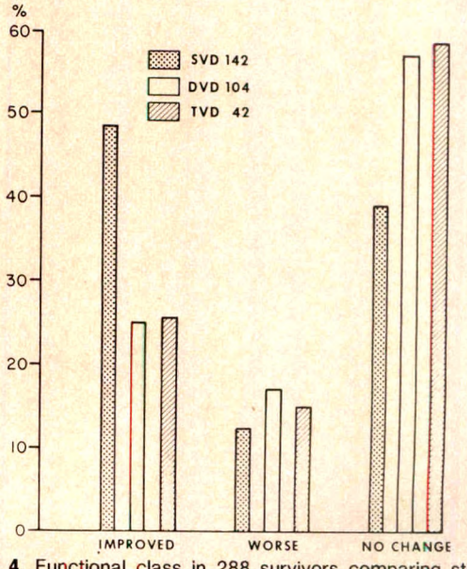

FIGURE 4. Functional class in 288 survivors comparing status at onset of study and 6 years later. SVD, DVD and TVD = single, double and triple vessel disease, respectively.

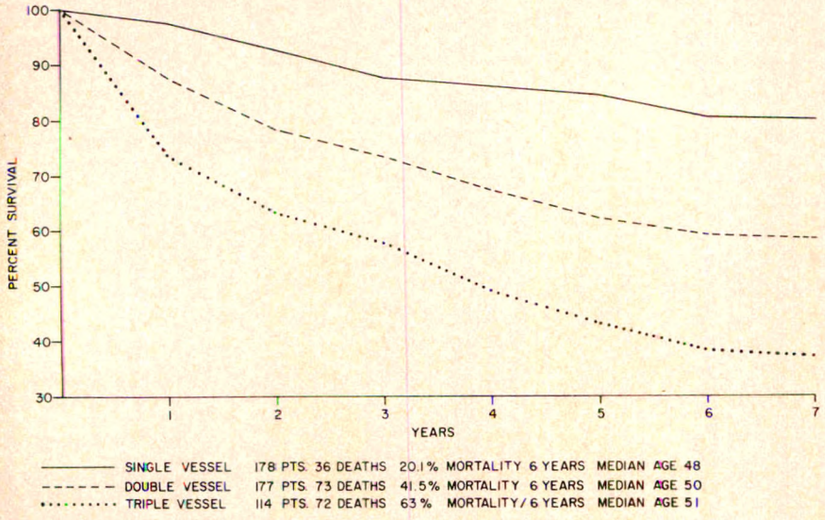

FIGURE 5. Survival rates in patients with single, double and triple vessel disease, at time of angiographic diagnosis. The lumen caliber was compromised 80 percent or more in each involved vessel.

ity rates were 35.4 percent (17 of 48) in patients with combined right coronary and left circumflex artery disease, 47 percent (24 of 51) for those with left anterior descending and left circumflex artery disease, and 41 percent (32 of 78) for those with right coronary and left anterior descending artery disease. Patients with combined lesions involving the left anterior descending artery had a slightly higher mortality rate than those with combined right coronary and left circumflex artery disease. However, mortality differences were not statistically significant among patients with the three combinations of double vessel disease.

Twenty-nine patients in our series had severe left main trunk lesions, 8 patients with isolated lesions and 21 with associated severe right coronary artery disease. The mortality rate was 50 percent (4 of 8) in patients with isolated left main trunk lesions and 71 percent (15 of 21) in those with associated right coronary artery disease. During the 6 year study period, the mortality rate was 47 percent for patients with combined left anterior descending and left circumflex artery disease and 63 percent for those with triple vessel disease. Thus the mortality rate was only slightly higher when a significant left main trunk lesion was present.

Those patients with left main trunk lesions underwent selective cardiac catheterization. Two patients in the group with combined left main trunk and right coronary artery disease died 1 and 3 days, respectively, after catheterization. These two deaths might have been related to catheterization, although both patients had coronary insufficiency and had class IV status before catheterization. Clinically, they seemed to tolerate the procedure well. In a previously reported series,[1] the mortality rate at the time of cardiac catheterization was 15.6 percent (5 of 32) in patients with severe left main trunk disease.

Left main trunk lesions must be treated with respect, and proper angiographic technique should

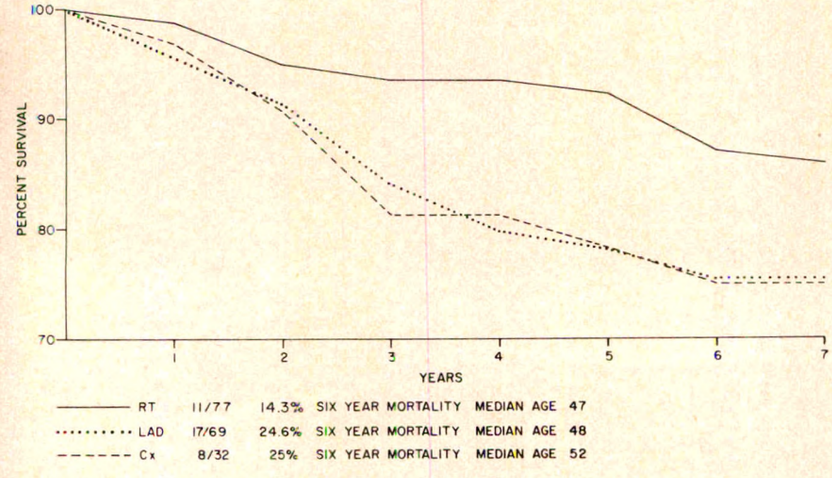

FIGURE 6. Survival rate in subgroups with isolated disease of the right coronary (RT), left anterior descending (LAD) or left circumflex (Cx) artery. Lumen obstruction was 80 percent or greater, as calculated at the time of angiographic diagnosis.

limit the number of injections in the ostium to those required for accurate diagnosis. However, caution and extreme care is necessary for all patients with triple vessel lesions or class IV status, or both. Our experience indicates that selective injection by the Sones-Shirey technique is safe in patients with left main trunk lesions when performed with due caution.

Age and sex: Factors that may influence survival are age, sex, presence of collateral circulation, location of the lesion above or below the major septal perforator in patients with left anterior descending artery disease, and prior myocardial infarction.

The death rates, in all decades, of patients with double and triple vessel disease were similar. This was also true of patients with single vessel disease of the left anterior descending artery. Figure 7 depicts mortality plotted against age before and after age 50. All patients with left circumflex artery disease died after age 50, and only 4 patients with right coronary artery disease died before age 50. The mortality in the group with left anterior descending artery disease was 23 percent before age 50 and 27 percent after age 50. Thus, age does not appear to influence survival in left anterior descending artery disease, perhaps indicating a more rapid rate of progression of disease in these patients.

As a group, women were equally affected by single, double and triple disease, and the death rate was parallel to that of men.

Collateral circulation: Collateral blood supply demonstrated by angiography was correlated with survival. We divided collateral circulation into two major categories. Good collateral supply was defined as clear opacification of the main trunk of an occluded or severely narrowed major coronary artery beyond the lesion and usually from a contralateral source. Poor collateral supply was defined as minimal or no opacification of the obstructed artery, with or without slight opacification of small secondary branches.

Figure 8 relates mortality to age and the presence or absence of good collateral blood supply demonstrated angiographically. Mortality from triple vessel disease was 63 percent in all age groups with or without angiographic evidence of good collateral circulation. In the group with double vessel disease, mortality rate was 38 percent in patients with good collateral circulation and 54 percent in those with poor collateral circulation (P <0.04). The mortality rate of patients with single vessel disease and good collateral supply was 15 percent in all age groups. That of patients with single vessel disease and poor or no collateral supply was also 15 percent before age 50; after age 50 the rate increased to 50 percent (P <0.00002). Thus, the older patients with single vessel disease and poor collateral supply did not fare well.

An important factor in evaluating collateral circulation is determining whether its source of origin is compromised or uncompromised. Usually the collateral blood supply arises from a contralateral coronary arterial source. Thus, in our series of patients with

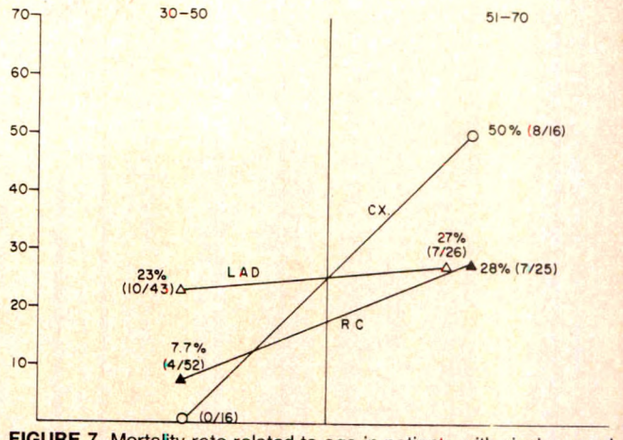

FIGURE 7. Mortality rate related to age in patients with single vessel disease. CX. = left circumflex artery; LAD = left anterior descending artery; RC = right coronary artery.

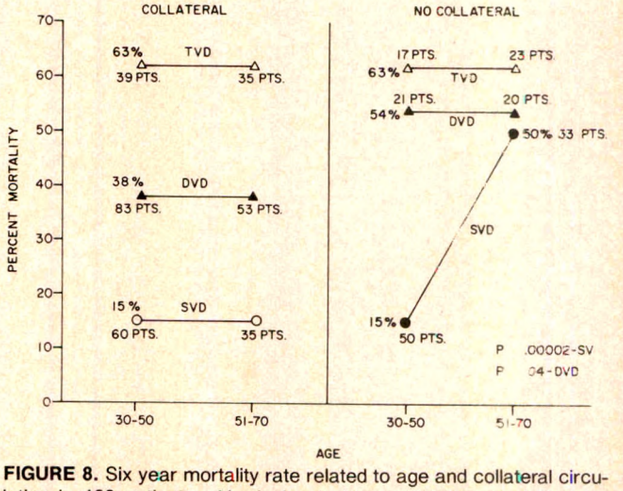

FIGURE 8. Six year mortality rate related to age and collateral circulation in 469 patients with single, double and triple vessel disease. SVD, DVD and TVD = single, double and triple vessel disease, respectively.

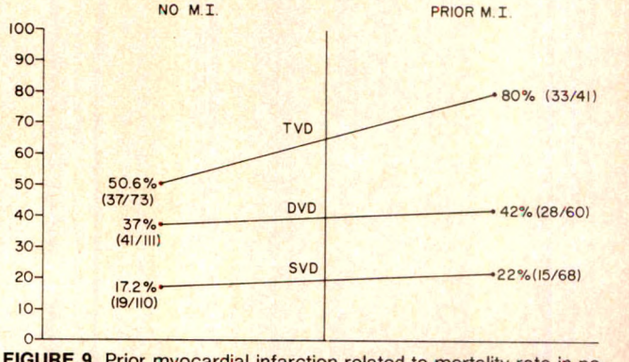

FIGURE 9. Prior myocardial infarction related to mortality rate in patients with single, double and triple vessel disease. SVD, DVD and TVD = single, double and triple vessel disease, respectively; M. I. = myocardial infarction.

single vessel disease collateral circulation was uncompromised at the time of the study. Patients with double and particularly those with triple vessel disease often have collateral circulation, but this is frequently compromised. Seventy percent of patients with double and triple vessel disease had angiographic evidence of collateral supply, indicating an intrinsic compensatory attempt to maintain adequate coronary perfusion. Previous reports[2–6] have demonstrated increased collateral blood supply in patients with double and triple vessel disease. Another interesting facet of single vessel disease and collateral protection was demonstrated in the 82 patients in our series with total occlusion of a single coronary artery. Eighteen patients in this group had poor collateral circulation manifested by angiography and 10 died during the 6 year study period, compared to 5 of the 64 patients with good collateral circulation, again demonstrating the protection offered by good uncompromised collateral blood supply.

Proximal vs. peripheral lesions: Empirically, severe lesions located proximal to the major septal perforator of the left anterior descending artery have been considered more serious than lesions peripheral to the major septal perforator. In our series of 69 patients with left anterior descending artery disease, 24 had the lesion above the major septal perforator, or compromising the ostium of the perforator, and 45 had the lesion below the major septal perforator. Mortality was 29 percent (7 of 24) in the first group and 21 percent (11 of 45) in the second group. Thus, the mortality rate was only 7 percent higher in patients whose lesion was in the more proximal position. The difference is not statistically significant.

Prior myocardial infarction: The number of vessels involved appears to be a more significant prognostic indicator than prior myocardial infarction. Prior myocardial infarction was defined as electrocardiographic evidence of transmural infarction, which was almost always supported by angiographic findings of scar tissue replacement. Patients with previous infarction and single and double vessel disease had the same survival rate as those without prior myocardial infarction. However, in those with triple vessel disease, mortality appeared greater in cases of prior myocardial infarction (Fig. 9). Since patients with triple vessel disease have a decompensated and threatened coronary circulation, it is not surprising that prior myocardial infarction might be an unfavorable prognostic sign.

Discussion

Clinical application of these data may be premature. However, surgical intervention in patients with double and triple vessel disease appears indicated because of the high average yearly attrition rate and poor 6 year prognosis with medical therapy only. Patients with double and triple vessel disease had 40 and 63 percent mortality rate, respectively, in 6 years. Relief of anginal disability is also a major goal in these patients.

Single vessel disease is a more complex problem. Prognosis appears to be excellent in patients with total occlusion of one vessel and good, uncompromised collateral blood supply and in patients with isolated lesions of the right coronary artery. Asymptomatic patients in these two groups are probably best managed medically. Since isolated disease of the left anterior descending artery is more lethal (4.0 percent average yearly attrition rate), surgical relief of the obstruction is more urgent unless uncompromised collateral circulation is present.

A study by Friesinger et al.[7] demonstrated an excellent prognosis in 32 patients with single vessel disease. However, the mean age of their patients was only 39.2 years and the severity of the lesion was poorly defined, ranging from 50 to 100 percent reduction in lumen caliber. In addition, no attempt was made to evaluate collateral blood supply and its possible role in increasing longevity. The total group was small, with even smaller subgroups, and the duration of the follow-up period averaged 54 months only. Therefore generalizations regarding prognosis from these data may be hazardous and may provide a false sense of security.

The ultimate role of surgery and other forms of treatment for coronary artery disease will be determined by careful follow-up of patients who have a clear morphologic diagnosis established by selective coronary angiography.

Addendum

Utilizing the data reported here as a control or comparison group Sheldon et al.[8] found improved longevity and functional status in a large group of patients who received bypass vein graft procedures for severe coronary arterial lesions. We hope that this basic information will prove of some value in evaluating current surgical interventions and perhaps newer evolving surgical and medical therapy for coronary artery disease.

Unstable Angina—Prospective and Randomized Study of Its Evolution, With and Without Surgery

Preliminary Report

CARLOS A. BERTOLASI, MD
JORGE E. TRONGÉ, MD
CÉSAR A. CARREÑO, MD
JORGE JALON, MD
MARCELO RUDA VEGA, MD

Buenos Aires, Argentina

A prospective and randomized study of 142 patients was undertaken to evaluate medical or surgical treatment in patients with unstable angina. The condition of each patient was classified according to one of three categories: intermediate syndrome (44 patients); progressive angina with and wihout previous infarction (53 patients); and postinfarction angina (14 patients). Of the 142 patients, 31 were excluded on the basis of specific criteria. A detailed research protocol, which included early blind random choice of medical or surgical therapy, was followed.

The results indicate the following: (1) It is possible to conduct a randomized study of patients with unstable angina, grouped in comparable categories; (2) these groups were statistically homogeneous in relation to the variables examined; (3) in spite of a mean follow-up time of only 8.3 months, the natural history of patients with an intermediate syndrome differed from that of patients with progressive angina, thus justifying the distinction; (4) patients with an intermediate syndrome treated surgically appeared to have a significantly reduced mortality rate and those who have survived surgery are in better clinical condition than medically treated patients; and (5) no such differences were found in patients with progressive angina, but a longer follow-up period is warranted.

In the past few years cardiologists have had to evaluate promptly new methods of therapy for coronary disease. Fowler[1] outlined clearly the problem when he stated: "If someone does not now perform adequately controlled clinical trials of [a new] procedure, in 10 years many lives perhaps will have been needlessly sacrificed and information may still be lacking for an objective decision about the place of this procedure in the management of either acute or chronic coronary artery disease."

Massive experience with several thousands of patients[2] followed up over the years will soon allow a precise and definitive evaluation of the merits of surgical revascularization of the myocardium in patients with chronic coronary artery disease. Quite a different challenge is that of assessing the efficacy of such surgical treatment in patients with any of the main clinical patterns of acute coronary disease: unstable angina or acute myocardial infarction or its complications.

In considering unstable angina, the first major problem is the lack of objective criteria for precise diagnosis. This is best shown by the fact that between the extremes of chronic stable angina and acute myocardial infarction there are many patients with clinical, hemodynamic and electrocardiographic changes that follow one of several comparable patterns. Second, information pertaining to the natural history of unstable angina, particularly over an extended period of time, is scarce and unreliable. Finally, since it is not easy to collect a large number of patients with this clinical syndrome, each research

project is limited to the size of a significant sample selected with accurate clinical criteria.

With these considerations in mind, in July 1970 we started a prospective study of all patients with unstable angina admitted to our coronary care unit, using the most precise definitions available. We report here our research procedure, and the means by which patients were assigned to comparable groups for valuation of different therapeutic programs. Although the follow-up period is too short for definitive assessment, our initial results show significant trends.

Material and Methods

Classification of Cases

The study began in July 1970, and the statistical evaluation continued until December 1972. There were 142 patients, with an average follow-up period of 8.3 months. Patients older than 68 years were not included in the study.

Unstable angina was considered to comprise three major categories: an intermediate syndrome, progressive angina and postinfarction angina.

Intermediate syndrome: A patient was admitted to the study under this classification if all of the following major criteria and at least two of the minor clinical criteria were met.

Major criteria: (1) Recurrent angina pectoris, prolonged and intense, not related to effort; (2) absence of extracardiac accessory factors; (3) normal serum enzyme levels or elevation below 50 percent of the normal maximum or 50 percent above basal levels; and (4) absence of severe pump failure or severe prolonged arrhythmias.

Minor criteria: (1) Little or no response to administration of nitrites; (2) transitory electrocardiographic changes of ventricular repolarization; (3) transitory cardiac arrhythmias; and (4) an interval of less than 1 month between onset of angina and admission to this study.

Progressive angina: A patient was admitted to the study under this category if no more than 3 months before the study he had experienced a change in the evolutionary pattern of angina, with an increase in the intensity, duration and frequency of pain but without the requirements postulated for the intermediate syndrome.

Postinfarction angina: This group included all patients who began to experience anginal attacks within the first month after an infarction.

The groups with the intermediate syndrome and progressive angina were further subdivided into two subgroups, patients with or without a previous infarct. In all instances the acute infarct had to have occurred at least 3 months before admission to the study.

Excluded patients: This group included all patients who met the clinical criteria but were later disqualified on other grounds. In some, arteriography disclosed no obstructive coronary artery disease or only minimal lesions; others were not candidates for direct myocardial revascularization (see Table VII).

Plan of Study

Phase A: This phase comprised three stages:

Stage 1: A patient with symptoms of possible coronary disease was admitted to the coronary care unit for a complete clinical examination, electrocardiogram, chest roentgenogram, phonocardiogram (in some cases), multistage exercise test (when indicated) and laboratory tests (serial determinations of serum glutamic oxaloacetic transaminase [SGOT], creatine phosphokinase [CPK] and lactic dehydrogenase [LDH]). Once all the results were evaluated, and if the criteria for admision to the study were met, a medical or surgical program of therapy was determined by blind random choice. In some instances the patient was referred to us with a previous clinical or surgical indication which was followed, but in all patients the decision was made before the angiographic study.

Stage 2: An angiographic study was performed by the Sones technique with 35 mm coronary cineangiography (Sones) and left ventriculography. The condition of each patient was graded according to a scale (Table I) we designed to facilitate statistical analysis. Obstructive lesions of the coronary arteries were considered in relation to their site, with classification of the right and left anterior descending coronary arteries into three segments, and the circumflex artery into the trunk, atrioventricular and lateral ventricular branches. Only obstructive luminal lesions of 70 percent or more were graded, and only the most important lesion of each vessel was considered. Collateral circulation influenced the grading by the addition of 4 points if absent, no points if poor, and the substraction of 4 points if good. The left ventriculogram was also graded according to the degree of anatomic or functional contractile change demonstrated.

Stage 3: Each patient was then presented to the surgical staff for determination of his suitability as a candidate for a direct revascularization procedure. At this stage a patient not considered a suitable candidate was classified in the "excluded" group. The surgical staff ignored the randomly chosen therapeutic prescription as it considered each case.

After a patient was accepted by the surgeons he entered either the surgical or the medical treatment program according to the decision made in Stage 1. He was offered the best medical treatment available, or whatever procedure the surgeons decided upon.

Medical treatment was adapted to the clinical state of each patient, following our usual protocol which included (1) surveillance in the coronary care unit for a minimum of 5 days, or 96 hours after the last significant complication; and (2) administration of the following agents: (a) nitroglycerin and long-acting nitrites; (b) analgesic agents, including opiates, if indicated; (c) sedatives (Diazepam®); (d) oxygen; (e) anticoagulant agents (heparin) unless contraindicated, particularly in young patients, the obese and patients with venous disease or a history of myocardial infarction; (f) digitalis and diuretic agents, only if there were signs of cardiac failure; and (g) beta adrenergic blocking agents (propranolol, 40 to 100 mg daily, and, more recently, practolol, 200 to 400 mg daily) in the absence of cardiac failure and depending on the tolerance of the patient.

Phase B: After each patient was finally assigned to a treatment group, he was followed up carefully until his return home. He was then reevaluated every 4 months (clinical examination, electrocardiogram at rest and with effort, using an ergometric bicycle) and graded clinically according to our follow-up index (Table II). After a year of follow-up studies, a new hemodynamic study was performed whenever possible.

In summary, the plan of study was as follows:

Phase A
- Stage 1
  - A. Clinical diagnosis
  - B. Random choice of therapeutic program
- Stage 2
  - A. Hemodynamic study
  - B. Acceptance of the case by the surgical group
- Stage 3
  - Medical or surgical treatment, as determined in Stage 1B

Phase B
1. Follow-up at 4 month intervals
   - A. Clinical evaluation
   - B. Electrocardiogram at rest and with graded effort
   - C. Updating of follow-up index
2. Hemodynamic study when feasible after 1 year

Finally, the data were examined statistically to determine if, on the basis of age, electrocardiographic changes and hemodynamic findings (coronary cineangiography and left ventriculography) the patients who underwent surgical treatment were indeed comparable to those who received only medical care.

Results

Clinical Features

This analysis will be limited to the 97 patients with the intermediate syndrome or progressive angina since only 14 patients had postinfarction angina. The mean age of the 97 patients was 53.3 years (range 34 to 68 years). Only 3 patients were women (Table III). The calculated t and P values suggested that the sample was homogeneous and without significant differences among the groups.

Four main risk factors were considered: arterial hypertension, diabetes, cigarette smoking and hypercholesterolemia. Their prevalence was similar to that found in patients with other types of coronary disease, and there was no significant difference among the groups.

Previous angina pectoris was a feature in all patients with progressive angina, but was present in

only 60 percent of those with the intermediate syndrome, being equal in each subgroup.

Electrocardiographic Findings

Basal electrocardiogram: There were no significant differences between patients with the intermediate syndrome and those with progressive angina, except for changes related to the presence or absence of a previous infarct. In all patients with the intermediate syndrome and no previous infarct there were changes of ventricular repolarization, most of them of the anterior wall. Eight patients with progressive angina and no previous infarction had a normal electrocardiogram.

Electrocardiogram during angina: The changes during an episode of angina pectoris in order of frequency were: (1) depression of S–T segment; (2) elevation of S–T segment (a finding more frequent in our series than in previously reported studies); (3) alterations of the S–T segment with arrhythmias; (4)

changes in intraventricular conduction, usually associated with changes in heart rate; and (5) T wave changes.

Hemodynamic Studies

All patients included in this study had obstructive lesions with luminal narrowing of 70 percent or more in at least one coronary artery. The left anterior descending coronary artery was the most frequently involved (94 of 97 cases) (Table IV).

Analysis of the left ventriculograms was based on a morphologic classification related to the extent of the ventricular wall involved and the degree of functional impairment of wall motion (akinesia, hypokinesia). There were two major groups (Table V). Group A included ventriculograms that revealed essentially normal findings or only minor lesions of wall motion. Group B included all ventriculograms demonstrating findings usually associated with a poor prognosis (akinesia, widespread dyskinesias, manifest hypokinesia of two walls, and the like). Almost all patients with previous infarction had obstructive lesions in at least two main coronary arteries, and their ventriculograms showed more ventricular wall damage than those of patients without infarction (Tables IV and V).

Finally, the hemodynamic data were examined together with the follow-up index described, and graded in relation to the mean for each group (Table VI). These results indicated no significant differences among the groups examined. Figure 1 illustrates three different left ventriculograms of patients with and without surgical treatment.

Excluded Patients

The need for this category indicates the importance of performing hemodynamic studies in research projects similar to ours. Table VII lists the angiocardiographic findings in this group. On the basis of these findings we excluded from surgery 10 patients

TABLE VII

Excluded Patients

Cause		Patients (no.)
A. Insufficient angiographic lesions		10
Single lesions of left circumflex artery	4	
Subaortic stenosis	2	
Aneurysm of coronary artery	1	
Hyperthyroidism and coronary spasm	1	
Normal coronary arteries	2	
B. Excessively severe angiographic lesion		5
C. Refused study		7
D. Other causes		9
Total		31

TABLE VIII

Mortality

	Patients (no.)	Mortality no.	Mortality %	χ^2	P
A. Intermediate syndrome					
Surgical treatment	24	2	8.5	4.09	<0.045
Medical treatment	20	7	35.0		
B. Progressive angina					
Surgical treatment	33	2	6.0	0.025	>0.87
Medical treatment	20	1	5.0		

with "insufficient" angiographic lesions and 5 patients whose demonstrable coronary disease was considered unsuitable for operation with use of the coronary bypass technique. In two cases, coronary arteriography demonstrated no coronary arterial alterations. In one, the patient had a uniform widespread diminution in the caliber of all coronary arteries and normal ventriculographic findings. In the other—a typical instance of progressive angina in a 44 year old man—the patient had marked electrocardiographic changes during episodes of severe pain and was studied twice by cineangiography to rule out errors in interpretation of the first film. A myocardial biopsy specimen showed only a striking increase in perinuclear lipofucsin-type pigment, as is seen in advanced cases of "senile heart."

Seven patients were excluded because they refused surgery. We excluded nine patients for "other" causes. Seven of these had a myocardial infarction between admission and definite inclusion in the study (two of these patients died). Two others,[5] permanent residents of a foreign country, experienced foreseen difficulties in remaining in the follow-up program.

Follow-Up Study

The average follow-up period of 8.3 months was not long enough to make definitive conclusions. In considering mortality rate (Table VIII), we grouped together patients with and without a previous infarc-

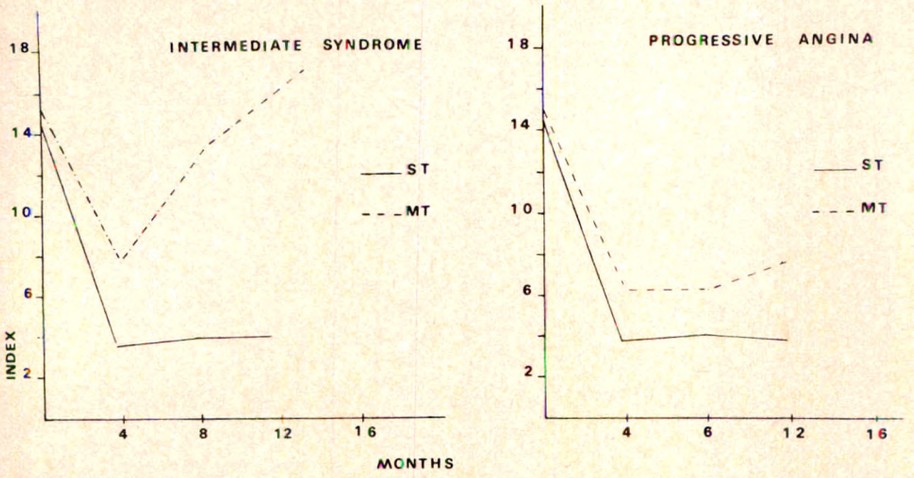

FIGURE 2. Clinical behavior of survivors after a year, in relation to the follow-up index (Table II). MT = medical treatment; ST = surgical treatment.

tion because of the small number of cases followed up for 1 year. In future studies, these two groups will be analyzed separately. Among patients with the intermediate syndrome, there was a statistically significant difference in survival rates with medical versus surgical treatment (65 vs. 95 percent). In contrast, patients with progressive angina had similar chances of survival with either mode of treatment.

Of the 57 patients operated on, only 4 died in the immediate postoperative period. To date, no late deaths have been recorded in the surgically treated group. Of the 40 patients treated medically, only 6 died in the acute period of their first hospitalization, and 2 died during the follow-up period, 8 and 6 months, respectively, after admission.

We considered of major interest an evaluation of the clinical state of the survivors. To this end, we used the index described in Table II, which grades changes in the findings of each patient examined at 4 month intervals. Figure 2 illustrates the lower scores achieved by the surgically treated patients, indicating improved clinical status.

Discussion

Classification of Patients with Unstable Angina

Unstable angina has been the subject of study since Sampson and Eliaser[3] and Feil[4] described the main clinical syndrome in 1937. Since then it has been reviewed under a variety of names: preinfarction angina,[5–7] intermediate coronary syndrome,[8,9] coronary insufficiency,[10] preinfarction syndrome,[11] premonitory symptoms of infarction,[12] unstable angina[13] and acute coronary insufficiency,[14] among others. However, we still lack reliable objective definitions that will allow grouping of patients in homogeneous categories. The need for such definitions has been emphasized by the availability of direct surgical revascularization procedures whose effectiveness must be proved or disproved.

There has also been disagreement about the true natural history of the disease. Several studies have shown a relatively good prognosis for patients with unstable angina. Fulton et al.[13] reported a mortality rate of 4 percent and a 15 percent rate of myocardial infarction. See et al.[20] recorded respective rates of 12 percent within the first year of onset, and Gazes et al.[21] followed up 40 patients with a first year mortality rate of 18 percent that 10 years later reached 40 percent. In contrast, Corday[22] reported a mortality rate of 50 percent, Beamish and Storrie[23] a rate of 60 percent and Vakil a rate of 23.7 percent with a 49.4 percent rate of infarction. These latter reports seem to indicate a high degree of risk in these patients. Since the marked discrepancies are clearly not due to faulty follow-up procedures, we must assume that each group of investigators described a population not comparable to others, perhaps because of different definitions of the patients included. Thus, our first aim was to establish clear-cut definitions that would describe as precisely as possible the subjects of our study.

We started by classifying unstable angina in three categories: the intermediate syndrome, progressive angina and postinfarction angina. To do this we drew on clinical experience gained from more than 2,000 patients admitted to our coronary care unit. Our hypothesis was that the clinical features of each group are different and are probably related to a different natural history. We excluded cases of angina of recent onset and angina of the Prinzmetal type.

The definition of the intermediate syndrome excluded patients with severe "pump failure." We believe that it is very rare to find shock or severe cardiac failure in association with an intermediate syndrome. Both occur rather frequently in subendocardial infarction, and to disregard this difference can be confusing during the first few hours of treatment.

We further subdivided each group of patients into those with and without previous myocardial infarction. Our preliminary data on the severity of coronary disease and the damage to ventricular wall motion seem to justify such a subdivision.

It is probably time to question the view of Blumgart et al.[25] in 1940 and Proudfit et al.[26] in 1967 that all patients with coronary disease have similar arterial lesions. Even if this hypothesis is true, we believe that clinical and physiopathologic behavior patterns allow the recognition of types of coronary disease of quite different evolutionary patterns and prognoses.

The protocol used in our study is complex, but we found no way to simplify the procedure. Our first problem was the decision to assign the therapeutic programs on a random basis. Our justification for making this difficult decision was that we honestly did not know at the start of the research program which group would be benefited or which would stand at a disadvantage. Furthermore, in daily practice a physician not totally convinced of a therapeutic measure often has to make a decision that later gives rise to serious doubts. We did not encounter the problem mentioned by Kayser,[27] that patients denied surgery would be lost to study because they would try to have surgery performed elsewhere. To date we have not lost a single medically treated patient to the follow-up study.

We agree with much of Kayser's description of the problems posed by a study of patients such as these. All methods used—random assignment of therapy, use of patients who refuse surgery as controls, individual preoperative or postoperative evaluation, study of patients with occluded grafts, or comparison of large groups—have important drawbacks. However, to study the features of acute coronary disease in which we are interested, the only method possible seems to be an analysis of carefully controlled small groups.

At the second stage of Phase A, a hemodynamic study was performed. Begg et al.[28] showed that the method could be used in acute cases, and we have not had any accidents due to the procedure. It may seem unnecessary to perform coronary arteriography on patients who will not be operated on. However, our findings indicate that any grouping of patients is valueless without angiographic evaluation. A research project such as ours cannot include as controls those patients without coronary disease or with minimal lesions, and there is no point in considering others with such severe disease as to contraindicate surgery. Even the most careful clinical selection will contain an error of approximately 10 percent. Of the 142 patients studied, 10 had minimal or no coronary disease, and 5 had extreme involvement; these findings created the need for a group of "excluded" cases.

The statistical comparison between patients who did and did not undergo operation revealed no significant differences on the basis of the data examined: age, clinical history, risk factors, coronary disease and ventriculograms. This requisite is essential to evaluate in the future the long-term prognosis of the disease. To this end we designed two indexes, one to gauge and compare the severity of coronary lesions and the ventriculograms, and the other to evaluate the evolution of survivors. Both indexes appear to be useful and valid.

Preliminary Results of Controlled Study

Long-term results undoubtedly require a longer follow-up period. At present we comment only upon some initial findings that have impressed us. First, it is apparent that there are important differences in the natural history of the intermediate syndrome and progressive angina, so that two separate clinical entities can be recognized that probably warrant a different therapeutic approach.

Second, as far as we can determine, mortality is significantly reduced after surgery in patients with the intermediate syndrome, and those surviving to date are in a better clinical condition. Nevertheless this result should be viewed with caution until the necessary time elapses to permit separate analysis of patients with and without previous infarction. We found no differences in mortality rates between medically and surgically treated patients with progressive angina, but a longer follow-up period is certainly warranted.

In the final stages of preparation of this manuscript our attention was drawn to an abstract on the same subject, by Théroux and Campeau.[29] These authors also found a difference in the natural history of the intermediate syndrome and progressive angina, and suggested the possibility of different therapeutic approaches. We do not know the method followed in their study, but it is interesting that their results seem essentially similar to ours.

Our purpose has been to demonstrate the feasibility of a strictly controlled study, and to find precise definitions valid enough to allow separation of homogeneous groups that can then be compared with each other. The use of indexes can be useful to this end. We expect that the continuation of our study will permit increasingly valid conclusions in due time.

Addendum

Since this paper was submitted for publication further cases were included in the study, up to March 31, 1973. The total number is now 162 patients, of whom 51 had the intermediate syndrome, 61 had progressive angina and 17 had postinfarction pain. In addition 33 other patients were excluded for the reasons given. The enlarged subgroups retain their original characteristics, and the results to date (July 1973) follow the pattern described.

Acknowledgment

Dr. René Favaloro and his team operated on these patients and the Department of Cardiovascular Disease and Cardiac Laboratory under Dr. Luis M. de la Fuente contributed valuable information. Dr. Luis Becú contributed significantly in the programming, discussion and development of our work, Professor Enrique Blaksley painstakingly reviewed the statistical analysis.

Right Ventricular Infarction

Clinical and Hemodynamic Features

JAY N. COHN, MD, FACC
NABIL H. GUIHA, MD*
MARTIN I. BRODER, MD†
CONSTANTINOS J. LIMAS, MD

Washington, D.C.

Six patients with acute myocardial infarction presented with hemodynamic evidence of predominant right ventricular failure, characterized by a mean right atrial pressure averaging 20.2 mm Hg and left ventricular filling pressure averaging 16.3 mm Hg. Autopsy in two cases revealed extensive involvement of the right as well as the left ventricle. Clinically the patients usually had evidence of diaphragmatic wall infarction, distended neck veins, hypotension and heart block. Pressure contours and mean pressure often showed no significant change as the catheter was advanced from the right atrium to the pulmonary artery. Shock in three patients was effectively treated with plasma volume expansion, to increase further right-sided pressure, or the administration of sodium nitroprusside, to reduce left-sided filling pressure. It is suggested that when right ventricular infarction accompanies left ventricular infarction, a unique clinical and hemodynamic syndrome occurs because the ability of the right ventricle to maintain adequate left ventricular filling is impaired. Recognition of this syndrome is vital if appropriate therapy is to be instituted.

Coronary artery disease usually involves the left ventricle, and acute myocardial infarction is almost always associated with hemodynamic evidence of predominant left ventricular dysfunction.[1] Although the right ventricle may be involved in a sizable proportion of patients dying with myocardial infarction,[2,3] the lesion is usually accompanied by left ventricular infarction. Isolated infarction of the right ventricle has been noted in less than 3 percent of autopsies revealing myocardial infarction.[2]

Little attention has been devoted to the circulatory events that might accompany infarction of the right ventricle. Since the studies of Starr and his associates[4] in 1943, it has generally been assumed that right ventricular damage does not significantly impair cardiac function. The circulatory failure that has been noted to complicate right ventricular infarction in a few autopsy cases has been attributed either to low input-output failure of the left ventricle[5] or to coexisting disease of the left ventricle.[6] Hemodynamic data in these patients have not been described.

While performing studies in patients with acute myocardial infarction we found six subjects with evidence of predominant dysfunction of the right ventricle. Two of these patients died with shock, and autopsy revealed extensive infarction of this chamber. These observations suggest that infarction of the right ventricle may result in a unique clinical syndrome. Since appropriate therapy for heart failure and shock complicating right ventricular infarction may be different from that for left ventricular infarction, differentiation is of considerable clinical importance. This report describes the clinical and hemodynamic findings that appear to be characteristic of infarction involving the right ventricle and offers an explanation for the observed heart failure.

TABLE I

Clinical and Hemodynamic Data in Six Patients with Right Ventricular Infarction

Case no.	Age (yr)	ECG	Chest X-ray	Cuff BP (mm Hg)	Pressures (mm Hg)					CI	Complications
					RA	RV	PA	PC	LVEDP		
1	63	DMI	Lungs clear	90/70	(16)	...	...	...	8	2.3	Complete heart block; shock despite dextran infusion; died
2	63	AMI	Pulmonary congestion	70/60	(18)	...	...	...	16	1.3	Complete heart block; shock; died
3	49	DMI	Pulmonary congestion	90/60	(28)	37/22	38/30 (32)	(28)	...	2.0	Frequent PVCs; survived
4	48	DMI	Lungs clear	90/60	(21)	30/19	30/19 (22)	(17)	...	2.6	Shock treated with nitroprusside; complete heart block; pacemaker; survived
5	52	DMI	Lungs clear	90/70	(20)	28/16	28/18 (22)	(16)	...	...	Shock treated with dextran; second degree heart block; pacemaker; survived
6	55	DMI	Lungs clear	80/60	(18)	30/15	30/15 (18)	(13)	...	...	Shock treated with dextran; complete heart block; survived

Figures in parentheses indicate mean pressures.

AMI = anterior wall myocardial infarction; BP = blood pressure (mm Hg); CI = cardiac index (liters/min per m²); DMI = diaphragmatic wall myocardial infarction; LVEDP = left ventricular end-diastolic pressure; PA = pulmonary arterial; PC = pulmonary capillary wedge; PVCs = premature ventricular contractions; RA = right atrium; RV = right ventricle.

Methods

Hemodynamic studies were carried out as part of the clinical management of patients with acute myocardial infarction admitted to the intensive care unit of the Washington, D.C. Veterans Administration Hospital. Written consent for the procedures was obtained after the patients were informed of the nature and purpose of the studies. The diagnosis of myocardial infarction was based on a history of acute chest pain accompanied by electrocardiographic evidence of myocardial injury or loss of forces and a typical pattern of elevated serum enzyme values. Studies were performed as soon as possible after hospitalization of the patient, usually within 24 hours of the onset of symptoms of acute myocardial infarction.

Left ventricular filling pressure was measured either as left ventricular end-diastolic pressure obtained by retrograde left ventricular catheterization[7] or as occluded pulmonary arterial pressure obtained by floating a balloon-tipped (Swan-Ganz) catheter into the pulmonary artery. Right ventricular filling pressure (mean right atrial or right ventricular end-diastolic pressure) was measured from a catheter advanced percutaneously from an antecubital or femoral vein. Pressures were recorded on a direct-writing Hewlett Packard recorder using Statham P23Db transducers positioned at the mid-chest. Cardiac output was determined by the indicator-dilution technique using indocyanine green dye and a Gilford or Waters cuvette densitometer. Withdrawn blood was reinfused after each output determination.

Results

The simultaneously measured right and left ventricular filling pressures in 78 patients with acute myocardial infarction are plotted in Figure 1. In 72 patients, left ventricular filling pressure (average 23.0 mm Hg) was greater than right ventricular filling pressure (average 10.1 mm Hg); in 6 patients, right ventricular filling pressure (average 20.2 mm Hg) was equal to or greater than the simultaneously measured left ventricular filling pressure (average 16.3 mm Hg). The ratio of right to left ventricular filling pressure averaged 0.47 ± 0.17 (standard deviation) in the 72 patients in the former group and 1.33 ± 0.36 in the 6 patients in the latter group ($P < 0.001$).

Clinical and hemodynamic observations in the 6 patients with predominant right ventricular dysfunction are outlined in Table I. None had symptoms or signs of primary pulmonary or pulmonary vascular disease or valvular heart disease. Patient 3 had had a previous myocardial infarction and had been treated with digitalis and diuretic agents for mild symptoms of congestive heart failure.

Clinical Observations

Three patients (Cases 3, 5 and 6) were admitted within 6 hours of the onset of typical substernal chest pain. Patient 4 was transferred from another hospital 18 hours after the appearance of symptoms of acute myocardial infarction. Patient 2 presented with the complaint of insidious weakness accompanied by mild chest pain during the previous 3 days. Patient 1

experienced shock 10 days after experiencing an acute myocardial infarction treated at another hospital.

All six patients had low auscultatory blood pressure on admission, including Patients 3 and 5 who gave a history of untreated hypertension before their acute illness (Table I). In five patients the diagnosis of shock was made on the basis of cool, clammy skin, disturbed sensorium, oliguria, or all three. Patient 3 had no signs of impaired peripheral blood flow and his arterial pressure increased spontaneously within the first 12 hours after hospitalization.

All six patients had marked systemic venous engorgement without orthopnea or significant shortness of breath. Chest X-ray film at the time of admission revealed clear lung fields in four patients and evidence of moderate pulmonary congestion in the other two.

Electrocardiogram

Five patients had electrocardiographic findings compatible with acute diaphragmatic wall infarction (Table I). In Patient 2, the electrocardiogram was consistent with anterolateral infarction.

Four patients had complete heart block, and one had second degree block within the first 24 hours after admission to the intensive care unit. Patient 1 died before normal rhythm could be restored; in Patient 6, administration of atropine and small doses of isoproterenol maintained an adequate ventricular rate until the block cleared. In the other three patients with block, a transvenous pacemaker was utilized to control ventricular rate for 48 to 72 hours.

Hemodynamics

Mean right atrial pressure was markedly elevated to levels ranging from 16 to 28 mm Hg (Table I). In two patients left ventricular catheterization revealed normal or only slightly increased left ventricular end-diastolic pressure. In the other four patients the pulmonary artery was catheterized. Systolic right ventricular and pulmonary arterial pressures were within the normal range, and pulmonary arterial diastolic and wedge pressures were only minimally increased in three patients. Patient 3 had the highest value for pulmonary wedge pressure (28 mm Hg), but even in this patient the left ventricular filling pressure was no greater than the mean right atrial pressure.

The demonstration of preponderant right ventricular failure in a patient with shock is highly suggestive of acute pulmonary embolization.[7] This diagnosis was suspected in Patients 1 and 2, who did not undergo bedside pulmonary arterial catheterization. Indeed, Patient 1 died in the catheterization laboratory while he was being prepared for emergency pulmonary arteriography. No pulmonary emboli were found at autopsy in either of these patients.

In the other four patients pressures recorded from the pulmonary artery revealed that the defect was not increased pulmonary vascular resistance but rather impaired pressure generation by the right ventricle. The mean level of pulmonary arterial pressure averaged only 2 mm Hg more than mean right atrial pressure. In three patients (Cases 4, 5 and 6), the contour of the pressure pulses remained practically identical as the catheter was advanced from the right atrium to the pulmonary artery. This finding produced some confusion during the blind catheterization with the balloon-tipped catheter, and it was necessary in each instance to document the location of the catheter by fluoroscopy or X-ray film. In Patient 4 repeat studies the following day in the catheterization laboratory using fluoroscopy and a Cournand catheter yielded identical results (Fig. 2).

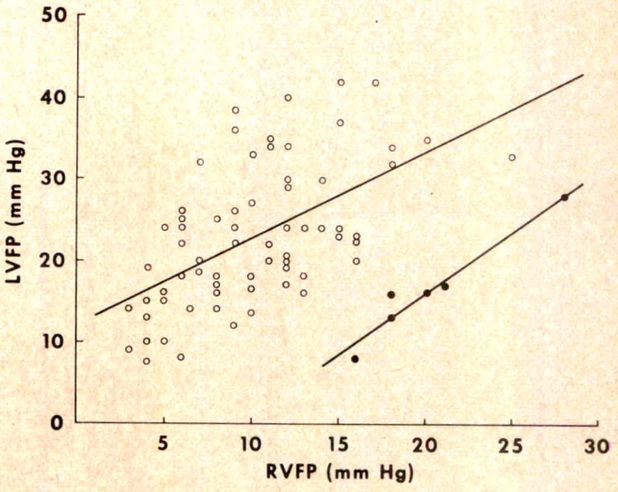

FIGURE 1. Simultaneous right ventricular filling pressure (RVFP) (mean right atrial or right ventricular end-diastolic pressure) and left ventricular filling pressure (LVFP) (left ventricular end-diastolic pressure or mean pulmonary wedge pressure) in patients with acute myocardial infarction. **Open circles** represent values in 72 patients with predominantly increased left ventricular filling pressure; **dots** represent 6 patients with predominantly increased right ventricular filling pressure. Regression lines for the two groups have been drawn.

Cardiac output, measured in four patients, was reduced in three and within the normal range in Patient 4. In Patients 1, 3 and 4, the hypotension seemed to be disproportionate to the modest reduction in cardiac output, and calculated total systemic vascular resistance was not elevated above normal levels.

Management of Shock

Because of the normal or near-normal left ventricular filling pressures, Patients 1, 5 and 6 were treated with rapid infusion of dextran, which increased arterial pressure and reduced the signs of impaired peripheral blood flow. Shock was corrected in Patients 5 and 6 but not in Patient 1, although cardiac index in this patient was increased to 2.5 liters/min per m^2. In Patient 4 shock was treated with an infusion of sodium nitroprusside which resulted in a marked improvement in peripheral blood flow.[8] In Patient 2 ar-

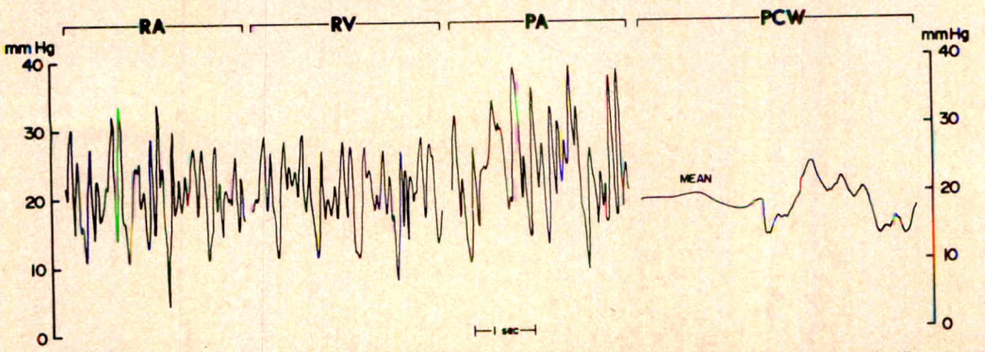

FIGURE 2. Case 4. Pressure tracings recorded on the second day of hospitalization as the catheter was guided under fluoroscopic control from the right atrium (RA) to the pulmonary arterial wedge position (PCW). Pressure fluctuations in the right ventricle (RV) and pulmonary artery (PA) were not synchronous with ventricular systole and probably represent the transmission of atrial pressure waves into the pulmonary artery through a noncontracting right ventricle.

terial pressure was maintained for approximately 24 hours with infusion of metaraminol, but the signs of shock were not corrected and he died. This patient was treated in 1969 before we understood the therapeutic implications of right ventricular infarction.

Autopsy Findings

Autopsy in Patient 5 revealed complete occlusion of the right coronary artery with extensive infarction of the posterior wall of the right ventricle, right atrial appendage and interventricular septum with extension to the posterior wall of the left ventricle. Mural thrombus was found in the right atrium and right ventricle. There was fibrinous pericarditis. Patient 2 had extensive disease involving all three coronary arteries with old and recent infarctions of the lateral wall of the left ventricle and patchy infarction involving most of the right ventricle. Mural thrombus was present in the right ventricle. No pulmonary emboli were identified in either patient.

Clinical Course

The four survivors had a relatively benign hospital course after the shock and rhythm disturbances cleared. All were able to walk without discomfort and were relatively asymptomatic at the time of discharge.

Patient 3 was recatheterized 3 weeks after his acute myocardial infarction. Mean right atrial pressure was reduced to 7 mm Hg, pulmonary arterial diastolic pressure was 14 mm Hg and pulmonary wedge pressure 9 mm Hg. The mean pulmonary arterial pressure was 18 mm Hg, so that the right ventricle was generating a mean pressure of 11 mm Hg compared to 4 mm Hg at the time of the first study. Cardiac index had increased only slightly to 2.2 liters/min per m^2. In Patient 4, right heart catheterization also was repeated 3 weeks after the first study, but the pulmonary artery was not entered. Mean right atrial pressure was 10 and right ventricular pressure was 20/12 mm Hg.

Discussion

Myocardial infarction involving the right ventricle has previously been diagnosed only at autopsy. Most of the reported infarcts have involved the posterior wall of the right ventricle, septum and adjacent left ventricle; they have usually been associated with occlusion of the main right coronary artery; and the electrocardiograms usually have been typical of posterodiaphragmatic wall infarction.[5,6,9] Occasionally, focal infarcts of the anterior wall of the right ventricle have been accompanied by electrocardiographic abnormalities consistent with anterior wall injury.[6] The circulatory failure observed in these fatal cases of right ventricular infarction has been attributed most often to involvement of the septum and left ventricle.[6] Thus, no specific circulatory pattern of right ventricular infarction has been recognized.

The six cases described here may represent the first instances of antemortem clinical diagnosis of right ventricular infarction. All patients presented with hemodynamic evidence of right ventricular failure disproportionate to left ventricular failure, an unusual finding in patients with acute myocardial infarction.[1] Catheterization data revealed that the right ventricle was generating very little pressure, and in three patients the pulmonary arterial tracing was nearly identical to that in the right atrium. Although right ventricular infarction could be documented anatomically only in the two patients who died, the typical clinical, electrocardiographic and hemodynamic features in the four survivors make it likely that these patients also had infarctions involving the right ventricle.

The absence of pressure generation by the right ventricle in these patients is reminiscent of the chronic right ventricular failure associated with Uhl's anomaly (parchment heart), in which the right ventricular myocardium is aplastic.[10,11] The transmission of right atrial *a* waves directly into the pulmonary artery without alteration by the right ventricle has been described both in patients with this syn-

drome[11,12] and in a patient with chronic right ventricular failure whose autopsy revealed extensive fibrosis of the right ventricle and a rudimentary right coronary artery.[13] The latter case may represent the chronic form of disability from right ventricular ischemic heart disease that was observed in its acute phase in our six patients.

Clinical features: The typical clinical features in our cases were electrocardiographic evidence of acute diaphragmatic wall infarction accompanied by hypotension and prominent venous engorgement complicated by the development of complete atrioventricular block. The heart block undoubtedly represents involvement of the region of the atrioventricular node supplied by the right coronary artery.[14] Previous human autopsy studies[6] and recent experimental data[15] have indicated that right ventricular infarction occurs only when the right ventricle is the site of preexisting hypertrophy. However, our patients had no signs or symptoms suggestive of previous right ventricular or pulmonary vascular disease although Patient 3 had had mild congestive heart failure.

It is unlikely that infarction was confined to the right ventricle in any of our patients. The only patient with a normal left ventricular filling pressure had autopsy evidence of infarction extending to the posterior wall of the left ventricle. In the other patients, left ventricular filling pressure (pulmonary wedge or left ventricular end-diastolic pressure) was slightly to moderately increased. Despite the presence of these features consistent with impairment of left ventricular function, right ventricular failure seemed to dominate the clinical findings. Symptoms of pulmonary congestion were absent in all six patients, and the lung fields were clear radiographically in four. Mean right atrial pressure was greater than left ventricular filling pressure in five patients and identical to left ventricular filling pressure in the patient with a history of previous myocardial infarction and chronic heart failure.

Hemodynamic consequences of right ventricular infarction and their treatment: The hypotension and reduced cardiac output in these patients could be attributed to inadequate left ventricular filling. In five patients the level of left ventricular filling pressure was below the 20 to 25 mm Hg range previously noted to provide optimal cardiac output in patients with left ventricular infarction.[16,17] In patients with normal right ventricular function, adequate pulmonary blood flow and filling of the acutely infarcted left ventricle usually can be maintained with only a slight increase in right atrial pressure.[1] However, when right ventricular contraction is severely impaired, as it apparently was in our patients, filling of the left ventricle is dependent on distension of the right atrium or right ventricle. Left ventricular filling could then be supported by any of these possible mechanisms: (1) increased right ventricular end-diastolic volume, which could augment contractile force of the residual functioning fibers in the damaged right ventricle; (2) increased right atrial contractile force, which might help to propel blood into the pulmonary artery in the absence of right ventricular contraction; or (3) passive flow along a right atrial-left atrial pressure gradient through the low resistance pulmonary vascular bed.[18] A similar modification of the pressure gradient to favor left ventricular filling could be accomplished if left atrial pressure were reduced to a greater extent than right atrial pressure.

These hemodynamic principles were utilized in selecting therapy for shock in four of our patients. Rapid intravenous infusion of dextran in three patients increased both right and left ventricular filling pressures and was thus effective in partly or completely restoring adequate arterial pressure and peripheral blood flow. In one patient shock was corrected by infusion of the vasodilator sodium nitroprusside, which increases systolic emptying of the left ventricle by reducing impedance to aortic flow.[8] The reduction of left atrial pressure during nitroprusside infusion therefore encourages enhanced inflow and increased cardiac output. The hemodynamic data and response to therapy in these patients are consistent with the hypothesis that they had left ventricular ischemic damage, causing a modest increase in left atrial pressure, perhaps in part because of a decrease in left ventricular compliance.[1,17] This left ventricular dysfunction probably would not in itself have precipitated circulatory failure but, because of the concomitant right ventricular damage, the right ventricle did not generate enough pressure to maintain optimal left ventricular filling in the presence of increased left atrial pressure.

Coexisting left ventricular damage may account in part for the increased central venous pressure and right ventricular failure observed in our patients in contrast to the nearly normal venous pressures noted by Starr et al.[4] after experimental right ventricular destruction. Tricuspid regurgitation due to dilation of the right ventricle or malfunction of the papillary muscles also can contribute to increased right atrial pressure. Nonetheless, the predominant right ventricular failure noted in our patients indicates that, contrary to the concept developed from Starr's observations, right ventricular damage produces evidence of right ventricular failure. Experimental evidence to confirm these clinical observations has been obtained in dogs studied in our laboratory.[19] However, unlike our patients, dogs subjected to massive destruction of the right ventricle may maintain nearly normal right ventricular and pulmonary arterial pressures.[19–21] It is not known whether these contrasting findings result from species differences, the effect of different modes or anatomic site of insult to the right ventricle, or the effect of concomitant left ventricular damage in our patients.

Prognosis: Although two patients with right ventricular infarction died with shock, three of the four survivors recovered from shock. This survival rate of 60 percent is considerably higher than we[1] and others[22] have reported in shock complicating left ven-

tricular myocardial infarction. Furthermore, studies repeated in two of these patients 3 weeks after the acute right ventricular infarction revealed that right-sided pressures had returned almost to normal. Patients with left ventricular infarction usually do not have normal left-sided pressures when restudied 3 weeks after infarction.[17] These observations suggest that the syndrome of shock that accompanies right ventricular infarction may be associated with less irreversible myocardial damage than shock accompanying left ventricular infarction. Data are not yet adequate to determine whether the hemodynamic improvement noted during convalescence represents recovery of right ventricular function or is the consequence of a passive reduction in right ventricular pressure due to a decrease in left ventricular filling pressure.

Incidence: The incidence of hemodynamically significant right ventricular infarction cannot accurately be assessed from our data. The patients with acute myocardial infarction submitted to study were not unselected, but rather represented primarily those with evidence of more severely disturbed cardiac performance. Since increased venous pressure, which was characteristic of the patients with right ventricular infarction, was one criterion used in selecting subjects for study, our data may overestimate the frequency of right ventricular involvement. Furthermore, the relation between predominant right ventricular failure and anatomic evidence of infarction of the right ventricle is unknown. Nonetheless, the 8 percent prevalence of right ventricular infarction based on hemodynamic observations in our study is not too dissimilar from the 14 percent prevalence of right ventricular involvement noted in previous autopsy studies[2] of patients with acute myocardial infarction.

Clinical management: Clinical recognition of right ventricular infarction may be important in patient management. Right ventricular infarction should be considered in any patient with an acute diaphragmatic wall infarction and evidence of systemic venous engorgement. Left ventricular or pulmonary arterial catheterization should be performed in such patients to document the severity of left ventricular dysfunction. Although the presence of distended neck veins in a patient with acute myocardial infarction is usually considered a contraindication to volume expansion, rapid infusion of dextran may reverse shock in these patients if left ventricular filling pressure is less than 20 mm Hg. If filling pressure is increased and if arterial pressure has not fallen to hypotensive levels, cautious administration of a vasodilator drug may reduce left atrial pressure and thus increase pulmonary flow.[8] Mechanical assist devices are now being used to manage shock complicating acute myocardial infarction, and counterpulsation with an intraaortic balloon could theoretically augment cardiac output by reducing left ventricular filling pressure even when right ventricular failure predominates. However, the technique is likely to be less effective than when it is used in massive left ventricular infarction, and our findings suggest that shock associated with right ventricular infarction may respond to less drastic measures.

Electrocardiographic and Serum Enzyme Changes of Myocardial Infarction After Coronary Artery Bypass Surgery

MALCOLM R. ROSE, MD
EPHRAIM GLASSMAN, MD
O. WAYNE ISOM, MD
FRANK C. SPENCER, MD

New York, New York

Serial preoperative and postoperative electrocardiograms were obtained in 50 patients undergoing coronary artery bypass surgery, 15 undergoing aortic valve replacement and 13 undergoing mitral valve surgery. Postoperative infarction was defined as the appearance of new Q waves on the postoperative electrocardiogram. Infarction occurred in 5 of 50 patients (10 percent) who underwent coronary artery bypass surgery. Age, preoperative hypertension or a pattern of left ventricular hypertrophy on the electrocardiogram did not correlate with infarction. Coronary disease was more severe in patients with than in those without infarction (mean of 3.2 vessels with 50 percent stenosis compared to 2.4 vessels). There was no correlation with bypass time or use of cross-clamping of the aorta during surgery. Postoperatively, 4 of 5 patients (80 percent) with infarction had serum values for glutamic oxaloacetic transaminase (SGOT) and creatine phosphokinase (CPK) of more than 200 and more than 2,000 international units, respectively, whereas 3 of 45 (7 percent) without infarction had this pattern ($P < 0.001$).

Of patients undergoing aortic valve replacement, 3 of 15 (20 percent) had postoperative infarction. All 3 of these patients had a serum glutamic oxaloacetic transaminase value of more than 200 and a creatine phosphokinase value of more than 2,000 units, compared to 2 of 12 (17 percent) without infarction. None of the 12 patients who underwent mitral valve surgery had postoperative infarction, and none had a serum glutamic oxaloacetic transaminase value of more than 200 or a creatine phosphokinase value of more than 2,000 units.

Myocardial infarction after coronary artery bypass surgery is more likely in patients with at least three-vessel disease but appears to be unrelated to pump time or aortic cross-clamping. Localized snaring or clamping of coronary arteries may be important. Postoperative serum glutamic oxaloacetic transaminase and creatine phosphokinase levels correlate with electrocardiographic evidence of infarction.

The rate of postoperative electrocardiographic evidence of infarction after internal mammary artery implantation into the myocardium has been reported to be about 20 percent.[1–4] Several recent reports have shown a similar rate of infarction pattern after coronary artery bypass surgery.[5–9] Although it has been shown that serum glutamic oxaloacetic transaminase (SGOT) and creatine phosphokinase (CPK) correlate with electrocardiographic evidence of infarction postoperatively, a recent communication[6] stresses the need for determination of creatine phosphokinase isoenzyme levels for accurate diagnosis of infarction.

This report describes a prospective study of 78 patients undergoing coronary bypass and valvular surgery. Evidence of infarction and other postoperative electrocardiographic changes are described in detail. Pre- and postoperative variables thought to be important in the

origin of infarction are evaluated, and postoperative electrocardiographic changes are compared with serum levels of glutamic oxaloacetic transaminase and creatine phosphokinase.

Methods

Preoperative and serial postoperative electrocardiograms were obtained in a consecutive series of patients undergoing operation by two cardiac surgeons at University Hospital from July 1972 to December 1972. Of 50 patients undergoing coronary artery bypass two had aortic valve replacement in addition. Of the 15 patients with aortic valve replacement, 4 had combined aortic and mitral valve surgery and 1 had repair of a ventricular septal defect. Twelve patients had mitral valve surgery and one had ventricular aneurysmectomy. For analysis, the latter patient is included in the group with mitral valve surgery.

Anesthesia was induced with thiopental sodium and succinylcholine chloride and subsequently maintained with halothane. Perfusion was at a flow rate of 2.25 liters/m^2 body surface area, temperature 30° to 34° C, using a Pemco roller pump and a Bentley disposable bubble oxygenator. The patients were heparinized with 300 units of heparin/kg body weight. The pump oxygenator was primed with 2,000 ml of Ringer's lactate solution and 1,000 to 1,500 ml of citrated blood. The pH of the citrated blood was adjusted to 7.4 with tromethamine (THAM®). In addition, 0.6 g of calcium chloride was given for each 500 ml of citrated blood, and 1 g of magnesium sulfate and 10 mEq of potassium chloride were added; 12.5 g of 50 percent glucose was added to the oxygenator.

Patients undergoing coronary bypass procedures either had electrically induced fibrillation with no aortic cross-clamping or intermittent aortic cross-clamping at 30° followed by 3 to 5 minutes of coronary perfusion. During aortic valve replacement, coronary perfusion was performed with silastic coronary cannulas at total flow rates of approximately 300 cc/min. Coronary perfusion was carried out for 3 to 5 minutes followed by ischemic periods of 10 to 15 minutes. Perfusion temperatures were 30° to 32° C.

Postoperative electrocardiograms were obtained on postoperative days 1 through 3, and then every several days until a stable pattern was noted. Tracings were obtained at least 1 week postoperatively in all patients. The tracings were evaluated independently by two of us. The criterion for definite transmural infarction was a Q wave not present

preoperatively of more than 0.04 second's duration, with or without corresponding S–T segment changes in one or more leads, and, for probable transmural infarction, a marked loss of R voltage in two or more leads without evidence of conduction block. S–T segment changes were not accepted as evidence for infarction but were listed under miscellaneous changes.

Patients were classified as hypertensive preoperatively if they had a history of hypertension requiring therapy or two independent blood pressure recordings with a systolic pressure of more than 140 or a diastolic pressure of more than 90 mm Hg. A diagnosis of left ventricular hypertrophy was made if the preoperative electrocardiogram showed an S wave in lead V_2 and an R wave in lead V_5 of 35 mv or greater with corresponding S–T and T wave changes in the left precordial leads. Preoperative angiograms were reviewed by the attending cardiology staff. Operative records were reviewed for duration of cardiac bypass and aortic cross-clamping and for perfusion pressures during bypass.

Serial serum glutamic oxaloacetic transaminase and creatine phosphokinase levels were obtained on postoperative days 1 through 3 in all cases, and for longer periods as indicated. Both enzyme levels were determined with use of the SMA-Flex system. The results were evaluated statistically using either Fischer's exact method for 2 by 2 tables or Student's *t* test.

Results

Coronary Artery Surgery

Of the 50 patients in this group, 4 had definite and 1 had probable transmural infarction postoperatively (Table I). There were three anterior and two inferior wall infarctions. All five patients manifested electrocardiographic evidence of infarction on postoperative day 1, and in each a bypass graft had been placed in the area of infarction. Among the 45 patients without an infarction pattern on the postoperative electrocardiogram, various changes were noted (Table I). Twenty patients showed changes in the T vector; in 13 patients the electrocardiogram was unchanged. The other changes listed were noted infrequently. Of particular interest are the two patients who demonstrated transient loss of R wave voltage or transient Q waves. In one case included under miscellaneous QRS changes, the precordial pattern changed from one of probable anterior infarction to one of normal precordial R wave progression.

There was no difference between patients with and without infarction in relation to the following preoperative variables: electrocardiographic evidence of previous infarction or left ventricular hypertrophy or clinical evidence of hypertension (Table II). The number of coronary vessels with more than 50 percent stenosis was greater in the group with infarction (3.2 vs. 2.7 vessels, Table III), and the majority of patients in each group had at least three-vessel disease. Although the distribution of diseased vessels was similar, three patients in the group without infarction had disease of the left main coronary artery compared to none in the group with infarction (Table II).

Patients with infarction had a mean of 3 bypass grafts; those without infarction averaged 2.4 grafts. All patients with infarction had three or more grafts compared to 27 of 45 patients without infarction. Each of the five patients with infarction had a single internal mammary artery bypass to the left anterior descending coronary artery in addition to the saphenous vein bypasses to the other vessels; 21 of 45 patients without infarction had one internal mammary artery bypass to the right or left coronary artery in addition to the other grafts, and five had double mammary artery bypass procedures. There was no significant difference in the prevalence of infarction between patients with and without internal mammary artery grafts.

Although mean cardiac bypass time was slightly longer in the group with infarction, the percentage of patients in each group with a pump time of more than 3 hours did not differ. Two of five patients with infarction and more than half of those without infarction underwent aortic cross-clamping. The mean duration of clamping time was shorter in the group with infarction, and none of these patients had a cross-clamping interval of more than 15 minutes; 13 of 24 patients without infarction underwent cross-clamping for more than 15 minutes. Perfusion pressures during cardiac bypass did not correlate with postoperative infarction.

There were significant differences between the two groups in peak serum glutamic oxaloacetic transaminase and creatine phosphokinase levels for postoperative days 1 through 3 (Table IV). Four of the five patients with infarction had serum glutamic oxalo-

acetic transaminase and creatine phosphokinase values of more than 200 and more than 2,000 international units, respectively; only 3 of 45 patients without infarction had this pattern ($P < 0.001$). Of these three patients, one had no change on the postoperative electrocardiogram, and the other two demonstrated T wave changes and deeper Q waves in leads II, III and aVF. Four of the five patients with infarction required vasopressors in the immediate postoperative period for prolonged hypotension, reduced central venous PO_2 or decreased urinary output; 24 of 45 patients without infarction received this therapy. Electrocardiographic evidence of infarction was present either before or within several hours after institution of vasopressor therapy. The two postoperative deaths occurred in the group with infarction. One patient had shock postoperatively and died with acute renal and hepatic failure and the other sustained cardiac arrest 4 days postoperatively with an area of posterior infarction noted at reoperation. Death secondary to Candida albicans sepsis occurred several months later. Electrocardiographic evidence of infarction was noted before these complications occurred.

Aortic Valve Surgery

Ten patients with isolated aortic valve replacement, four with combined aortic and mitral valve surgery, and one with aortic surgery and ventricular septal defect repair are included in this group. Two patients demonstrated definite infarcts on the postoperative electrocardiogram and one evidenced a probable infarct. The other electrocardiographic changes are listed in Table I. The distribution was similar to that in patients who underwent coronary artery bypass surgery. Preoperatively, hypertension and a pattern of left ventricular hypertrophy on the electrocardiogram occurred more often in patients with infarction (Table V). Only three patients had one-vessel coronary disease. The patients with infarction tended to have longer periods of bypass pump and coronary ischemia and greater perfusion pressures than those without infarction. The small numbers in this group preclude statistical evaluation. As in the patients who underwent coronary bypass, postoperative enzyme studies separated the two groups: 2 of 12 without infarction had serum values for glutamic oxaloacetic transaminase and creatine phosphokinase of more than 200 and more than 2,000 international units, respectively, whereas all of the patients with infarction manifested this pattern. In this group, the serum levels of these enzymes were generally higher than levels in the group undergoing coronary artery bypass (Table IV).

Mitral Valve Surgery

This group comprised 12 patients with rheumatic heart disease who had mitral valve surgery and 1 patient with left ventricular aneurysmectomy. No postoperative infarctions were noted; other electrocardiographic changes are listed in Table I. One patient had left bundle branch block postoperatively. The patient with left ventricular aneurysmectomy had three-vessel coronary disease, as did the patient with mitral valve replacement who had postoperative left bundle branch block. Eleven of 13 of these patients had aortic cross-clamping during surgery but none had coronary perfusion (Table VI). Mean pump time was less than in the groups that underwent coronary artery bypass or aortic valve replacement. None of these patients had a serum glutamic oxaloacetic transaminase value of more than 200 or a creatine phosphokinase value of more than 2,000 units (Table IV).

Discussion

Several studies[1–4] have demonstrated postoperative infarction in 17 to 20 percent of patients undergoing Vineberg procedures; only new Q waves were accepted as evidence of infarction. Recent reports suggest a similar rate of infarction after coronary bypass surgery. Brewer et al.[5] reported infarction in 17 percent of 220 patients surviving operation. When autopsy studies on patients dying at operation are included, the overall prevalence was 20 percent. Dixon et al.[6] noted infarction in 20 percent of 40 patients undergoing coronary artery bypass grafting. Anderson et al.,[7] using electrocardiographic and vectorcardiographic criteria for diagnosis, reported infarction in 17 percent of 46 patients undergoing coronary artery bypass surgery. Thirty percent of 44 patients

undergoing such surgery had new Q waves in the series of Espinoza et al.[8] Finally, Friedberg et al.[9] studied pre- and postoperative vectorcardiograms in 193 consecutive patients undergoing coronary artery bypass surgery and found evidence of infarction in 8 percent.

The frequency of infarction in the 50 patients undergoing coronary artery bypass in our series was 10 percent. Because the Q wave criterion alone was used, it is possible that subendocardial infarcts, manifested only by S–T and T wave changes, may have been missed. However, all of the series noted used similar criteria and thus the results may be compared. Except for Friedberg's series,[9] the reported rate of infarction after coronary artery bypass graft surgery ranges from 17 to 30 percent. Brewer et al.[5] included changes of left bundle branch block and left anterior hemiblock in their group with infarct. Only one patient in our series had left anterior hemiblock postoperatively. Similarly, although Brewer et al. included several operative deaths with autopsy-proved infarcts in their report, only one patient in our series died during coronary bypass surgery; autopsy was not performed. Patients in our series were not excluded from operation if total occlusion of a vessel was noted on angiograms and the distal vessel was not visualized, or if distal vessels were visualized but were severely reduced in diameter. Similarly, patients with increased left ventricular end-diastolic pressure and areas of left ventricular dyskinesis were included in our group, and the majority had disease of at least two coronary arteries. Therefore, our patients were not likely to be "better risks" than others studied. The wide range in reported occurrence of postoperative infarction may be related to differences in operative technique and establishment of patent saphenous vein-coronary artery anastomoses.

Mean clamping time (min)	20.5
Aortic clamping >15 minutes	4 of 13

* No patient who underwent mitral valve surgery had postoperative infarction.

Possible causes of postoperative Q waves: The presence of new Q waves postoperatively may be related to factors other than direct damage to the myocardium or compromised coronary arteries. Chamberlain and Edmonds-Seal[10] studied the effects of general anesthesia on 217 patients with evidence of either ischemia or left ventricular hypertrophy on the preoperative electrocardiogram. All 217 patients underwent nonthoracic surgery, and new Q waves were noted in 3. Topkins and Artusio[11] studied the effect of anesthesia and general surgery on 12,054 patients with no previous history of myocardial infarction and found postoperative infarction in 0.66 percent. Of 658 patients with a prior history of infarction, 6 percent had postoperative infarction.

Kline et al.[12] noted transient Q waves in 8 of 30 patients during coronary bypass surgery and offered several possible explanations, including hypothermia, transient ischemia and localized hyperkalemia. These factors would not explain persistence of Q waves postoperatively. In our series, however, we noted transient postoperative Q waves in 2 patients and S–T and T wave changes in 26. Pericarditis in the postoperative period also might explain some of these findings.

Correlation with coronary disease, perfusion time and aortic cross-clamping: Infarction may occur after cardiac surgery in patients without significant coronary artery disease. Infarction, defined as new Q waves, was noted in 8 of a series of 126 patients[13] undergoing aortic or mitral valve surgery; infarction correlated with perfusion time but not with aortic cross-clamping. In our series, infarction was noted in 3 of 15 patients undergoing aortic valve replacement, and only 1 of these 3 had single-vessel coronary disease. Thus, coronary disease is an unlikely cause of infarction in our group. No infarctions were noted in the patients undergoing mitral valve surgery. (Although the mean cross-clamping time was shorter in this group, coronary perfusion was performed only in the group undergoing aortic valve surgery.) The critical factor may be the left ventricular hypertrophy noted in the patients undergoing aortic valve replacement. Coronary perfusion may, in some cases, be inadequate to meet the oxygen requirements of the hypertrophied left ventricle.

Brewer et al.[5] observed significant correlations between postoperative infarction and the number of bypass grafts and operative pump time. In their series the group with infarction had more extensive coronary artery disease and a slightly longer mean pump time than the group without infarction, but the differences were not statistically significant. However, the number of patients with a pump time of more than 3 hours did not differ significantly in their two groups. In addition, only 2 of 5 patients in their group with infarction underwent aortic cross-clamping, a factor thought to be important in the genesis of

postoperative infarction. In patients without aortic cross-clamping, a dry operative field was obtained either by snares or bulldog clamps proximal and distal to the site of coronary anastomosis. This procedure may lead to localized trauma to the coronary arteries, with resultant infarction. The status of the coronary bypass graft is likely to be of critical importance in the development of postoperative infarction in the presence of damage to the native coronary circulation.

Value of serum enzyme determinations: Dixon et al.[6] have stressed the need for creatine phosphokinase isoenzyme determinations in the assessment of postoperative infarction, since serum creatine phosphokinase and glutamic oxaloacetic transaminase levels are elevated by musculoskeletal operative trauma. However, several reports have noted good correlation between postoperative electrocardiographic changes and serum glutamic oxaloacetic transaminase and creatine phosphokinase levels in patients undergoing the Vineberg procedure.[1–4] In our series, serum glutamic oxaloacetic transaminase and creatine phosphokinase values of more than 200 and 2,000 units, respectively, separated patients with infarction from those without infarction. Only one patient with infarction did not show this enzyme pattern, and there were three false positive values.

Prognosis: Brewer et al.[5] noted that patients with infarction did not have a more severe postoperative course after bypass grafting than those without infarction. In our series, the two postoperative deaths occurred in patients with postoperative infarction. Both the shock syndrome and cardiac arrest noted in these patients may have been directly related to myocardial necrosis after operation. Thus, postoperative infarction may result in any of the usual complications of infarction including reduced cardiac output and arrhythmia.

New Q Waves After Coronary Artery Bypass Surgery for Angina Pectoris

JAIME ESPINOZA, MD
JANET LIPSKI, MD
ROBERT LITWAK, MD, FACC
EPHRAIM DONOSO, MD, FACC
SIMON DACK, MD, FACC

New York, New York

Pre- and postoperative electrocardiograms were evaluated in 44 patients with angina pectoris who underwent single or multiple coronary artery bypass procedures. Two groups were identified: Group A, 37 patients with bypass procedures only, and Group B, 7 patients with bypass procedures and additional surgery (valve replacement in 4 and ventricular resection in 3).

Preoperative electrocardiograms showed abnormal Q waves in 14 of 37 patients in Group A and in 3 of 7 patients in Group B. After coronary artery bypass, new Q waves appeared in 11 of 37 patients (30 percent) in Group A, including 1 of 9 (11 percent) with one-vessel disease on preoperative coronary arteriograms, 7 of 20 (35 percent) with two-vessel disease and 3 of 8 (37.5 percent) with three-vessel disease; new intraventricular conduction abnormalities appeared in 4 of the 37. None of the seven patients in Group B had new Q waves postoperatively, but three had intraventricular conduction abnormalities. There was no correlation between new Q waves and preoperative values for left ventricular end-diastolic pressure. In Group A, new Q waves were demonstrated in 2 of 9 patients (22 percent) with one coronary bypass procedure, 5 of 21 patients (24 percent) with two bypass procedures and 4 of 6 patients (67 percent) with three bypass procedures. The single patient who had four coronary artery bypass procedures had no new Q waves after operation.

It is evident that the prevalence of new Q waves was greater in patients who had two- or three-vessel disease by coronary arteriography as well as in those who had three coronary artery bypasses. Postoperative clinical course and mortality were not affected.

Myocardial revascularization utilizing direct saphenous vein bypass graft has been used extensively, and several reports of postoperative electrocardiographic changes have appeared. Diethrich et al.[1] in 1968 reported electrocardiographic changes compatible with acute myocardial infarction in 11 of 40 patients (27.5 percent) who underwent the Vineberg procedure. The reported frequency of electrocardiographic changes compatible with myocardial infarction after coronary artery bypass has ranged from approximately 8 to 35 percent.[2–10] This electrocardiographic study was undertaken to assess the frequency of new Q waves after saphenous vein bypass surgery for occlusive coronary artery disease.

Material and Methods

The pre- and postoperative electrocardiograms, together with preoperative coronary arteriograms and left ventriculograms, were studied in 44 patients who underwent coronary artery bypass surgery at this hospital. Five other patients who died on the day of operation were not included because postoperative 12 lead electrocardiograms were not obtained. The study group comprised 37 men and 7 women whose ages ranged from 32 to 68 years.

Since S–T segment and T wave changes occur frequently after cardiac surgery and their specificity for myocardial infarction is doubtful, only the QRS complexes were analyzed during this period. The New York Heart Association's criteria[11] for an abnormal Q wave were used. Pre- and postoperative abnormal Q waves were analyzed. Preoperative coronary arteriograms were obtained in all patients. Arterial obstruction of greater than 50 percent was considered significant, and the number of arteries involved was tabulated. Left ventricular end-diastolic pressure, determined in 38 patients, was considered abnormal if it exceeded 12 mm Hg. Postoperative electrocardiograms were analyzed by at least four of us, and new Q waves were correlated with selective coronary arteriographic data, left ventricular end-diastolic pressures and the number of arteries bypassed.

The 44 patients were classified in two groups. Group A comprised 37 patients who had single or multiple coronary artery bypass procedures only. Group B comprised seven patients who had single or multiple bypass procedures and additional surgery: valve replacement in four (two aortic and two mitral) and ventricular resection in three (for ventricular aneurysm [2 patients] and idiopathic hypertrophic subaortic stenosis [one patient]).

Results

Preoperative Findings

Preoperative electrocardiograms indicated previous myocardial infarction in 17 patients, 14 of 37 in Group A (38 percent) and 3 of 7 in Group B (43 percent). The infarction was located in the inferior wall in 12, the anterior wall in 4 and the inferolateral wall in 1. Right bundle branch block was present in three patients, including one with evidence of old myocardial infarction. Twenty patients had S–T segment and T wave changes only, and five had normal electrocardiographic findings (Table I).

Coronary arteriograms in Group A disclosed one-vessel disease in 9 patients, two-vessel disease in 20 and three-vessel disease in 8 (Table II). In Group B, one-vessel disease was present in three patients, two-vessel disease in two and three-vessel disease in two. Previous myocardial infarction was present in 4 of the 12 patients with one-vessel disease (3 in Group A and 1 in Group B), 10 of the 22 patients with two-vessel disease (9 in Group A and 1 in Group B) and 3 of the 10 patients with three-vessel disease (2 in Group A and 1 in Group B) (Table II).

Postoperative Findings

Postoperative electrocardiograms revealed abnormal new Q waves in 11 of the 37 patients in Group A (30 percent) but in none of the 7 patients in Group B. Four patients in Group A (11 percent) had new conduction abnormalities, intraventricular conduction delay (three patients) and left bundle branch block (one patient) (Table III). In Group B, three of seven patients (43 percent) manifested a new left bundle branch block.

Of the 11 patients in Group A who had new Q waves, only 2 (18 percent) had electrocardiographic evidence of previous myocardial infarction. Before operation, three of these patients had three-vessel disease, seven had two-vessel disease and one had one-vessel disease (Table II). Preoperative left ventricular end-diastolic pressure data were available in 32 patients in Group A and in 6 patients in Group B (Table IV). In Group A, 23 patients had normal values and 9 had increased values (13 to 33 mm Hg). In Group B, two patients had normal values and four had abnormal values (13 to 23 mm Hg). After coronary artery bypass, 6 patients in Group A with previously normal left ventricular end-diastolic pressure manifested new Q waves, 2 had conduction abnormalities and 15 showed no change; of the 9 patients with abnormal left ventricular end-diastolic pressure, 3 manifested new Q waves and 6 no change. In the two patients in Group B with normal left ventricular

end-diastolic pressure, one had a conduction abnormality and one showed no change. In the four patients with abnormal left ventricular end-diastolic pressure, two had conduction abnormalities only (Table IV).

In Group A, correlation of electrocardiographic data with the number of arteries bypassed (Table V) disclosed new Q waves in 2 of 9 patients (22 percent) who had one coronary artery bypass procedure, 5 of 21 patients (24 percent) who had two bypass procedures and 4 of 6 patients (67 percent) who had three bypass procedures. The single patient with four bypass grafts manifested no electrocardiographic changes after operation.

Of the 44 patients studied, 42 were discharged from the hospital and 2 died. The presence of new Q waves did not appear to affect hospital mortality rate. One patient with new Q waves postoperatively had mediastinitis and intraventricular conduction abnormality and died of sepsis. The other patient manifested a postoperative intraventricular conduction disturbance on the electrocardiogram and died with shock secondary to a bleeding disorder.

Discussion

The overall frequency of postoperative myocardial infarction in 12,712 patients who underwent a general surgical procedure during a 5 year period at the New York Hospital was reported to be 0.95 percent.[12] In the presence of previous postoperative myocardial infarction this rate rose to 6.5 percent. Our study reveals that of 37 patients who underwent coronary artery bypass surgery alone, 11 (29.7 percent) manifested new Q waves.

Transitory Q waves may be seen on the electrocardiogram under various circumstances and may not represent myocardial necrosis. Q waves were observed after shock and severe metabolic stress by Shugoll,[13] after cross-clamping of the aorta and during the initiation of extracorporeal circulation by Klein et al.[14] and during atrial pacing by De la Fuente et al.[15] The explanations given by these investigators do not apply to our study since the new Q waves in our patients were not transitory but persisted at least until discharge from the hospital. We believe that these Q waves represent acute myocardial infarction occurring during or immediately after coronary artery bypass surgery.

There have been attempts to evaluate objectively the accuracy of diagnosis of acute myocardial infarction after thoracic surgery. Although many factors may affect serum enzyme values, several reports suggest that these values correlate well with the presence or absence of myocardial infarction.[1,16–19] However, our patients did not have serial postoperative enzyme studies.

The frequency of postoperative myocardial infarction in patients undergoing a Vineberg procedure for coronary artery disease ranges from 9 to 27.5 percent.[1,16,17,20] The reported frequency of acute myocardial infarction after coronary artery bypass surgery has varied. Dawson et al.[2] reported a rate of 22 percent (30 of 134), Brewer et al.[3] a rate of 20 percent (49 of 243), Sheldon et al.[4] a rate of 9 percent (9 of 100) and Hultgren et al.[5] a rate of 34 percent (17 of 50); the latter series represents a mixed group of saphenous vein bypass grafts, Vineberg and other revascularization procedures. More recently, Anderson et al.[6] reported a 17 percent frequency (8 of 46), Kansal et al.[7] a 10 percent frequency (15 of 151) and Williams et al.[8] a 23 percent frequency (23 of 100). Vectorcardiographic analysis of acute myocardial infarction revealed a 6 percent prevalence (6 of 100) in the study of Friedewald et al.[9], an 8 percent prevalence (15 of 193) in that of Friedberg et al.[10] and a 35 percent prevalence (6 of 17) in that of Anderson et al.[6]

Selection of patients may be a significant factor in these differences since, in our patients with extensive disease requiring more than one bypass, acute myocardial infarction occurred more frequently than in those with less severe disease. The time that patients remained under extracorporeal circulation during operation was implicated by Brewer et al.,[3] who found that myocardial infarction occurred more frequently

UNIVERSITY OF COLLEGE OF MEDICINE LIBRARY

in patients who had more than 120 minutes of pump time.

The anoxic arrest of 10 to 15 minutes for each coronary artery anastomosed may be a significant factor in a patient with severe preexisting coronary artery disease. This was manifested in our study by a greater prevalence of new Q waves in patients with three coronary artery bypasses (67 percent) than in those with one or two bypasses (22 and 24 percent, respectively). Technical factors may also play a role in the development of myocardial infarction and should be evaluated and analyzed further. Recently a high rate of myocardial infarction after combined coronary endarterectomy and coronary artery bypass was reported,[2,21] but only one patient in our series had this procedure.

Nine of our patients who had no previous electrocardiographic evidence of myocardial infarction manifested new Q waves. However, of 14 patients with electrocardiographic changes of previous myocardial infarction, only 2 had new Q waves. New intraventricular conduction abnormalities that developed in four patients in Group A made the diagnosis of acute myocardial infarction impossible. Therefore, this change may have masked a higher frequency of new Q waves. None of the seven patients in Group B had new Q waves; however, four had new conduction abnormalities that may have masked the electrocardiographic findings. Electrocardiographic changes did not correlate significantly with preoperative left ventricular end-diastolic pressure data.

In conclusion, it appears that the greater the severity of coronary artery disease, the greater the prevalence of myocardial infarction after saphenous vein bypass surgery. The immediate operative mortality in our series was not affected. These electrocardiographic changes require further evaluation by longer follow-up studies, and their ultimate clinical significance should be considered in the overall evaluation of coronary artery bypass surgery.

Correlation of Serum Magnesium Levels and Cardiac Digitalis Intoxication

GEORGE A. BELLER, MD
WILLIAM B. HOOD, Jr., MD
THOMAS W. SMITH, MD
WALTER H. ABELMANN, MD, FACC
WARREN E. C. WACKER, MD

Boston, Massachusetts

A prospective study was undertaken to compare the prevalence of hypomagnesemia and hypermagnesemia in patients with cardiac digitalis toxicity and in digitalized patients without toxicity. During an 8 month period on a general medical service, there were 38 patients with "definite" or "possible" digitalis toxicity, by serial electrocardiographic studies, among 120 digitalized patients whose serum magnesium levels were obtained. Serum magnesium concentrations were measured by atomic absorption spectrometry.

Hypomagnesemia was present in 21 percent of patients with and 10 percent of those without digitalis toxicity. Hypomagnesemia was not more prevalent in patients with toxicity but relatively lower serum levels of digoxin or digitoxin. The presence of hypermagnesemia was significantly greater in patients with toxicity (18 percent) than in those without toxicity (5 percent), and appeared to be related to a significantly greater prevalence of abnormal renal function in the former group. The potential value of magnesium administration in hypomagnesemic patients with cardiac digitalis toxicity warrants investigation. Caution should be exercised in the administration of magnesium sulfate to digitalis-toxic, azotemic patients who may already be hypermagnesemic.

It has been suggested that hypomagnesemia may contribute to the development of digitalis intoxication.[1–4] Animals made chronically magnesium deficient by diet[5–7] or rendered acutely hypomagnesemic by hemodialysis with a magnesium-free dialysate[3] show an increased sensitivity to digitalis with a lower threshold for toxic rhythm disturbances. A significant decrease in serum magnesium concentration has been reported in patients with congestive heart failure, and has been attributed to an increase in urinary magnesium excretion induced by diuretic agents.[8–11] Hypomagnesemia has been reported in patients with clinical digitalis intoxication,[3] and parenterally administered magnesium has suppressed rhythm disturbances caused by digitalis in both man and animals.[1,3]

The prospective study described here was undertaken to compare the prevalence of hypomagnesemia in patients having cardiac digitalis toxicity with that in digitalized patients without toxicity. Detailed epidemiologic data in these patients have been reported previously.[12]

Methods

All admissions to a single medical service were surveyed for an 8 month period. Drug histories were obtained on admission to determine whether a patient was taking a digitalis preparation up to at least 48 hours before entry. The prevalence of cardiac toxicity was determined by electrocardiographic criteria defined before the inception of the study. Patients manifesting ectopic ventricular arrhythmias, atrioventricular junctional escape or accelerated rhythms, paroxysmal atrial tachycardia with atrioventricular block, Mobitz type I second degree atrioventricular block or sinoatrial exit block were

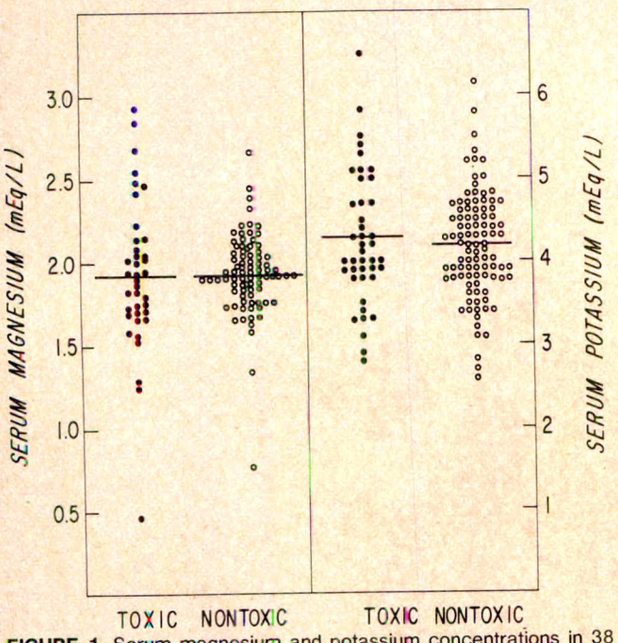

FIGURE 1. Serum magnesium and potassium concentrations in 38 patients with definite or possible digitalis toxicity and 82 patients without toxicity.

considered to have *definite* digitalis toxicity if the rhythm disturbance disappeared with discontinuance or reduction in dose of digitalis. Patients were considered to have *possible* toxicity if the aforementioned rhythm disturbances were only partially resolved with discontinuation of the drug or were associated with concomitant changes of acute myocardial infarction or ischemia, or if the patient left the hospital before complete serial electrocardiographic tracings could be obtained.

During the 8 month period of surveillance, 34 patients fulfilled the criteria for definite digitalis toxicity, and 9 patients were judged to have possible toxicity. During this period, 96 digitalized patients were admitted with no evidence of cardiac toxicity. Serum magnesium concentrations were measured by atomic absorption spectrometry[13,14] in 30 patients with definite and 8 with possible toxicity and 82 patients without toxicity admitted to the study; these patients represented 88 percent of the entire group. The accuracy of the serum magnesium measurements was determined by performing the analysis with use of both emission flame and atomic absorption spectroscopic techniques. Measurements of the same sera by the two methods gave virtually identical results using National Bureau of Standards certified standards.[13] The serum magnesium values were made known to the clinical investigators only after completion of the initial epidemiologic study[12] and were then correlated with clinical and biochemical data obtained from these patients. Serum magnesium determinations were performed in 16 healthy male volunteers, and the mean concentration in this group was 1.96 ± 0.26 (±2 standard deviations) mEq/liter. This range is comparable to normal values previously reported from this laboratory.[13,15,16] Hypomagnesemia was therefore defined as a serum magnesium level lower than 1.70 mEq/liter, which is 2 standard deviations below the mean for the control group.

Data pertaining to the type and dose of digitalis, supplementary medications such as diuretic agents, and clinical diagnoses were collected from patients with and without toxicity on admission to the study.

Blood urea nitrogen, serum creatinine, sodium (Na^+), potassium (K^+), chloride, bicarbonate and calcium were determined by standard laboratory techniques.

Duplicate determinations of serum digoxin and digitoxin concentrations were performed in the digitalized patients by radioimmunoassay methods previously reported.[17–19] Sera drawn from patients taking digitalis leaf were assayed for digitoxin concentration.

The means or prevalence percentages of all data were compared by Student's t test or the chi square test, where appropriate.

Results

Hypomagnesemia: Serum magnesium and potassium concentrations in the 30 definitely toxic, 8 possibly toxic and 82 nontoxic patients in whom these measurements were made are shown in Figure 1. Mean (± standard deviation) serum magnesium concentration was 1.93 ± 0.47 mEq/liter in patients with clinical toxicity (definite and possible) and 1.92 ± 0.24 in patients without toxicity. Thus, there was no significant difference between the two groups in mean serum magnesium or serum potassium values. However, the prevalence of patients with hypomagnesemia was two-fold greater in the group with digitalis toxicity ($0.05 < P < 0.10$). Hypomagnesemia (serum magnesium less than 1.70 mEq/liter) was found in 8 of 38 patients with definite or possible toxicity (21 percent) and in 8 of 82 patients without toxicity (10 percent). Hypokalemia, defined as a serum potassium value less than 3.5 mEq/liter, was present in 6 of the 38 patients with toxicity (16 percent) and in 11 of the 82 without toxicity (14 percent) (not significant). However, the combination of hypokalemia and hypomagnesemia was present in only one patient with toxicity and in no patient without toxicity.

There was no significant difference between use of diuretic agents in hypomagnesemic patients (56 percent) and in patients with normal or elevated serum magnesium levels (52 percent). Nineteen percent of digitalized hypomagnesemic patients were judged to be alcoholic, compared to a 7 percent prevalence of alcoholism in patients with normal or elevated serum magnesium levels (not significant). Twenty-five percent of hypomagnesemic patients and 28 percent of those with elevated or normal magnesium levels were diabetic. No patient had diabetic ketoacidosis when blood was drawn for serum magnesium determination. Only one patient in either group had clinical and laboratory evidence of intestinal malabsorption, and this patient had no digitalis toxicity and a normal serum magnesium concentration. Thus, there was no significant difference in the prevalence of diuretic administration, acute or chronic alcoholism, diabetes mellitus or malabsorption syndrome between hypomagnesemic patients and patients with normal or elevated serum magnesium levels.

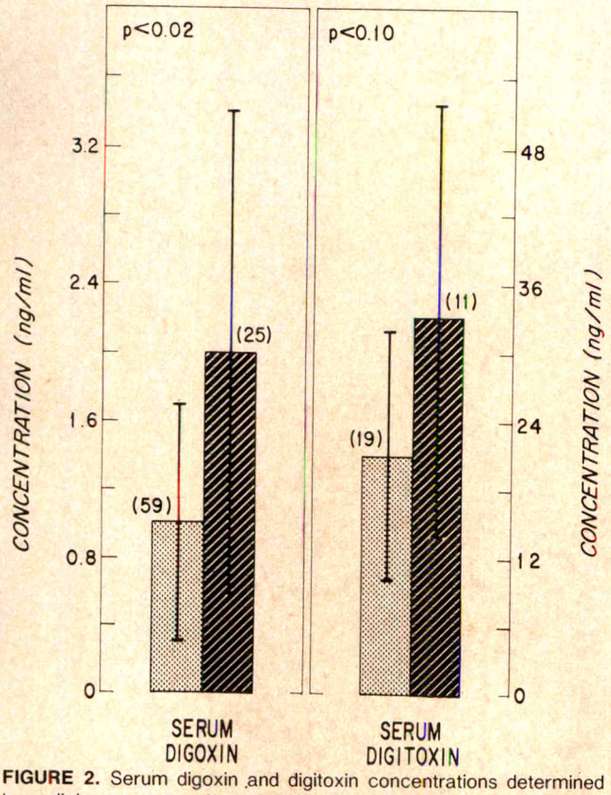

FIGURE 2. Serum digoxin and digitoxin concentrations determined by radioimmunoassay in patients without digitalis toxicity **(stippled bars)** and in patients with definite or possible digitalis toxicity **(hatched bars).** Data are presented as means ± standard deviation. The number of patients in each group is shown in parentheses.

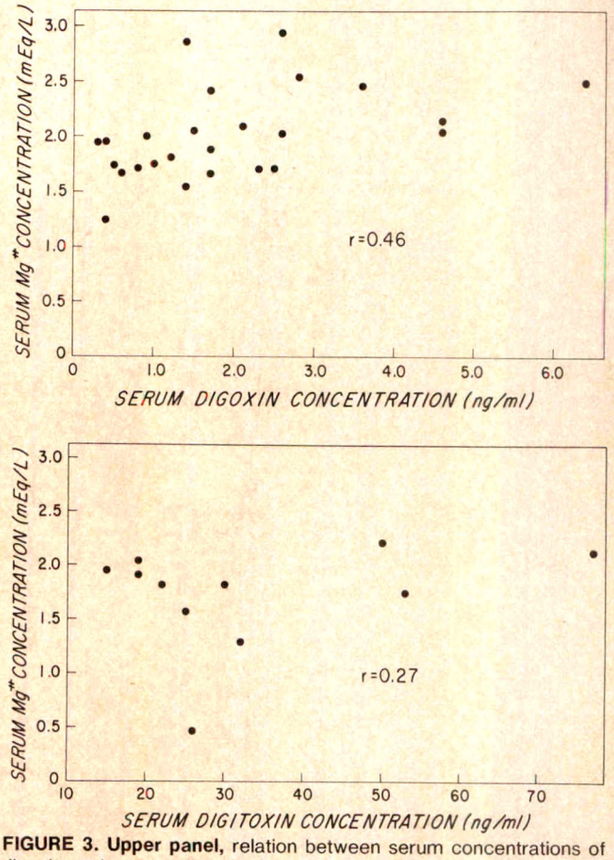

FIGURE 3. Upper panel, relation between serum concentrations of digoxin and magnesium in 25 patients receiving digoxin and manifesting toxicity. **Lower panel,** relation between serum digitoxin and magnesium concentrations in 11 patients receiving digitoxin or digitalis leaf and manifesting toxicity.

There was no significant difference between patients with and without toxicity in mean serum sodium, chloride, bicarbonate, and calcium concentrations.

Hypermagnesemia: The percentage of patients with hypermagnesemia was significantly higher in the group with toxicity than in the group without toxicity. Seven of 38 in the former group (18 percent) and 4 of 82 in the latter group (5 percent) had serum magnesium values greater than 2.22 mEq/liter. The mean (± standard deviation) serum creatinine and blood urea nitrogen concentrations were significantly higher in digitalized hypermagnesemic patients (creatinine 2.8 ± 1.9, blood urea nitrogen 65 ± 32 mg/100 ml) than in patients with normal or low serum magnesium levels (creatinine 1.3 ± 0.5, blood urea nitrogen 29 ± 16 mg/100 ml) (P <0.001). Hypermagnesemia has previously been reported in patients with azotemia.[20,21]

Serum digoxin and digitoxin levels: Mean serum digoxin and digitoxin concentrations in patients with and without toxicity who had serum magnesium levels determined in the study are shown in Figure 2. The mean serum digoxin concentration in the group with toxicity was 2.0 ± 1.5 (standard deviation) ng/ml compared to 1.0 ± 0.7 ng/ml in the group without toxicity (P <0.02). The mean serum digitoxin or digitalis leaf assayed as digitoxin in the group with toxicity was 33 ± 19 ng/ml compared to 21 ± 11 ng/ml in the group without toxicity ($0.05 < P < 0.10$). As shown by the standard deviations, there was considerable overlap in serum digitalis levels in the two groups.

The relation between serum digoxin and digitoxin levels and serum magnesium concentrations is shown in Figure 3. In the patients with toxicity, hypomagnesemia was not more prevalent among those with relatively lower levels of serum digoxin or digitoxin than in those with relatively higher levels. Three of 16 patients (19 percent) with serum digoxin levels less than 1.7 ng/ml or digitoxin levels less than 25 ng/ml were hypomagnesemic, whereas 4 of 20 (20 percent) patients with toxicity and serum digitalis levels greater than these values were hypomagnesemic. Thus, hypomagnesemia was not more prevalent, and did not appear to explain the increased sensitivity to digitalis in this group of patients with relatively lower serum concentrations of digoxin or digitoxin.

Discussion

Recent advances in the analytic methods for serum magnesium determination have made the rapid and accurate measurement of this ion a useful clinical tool in a variety of disease states. Our prospective study demonstrated a wide prevalence of hypomagnesemia in cardiac patients receiving digitalis glycosides. Hypomagnesemia occurred more frequently in patients with cardiac digitalis toxicity and was not associated with hypokalemia, although these findings were of borderline statistical significance. However, total body potassium may have been diminished in these patients without being reflected in the serum concentration. Hypermagnesemia was also more prevalent in patients with digitalis toxicity and was apparently related to the greater prevalence of impaired renal function in this group.

Causes for the development of hypomagnesemia: The causative factors for the low magnesium levels in the digitalized patients in our study are not apparent. Magnesium depletion has been reported to occur frequently in patients receiving diuretic agents,[8–11] and in patients with alcoholism,[22] diabetes mellitus[23] and intestinal malabsorption.[24] There was no increased prevalence of diuretic administration, alcoholism, diabetes mellitus or malabsorption in the group with hypomagnesemia. However, other possible etiologic factors such as nutritional status were not investigated in detail.

Magnesium and digitalis toxicity: Increased sensitivity to the development of toxic rhythm disturbances has been observed when digitalis has been administered to monkeys[5] and puppies[6] made magnesium-deficient by dietary means. Less glycoside was required to produce cardiac arrhythmias, and the duration of the arrhythmia was significantly longer than in control animals.[7] In another study, serial acetyl strophanthidin infusions in dogs made hypomagnesemic by Kiil kidney dialysis with a magnesium-free dialysate demonstrated a 26 percent reduction in the amount of acetyl strophanthidin required to produce a toxic arrhythmia.[3] Intravenous infusion of magnesium sulfate subsequently suppressed the arrhythmias in the majority of these animals. Cats intentionally made digitalis-toxic to the point where ventricular ectopic beats developed responded with restoration of sinus rhythm when magnesium sulfate was administered.[1] Empirically, parenterally administered magnesium has also been found effective in abolishing ventricular bigeminy and ventricular tachycardia in patients with cardiac digitalis-toxicity.[1] In addition, magnesium depletion has been shown to alter the myocardial uptake of tritiated digoxin; more of the drug was found in myocardial tissue of magnesium-deficient animals more than 3 hours after administration.[25]

Clinical implication: Our study showed a rather wide prevalence of hypomagnesemia in digitalized cardiac patients. Investigation of the efficacy of magnesium administration in hypomagnesemic patients with cardiac digitalis toxicity seems warranted. Caution should be used in the parenteral administration of magnesium sulfate to azotemic patients who may already be hypermagnesemic. Routine measurement of the serum magnesium concentrations in digitalized patients, or those taking diuretic agents, may obviate this problem.

Acknowledgment

The excellent technical assistance of Mrs. Kirsten Johansen is gratefully acknowledged. We also thank Miss Ella Munro for her assistance in the statistical analyses.

Influence of Exercise on Arrhythmias Induced by Digitalis-Diuretic Therapy in Patients with Atrial Fibrillation

ALDEN S. GOOCH, MD
GANGAIAH NATARAJAN, MD
HARRY GOLDBERG, MD, FACC

Browns Mills, New Jersey

Serial low-level treadmill exercise testing was performed by 20 ambulatory patients with atrial fibrillation to provoke and study drug-related arrhythmias. All 20 were receiving long-term digitalis therapy; 19 were also receiving potassium-losing diuretic agents, and 3 had hypokalemia. The subjects were selected on the basis of resting electrocardiograms compatible with strong digitalis effects: prominent ST–T–U changes, intermittently occurring junctional beats, controlled ventricular rates (range 40 to 70/min) or ventricular premature beats. Arrhythmias suggesting digitoxicity were induced by exercise in all 20 subjects. Those occurring most often were junctional tachycardia with or without Wenckebach exit block, frequent ventricular premature beats and bigeminy. Idioventricular rhythm was induced in two subjects and ventricular parasystole in one. After withdrawal of digitalis and diuretic agents, subsequent exercise tests demonstrated increased ventricular rates, a decrease in ST–T–U changes and in the occurrence of most arrhythmias. In 18 patients, brief runs of junctional tachycardia persisted but occurred less often. Low-level exercise testing provides a simple method for provoking latent cardiac irritability in patients with suspected digitalis and diuretic toxicity; serial exercise testing after withdrawal of the drugs can demonstrate the devolution of arrhythmias.

Although digitalis remains the most important drug for treating heart disease, the appropriate dose is not always easily determined for individual patients. The problem of prescribing digitalis is often complicated by the concomitant use of potent electrolyte-deranging diuretic agents. In these circumstances, even small or otherwise appropriate doses of digitalis may produce unwanted arrhythmias or other toxic changes. Whether to increase, decreass or stop digitalis-diuretic administration often poses a clinical dilemma. The ventricular rate response to exercise has been extensively studied and provides a well known guide to digitalis therapy in patients with atrial fibrillation.[1–6] Although exercise is known to provoke rhythm and conduction disturbances,[7–10] there has been no systematic study of exercise-induced arrhythmias in relation to digitalis therapy. This report describes the use of low-level treadmill electrocardiographic tests to assess sequential exercise-induced arrhythmic changes before and after withdrawal of both digitalis and diuretic agents.

Subjects and Methods

The 20 subjects of this study were ambulatory patients with heart disease who had been referred for evaluation. They had been receiving long-term maintenance doses of a digitalis preparation (digoxin in 19 patients, digitoxin in 1 patient). Nineteen patients had also been taking potassium-losing diuretic agents without potassium supplements for several months. Nineteen had rheumatic heart disease, and one had coronary artery disease. One patient had mild nausea and anorexia, and others were asymptomatic. Hypo-

kalemia (serum potassium less than 3.5 mEq/liter) was present in three patients. None had renal insufficiency, as judged by blood urea nitrogen concentrations. All patients had atrial fibrillation and were selected for serial exercise testing on the basis of 12-lead electrocardiographic findings suggesting a strong digitalis effect or digitalis excess. The electrocardiographic changes included slow ventricular rates (40 to 70/min), prominent ST–T–U wave changes, occasionally regular R–R intervals (all subjects) or the presence of junctional or ventricular premature beats. One patient had bigeminy, and 12 patients had brief runs of junctional tachycardia in the 2 minutes immediately before exercise.

Each patient walked on a 7 percent grade motorized treadmill with increasing increments in speed at 3 minute intervals. Bipolar electrocardiographic lead V_5 or V_6 was recorded continuously before, during and for 8 minutes after exercise. Exercise was limited to low levels: usually to a peak level of 1 or 2 miles/hour; an occasional patient walked comfortably at 3 miles/hour. The duration of exercise was often brief (range 1 minute, 10 seconds to 8 minutes, 5 seconds). Exercise was stopped with the appearance of mild dyspnea or fatigue, or both. After the first exercise test, digitalis and diuretic agents were discontinued and orally administered potassium chloride was prescribed. Similar exercise tests were repeated periodically over several days to assess sequential changes in cardiac rhythm and rate. Digitalis therapy was reinstituted and exercise testing discontinued if signs of cardiac congestion appeared or resting ventricular rates became persistently rapid. Each patient underwent more than one exercise test (Table I), the number depending on patient availability and time of disappearance of electrocardiographic signs of digitalis excess. The 20 patients performed a total of 72 exercise tests. The interval between the first and last exercise tests ranged from 5 to 27 days (mean 9.4).

Arrhythmias Induced by Exercise Testing

Arrhythmia	During or Immediately After Exercise: no. of Subjects First Test	Trends on Serial Testing	
Junctional	20	Less frequent	18
		Disappeared	2
Junctional tachycardia with Wenckebach exit block	13	Disappeared	3
		Persisted	10
		New appearance	7
Wide QRS beats (ventricular ectopic beats or aberrant beats)	20	Disappeared	1
		Less frequent	16
		More frequent	3
Bigeminy	11	Disappeared	10
		Persisted	1
Idioventricular rhythm	2	Disappeared	2
Ventricular parasystole	1	Disappeared	1

Definition of Terms

Junctional beats in the presence of atrial fibrillation were identified by the occurrence of several pairs with identical R–R intervals and similar QRS configuration.[11,12] The second beat of each such pair was presumed to be of junctional origin whether formed by automatic activity or by intranodal reciprocal mechanisms. Junctional rhythms were recognized by "regularization of ventricular response" [13–16] with at least five successive beats of similar R–R intervals (within 0.02 second).[16–18] If the manifest rates exceeded 60/min, the term *junctional tachycardia* was used.[12,16] We did not differentiate the paroxysmal from the nonparoxysmal type although appearance of the latter has been considered an indication for discontinuing digitalis therapy.[19,20] The main reason for not using this well known classification is the appearance of many bouts of junctional tachycardia, often with widely differing rates, during a single exercise test. Difficulties with this classification have also been recognized by others.[17]

Junctional tachycardia with Wenckebach exit block was identified by grouping of beats exhibiting a progressive decrement in R–R intervals followed by a pause of less than twice the length of the preceding R–R interval. The R–R interval preceding the pause, by definition, was the shortest interval of the sequence. In addition, we required the presence of at least three such successive groupings to avoid a false diagnosis of Wenckebach exit block due to a chance occurrence of such beats in atrial fibrillation. The cycle length of the basic junctional focus was derived by dividing the duration of an individual Wenckebach grouping by the number of observed QRS complexes plus one[16,21–23] (Fig. 1). Second degree exit block of the 2:1, 3:1 or 4:1 type was recognized by the presence of frequent R–R intervals that were exact multiples of the cycle lengths of observed junctional tachycardia, as calculated from the Wenckebach sequences.[16,21] In many instances, junctional beats and junctional tachycardia might be thought to result from reciprocal mechanisms, but the absence of P waves rendered this degree of definition uncertain.[16,24,25]

Wide QRS complexes (0.10 second or more) may be designated as ventricular premature beats or aberrantly conducted supraventricular beats with the aid of the criteria suggested by Marriott and Sandler.[26] This classification is not entirely adequate,[27] and lead V_1 was not used in this study. However, the presence of aberration was suggested, although not proved, when wide QRS beats occurred at times when a supraventricular beat was expected in groups of beats interpreted as junctional tachycardia with Wenckebach exit block (Fig. 1). Runs of bigeminy due to aberrancy and those due to ventricular ectopy were not differentiated since we were unable to obtain His bundle recordings during walking exercise.

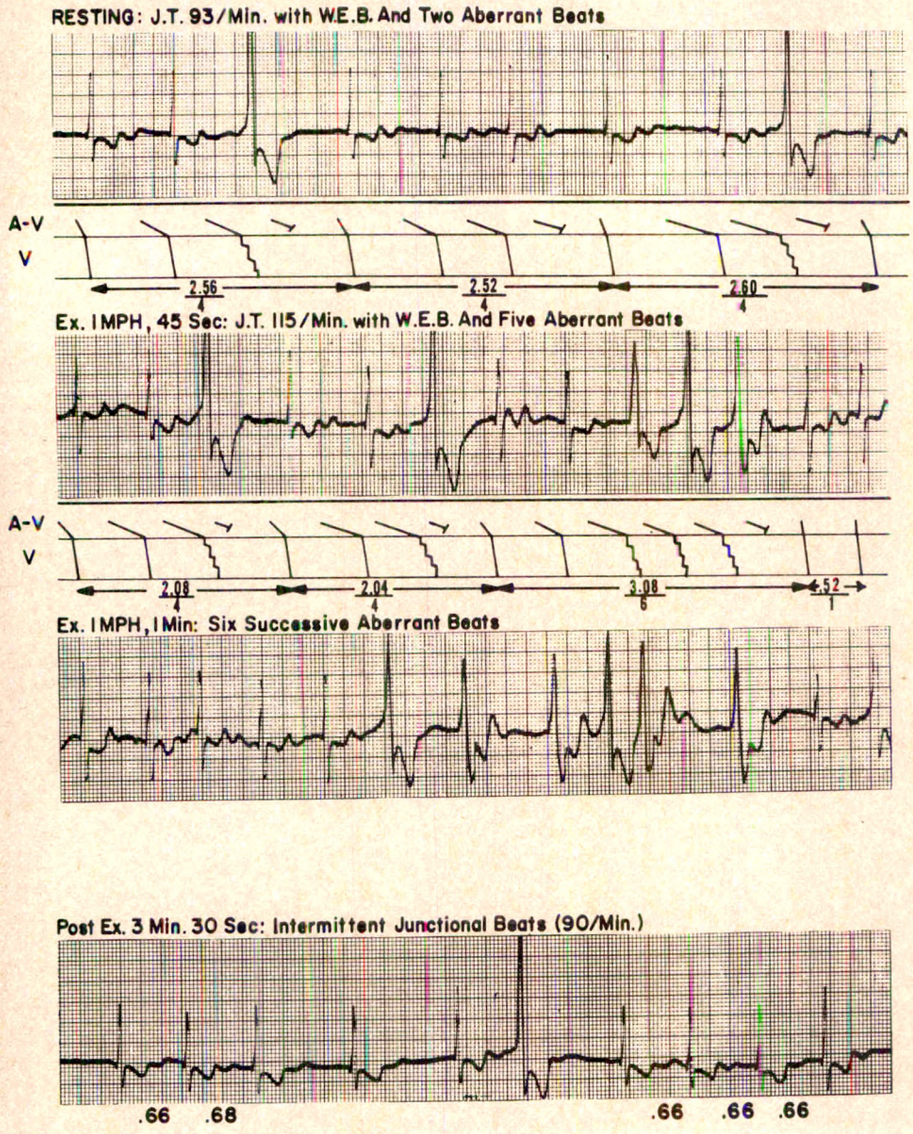

FIGURE 1. Selected portions of the first exercise electrocardiogram of a patient with rheumatic heart disease, before discontinuation of digoxin and furosemide. Junctional rhythm is present at rest in addition to two wide QRS complexes. With walking at 1 mile/hour **(second strip),** wide QRS beats occur more frequently; their appearance in Wenckebach groupings along with other beats with narrow QRS configuration in similar sequences suggests that they may be due to aberrancy. Later **(third strip)** beats of identical configuration appear without a Wenckebach grouping. Both wide QRS beats and junctional mechanisms were absent during the fourth exercise test, 6 days later. J.T. = junctional tachycardia; W.E.B. = with exit block.

Results

The first exercise test increased arrhythmias in all patients (Table II). With serial testing, exercise-induced ST–T–U changes became less prominent; ventricular rates gradually became more rapid, and the arrhythmias attributed to digitalis-diuretic excess tended to diminish or disappear. After each patient was studied, administration of digoxin was resumed, usually at similar dose schedules but without concomitant daily use of potent diuretic agents.

Junctional rhythms: Brief paroxysms of junctional rhythm with rates of 38 to 154/min were evident in 12 of the 20 patients' electrocardiograms recorded immediately before the first exercise test (Fig. 1 and 2). They were not found in the subsequent preexercise electrocardiograms of 9 of these 12 patients; 4 additional patients had junctional rhythm at rest for the first time in later tests only. Electrocardiograms recorded during and after exercise revealed junctional tachycardia, with rates between 71 and 210/min, in 70 recordings (97 percent) (Fig. 1 to 3). The first paroxysm of junctional tachycardia usually began within a few seconds after the beginning of exercise and the duration of each episode was usually limited to approximately 10 to 20 seconds. Long runs of junctional tachycardia, lasting 30 seconds or more, were encountered in only one patient. The rates of junctional rhythms varied from time to time during the same test, with a tendency toward acceleration during exercise (Fig. 1, 2 and 4). On serial testing, the rates of junctional rhythm became faster in eight patients, remained similar in six patients and varied inconsistently from test to test in six patients. The occurrence of junctional tachycardia tended to be less frequent in the later tests, although brief runs of this arrhythmia were evident in the last tests of 18 patients.

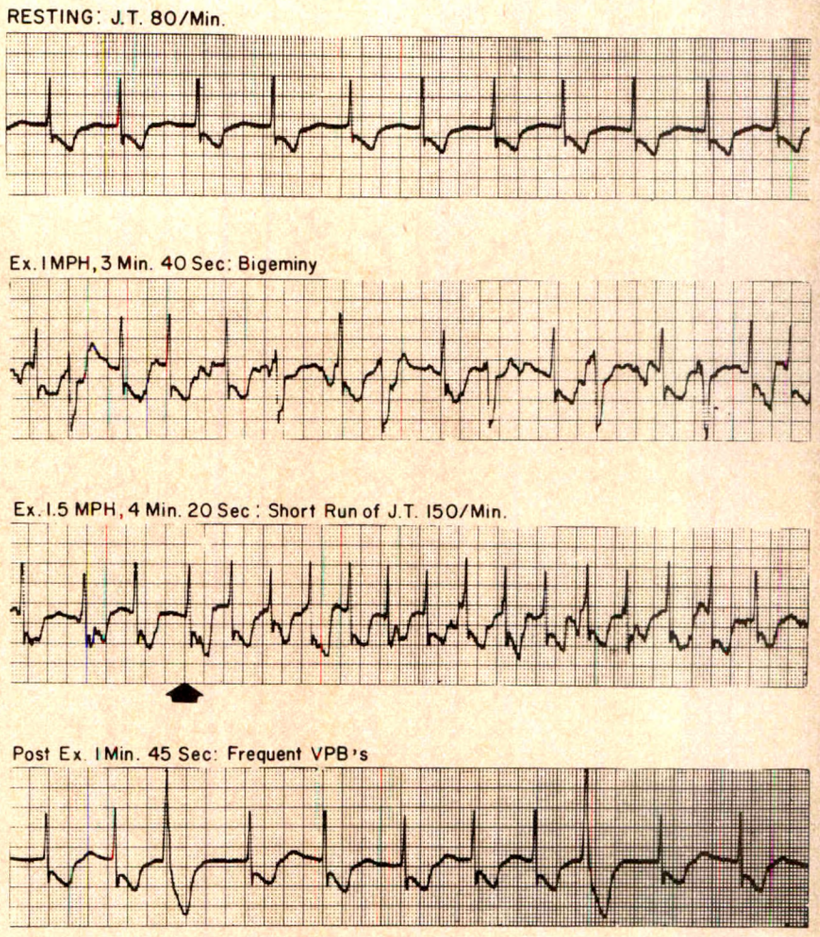

FIGURE 2. Exercise electrocardiogram of patient taking digoxin and a thiazide diuretic agent. The resting tracing showed intermittent runs of junctional rhythm. At 1 mile/hour bigeminal sequences are induced. At 1.5 miles/hour a short burst of junctional tachycardia (J.T.) is seen **(onset at arrow).** After exercise, ectopic beats are still present and the U waves are more prominent. VPB's = ventricular premature beats.

Junctional exit block: Four patients had intermittent junctional rhythm with Wenckebach periods on the preexercise electrocardiogram (Fig. 1); in 13 patients these changes developed during exercise. Wenckebach groupings continued to appear with exercise long after the drugs had been discontinued. When Wenckebach exit block occurred in more than one exercise test (four patients), it usually appeared with higher rates in the later tests.

Ventricular premature beats: Frequent ventricular premature beats were seen on the immediate preexercise electrocardiogram of 3 subjects and were induced in the first exercise test of 10 patients. With subsequent testing, they tended to appear less often in seven patients, disappeared in one patient and increased in two patients. With exercise, 13 of 20 patients had increased frequency of wide QRS beats that may have been either ventricular in origin or aberrant. These beats were often of multiform configuration and, when they occurred in succession, simulated ventricular tachycardia on casual inspection (Fig. 1). They were usually independent of preceding cycle lengths. On serial testing they appeared less frequently in 12 patients and tended to be of more uniform configuration. In one patient they appeared more frequently during the course of five serial tests. In one patient, ventricular parasystole developed during the first two tests but not in the three tests performed after the withdrawal of drugs. Two patients had runs of idioventricular rhythm during their first exercise test and none thereafter. Paired ventricular beats were seen occasionally, but runs of regular ventricular tachycardia were not encountered.

Bigeminy: Wide QRS bigeminy was seen intermittently in one patient before exercise. Bigeminy due either to ventricular premature beats or to aberrant beats was seen in an additional 10 patients on the first treadmill exercise electrocardiogram, both during and after exercise (Fig. 2, 5 and 6). Bigeminy failed to appear on serial testing in all but one patient in whom it appeared briefly in all six tests performed.

Discussion

Determination of digitalis dosage for the individual patient remains a clinical decision. The net result of digitalis action on each patient, influenced by many known and unknown factors, continues to provide clinical guidelines for digitalis requirements. The identification of digitoxicity has been the subject of many investigations. Attention has been drawn to the

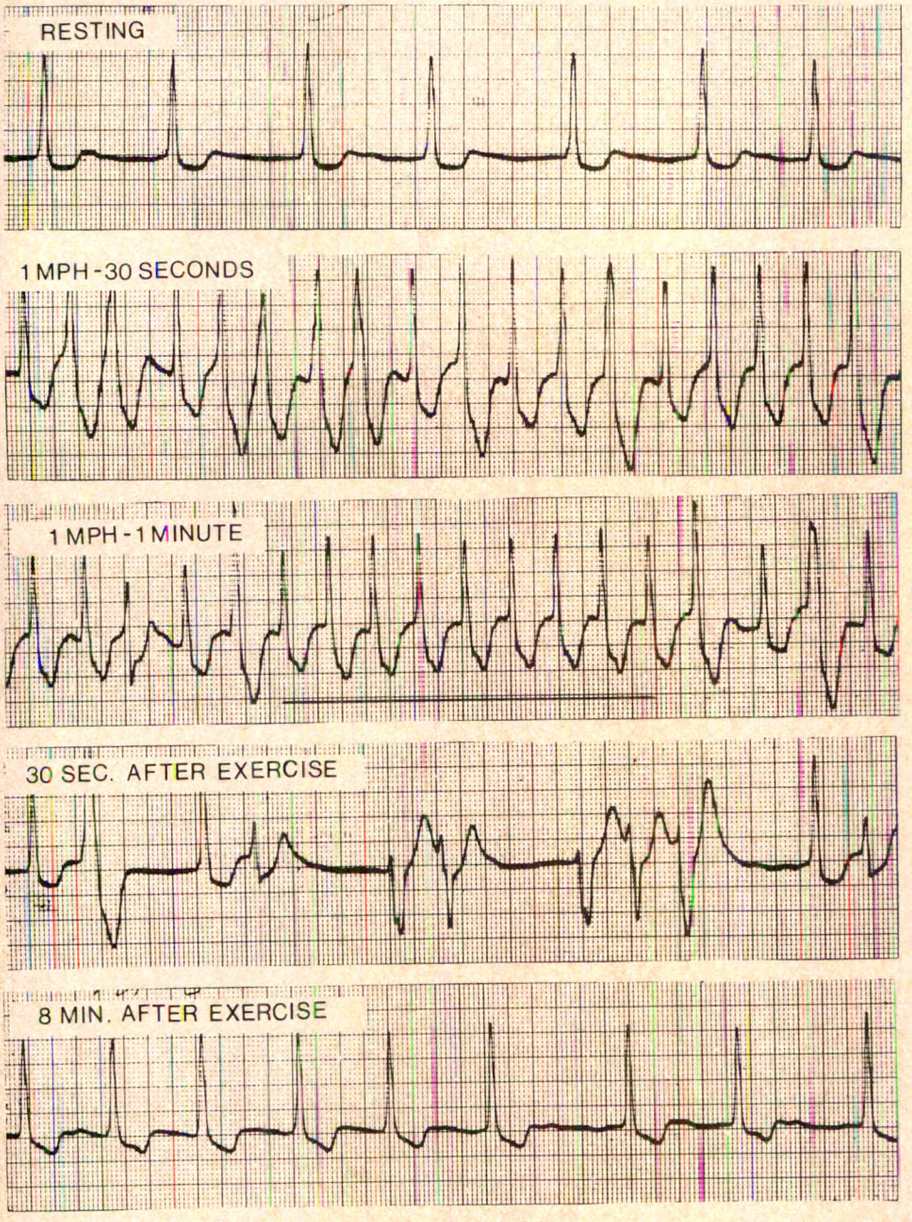

FIGURE 3. Portions of exercise electrocardiogram of a 52 year old man with rheumatic mitral regurgitation. He had been taking digoxin and daily doses of furosemide for many months. The resting record shows a slow (nearly regular) ventricular rate and ST–T–U changes. During walking at 1 mile/hour, the ST–T changes are more marked and the ventricular rate is rapid. After 1 minute of walking a brief run of junctional tachycardia is seen **(third strip)**. After exercise, the rate slows abruptly with pauses interrupted by several wide QRS escape beats. Eight minutes of rest was required to return the electrocardiographic pattern to the preexercise condition. Serial testing after discontinuation of the drugs revealed a gradual decline in these changes over a 16 day period.

pulse or heart rate at rest and after exercise, particularly in patients with atrial fibrillation, for evaluating the adequacy of digitalis therapy. Several digitalis-related arrhythmias occurring at rest have been recognized as having important prognostic implications. These include atrial tachycardia with various degrees of block, junctional rhythms, frequent ventricular beats and ventricular tachycardia. On the basis of an analysis of resting electrocardiograms, junctional tachycardia has been classified as paroxysmal or nonparoxysmal depending on heart rate[19]; and appearance of the nonparoxysmal type has been considered an indication for discontinuing administration of digitalis.[19,20,23] In our study, gross variations in the manifest rates of junctional tachycardia, both paroxysmal and nonparoxysmal forms, was observed in every patient during and after exercise. Classifying exercise-induced junctional tachycardia on this basis and assigning different etiologic, therapeutic and prognostic implications does not seem justified.

Recent methods for assaying blood glycoside levels have proved valuable in some cases, but the untoward effects of digitalis are not consistently reflected by such measurements.[28–30] Serum digoxin determinations were not available for the 20 subjects during the period of our study. However, in the subsequent evaluation of 14 additional patients with similar exercise-induced arrhythmias, we found only four (35 percent) with elevated digoxin levels in excess of 2.2 ng/ml.

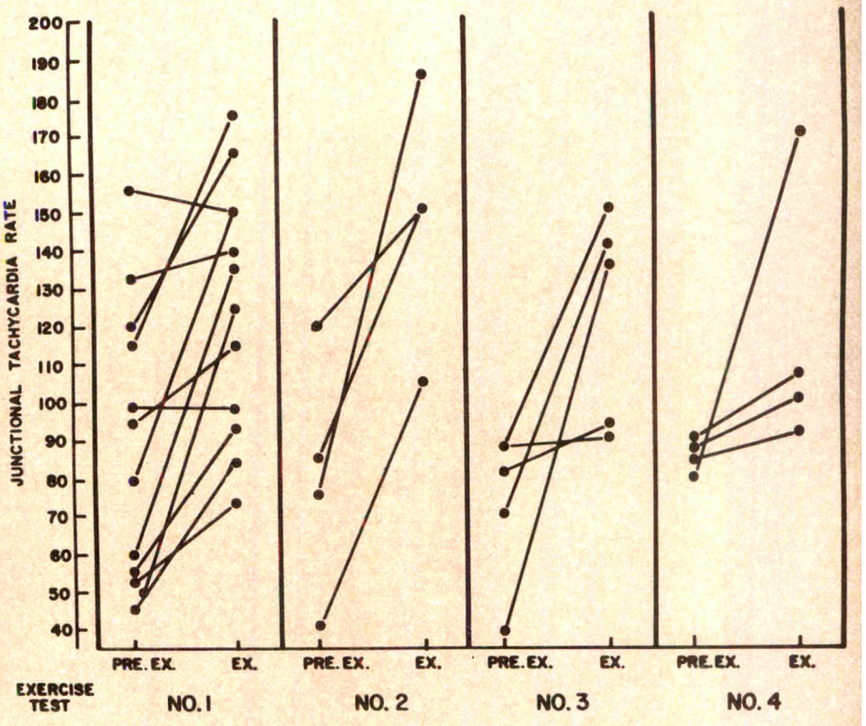

FIGURE 4. Heart rates during brief runs of junctional rhythm before (PRE. EX.) and during exercise (EX.) Digitalis and diuretic agents had been discontinued after the first test. With serial testing fewer patients had junctional rhythms and these arrhythmias occurred less frequently, persisting in four. Exercise produced faster rates with few exceptions.

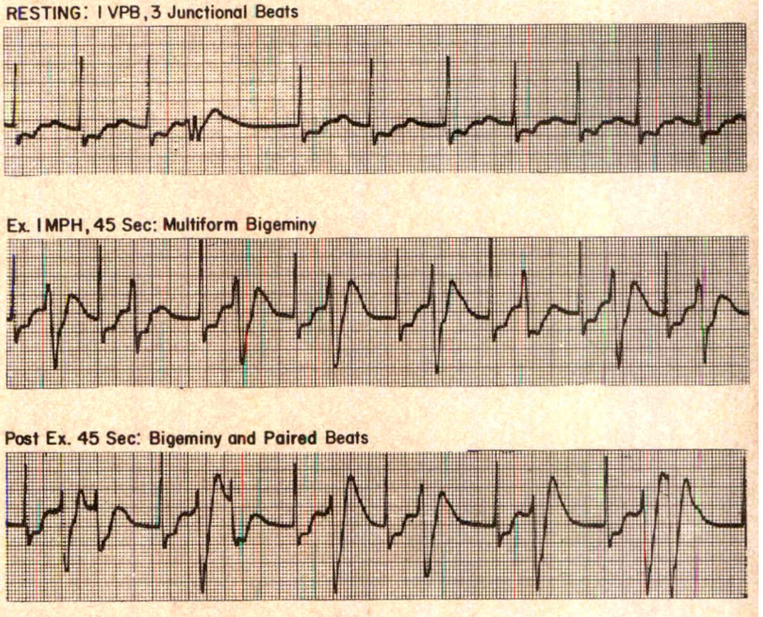

FIGURE 5. First exercise test of a 42 year old woman with chronic mitral valve disease. At rest, ST–T–U changes are present as well as some regular R–R intervals and an occasional wide QRS early beat. Walking at 1 mile/hour **(second strip)** induced bigeminy which persisted throughout exercise and for several minutes after exercise **(third strip).** Paired beats also occurred after exercise. VPB = ventricular premature beat.

A few brief and fragmentary references are available on the possible influence of exercise on digitalis-induced arrhythmias. Lown and Levine[15] noted that "slight exertion, deprivation of oxygen therapy, straining on the bed pan or emotional upset" may bring on bigeminy in digitoxic patients. Scherf and Cohen[17] suggested an accelerating effect of exercise on junctional tachycardia as a differential feature to distinguish this arrhythmia due to digitoxicity from the so-called paroxysmal type. Gooch and McConnell[9] recorded an instance of exercise-induced tachyarrhythmias that did not reappear on repeat exercise tests performed after the digitalis dose was decreased. Surawicz and Mortelmans[31] cite a patient with atrial fibrillation and a slow ventricular rate and bigeminy at rest who had a more rapid rate after walking. Examination of their tracing reveals intermittent junctional mechanisms accelerated by exercise. In reporting the "effect of different digoxin doses on subjective symptoms and physical working

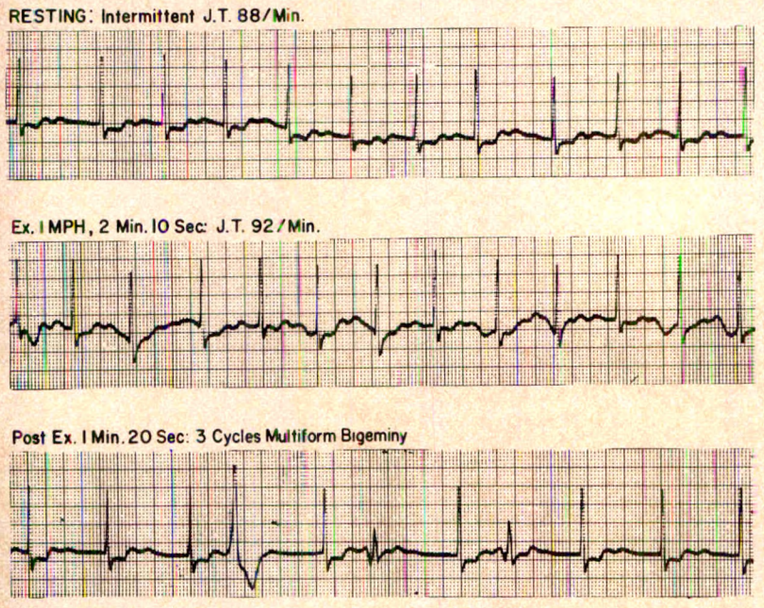

FIGURE 6. Second exercise test (same patient as in Fig. 5) performed 4 days after discontinuation of digoxin and diuretic therapy. Regular (junctional) intervals (J.T.) are still present at rest. Bigeminy continues to be present although it is less frequent, of multiform configuration, and occurs only after exercise.

capacity" and "digoxin dosage and ventricular rates at rest and exercise," Redfors[6] observed an increase in the number of aberrant beats during exercise in patients with atrial fibrillation receiving digoxin.

The persistence of brief paroxysms of junctional tachycardia in 90 percent and Wenckebach exit block in 65 percent of our patients after withdrawal of digitalis and diuretic agents deserves comment. Junctional tachycardia did not occur in long regular runs but in brief groupings, as recorded by Chung.[32] Apparently these arrhythmias with incomplete atrioventricular dissociation outlast the period of "digitoxicity" as reflected by both the response of ventricular rate to exercise and the appearance of cardiac decompensation requiring redigitalization. Perhaps they are due to more prolonged effects of electrolyte derangements on the heart although not indicated by serum potassium levels. Also, in some patients with atrial fibrillation, enhancement of junctional mechanisms may be a usual response to exercise rather than an indication of excessive digitalis.

In contrast to ventricular premature beats, aberrant beats are not usually considered a manifestation of digitalis excess.[33,34] Similarly, intraventricular conduction defects are not usually attributed to digitoxicity,[15,23,33] In our study, exercise frequently induced beats suggestive of aberrancy in several patients during their first test. These beats were not related to preceding cycle length or to rate-related changes of physiologic refractory periods. The gradual decrease of these beats in later tests in most patients suggests that their appearance had been provoked either by a direct action of the drugs on conducting tissue or by an overall effect of slower rates. The tendency toward multiform beats only in the earlier tests may also have a similar significance. Although this evidence is suggestive, further study is needed regarding the influence of digitalis on aberrant conduction.

Digitalis has been identified as one cause of bigeminy.[35–37] Bigeminy was apparent on the resting electrocardiogram of only one of our patients but appeared during exercise in 11. It disappeared in all but one in subsequent tests. The persistence of short runs of bigeminy in all six tests of one patient might be related to the underlying heart disease rather than to the effect of drugs.

It seems appropriate to compare the results of our study with the systematic observations by Redfors[6] concerning digitalis-induced arrhythmias during exercise. Junctional rhythms were not observed in his patients, although the sophisticated methods of his study were well adapted to identify such arrhythmias. He found aberrant beats to be more frequent during exercise in 65 percent (9 of 14) of the patients receiving digoxin, but the frequency of exercise-induced aberrancy increased with increasing doses of digoxin in only 14 percent (2 of 14) of patients. No difference was noted in the frequency of ventricular ectopic beats at rest and during exercise in the two patients who had such beats. Thus, with reference to junctional tachycardia and wide QRS beats, the findings of Redfors are at variance with ours. This discrepancy may be due to the prolonged use of electrolyte-deranging diuretic agents in our subjects and to the fact that our patients had had no abrupt changes in digitalis dosage for several months or years before the first exercise test.

Clinical implications: Junctional rhythm with or without exit block, ventricular ectopic beats and bigeminy are commonly seen with digitoxicity. The underlying metabolic and electrophysiologic mechanisms responsible for the increased arrhythmicity during and after exercise are beyond the scope of our clinical study. The tendency of arrhythmias to decrease or disappear after withdrawal of digitalis and diuretic agents suggests a decisive influence of drugs. The concurrent appearance and parallel behavior of

idioventricular rhythm and parasystole may indicate a similar relation. Nineteen of the patients of our study had no symptoms that could be specifically attributed to digitoxicity although all of them had chronic fatigue, as indicated by reported improvement during the study period. When first seen, only one patient had occasional nausea and loss of appetite. These symptoms cleared after discontinuation of digitalis and diuretic therapy.

A diagnosis of digitalis-related arrhythmias may be suspected but cannot be confirmed by performance of only one exercise test. The demonstration of arrhythmic change with exercise may be related to the underlying cardiac condition, and serial testing after withdrawal of drugs is needed to indicate cause-and-effect relations. For example, exercise may induce ventricular bigeminy, and subsequent testing over several weeks may demonstrate a persistence of the arrhythmia[38] long after the disappearance of any possible drug effect. Maximal exercise levels were not necessary to induce the arrhythmias in our study, and treadmill walking to high levels is not recommended in such patients.

The resting 12 lead electrocardiogram of all patients was indicative of strong digitalis-diuretic effect (or mild digitoxicity, depending on arbitrary definitions). In searching for patients with such changes for inclusion in our study, we found only one who was not also being treated with potassium-losing diuretic agents. Because electrolyte-deranging diuretic agents may enhance the effect of digitalis, with or without hypokalemia,[15,35] the transient exercise-induced arrhythmias were probably due to the combination of drugs.

Effect of Procainamide on Fibrillation Threshold of Normal and Ischemic Ventricles

MYUNG S. YOON, MD
JAOK HAN, MD, PhD, FACC
BRIJ G. GOEL, MD
PAULA CREAMER, BS

Albany, New York

The effect of procainamide on ventricular fibrillation threshold was studied in anesthetized open chest hearts in 12 dogs without coronary occlusion and in 11 dogs during acute coronary occlusion. The minimal current required to induce ventricular fibrillation was determined by delivering a train of rapid rectangular pulses (100/sec) to the ventricle during its vulnerable period. Procainamide was administered as a single intravenous injection in a dose of 10 to 20 mg/kg body weight. Blood levels of the drug reached their peak immediately, fell to therapeutic levels (5 to 10 μg/ml) within about 30 minutes and then remained at those levels up to 80 minutes after the injection. The effect of procainamide on the fibrillation threshold correlated with procainamide blood levels. The increase, peak level and decrease in blood concentration paralleled changes in fibrillation threshold. Procainamide at therapeutic blood levels increased the mean fibrillation threshold from the control value of 16 to 30 ma (88 percent increase) in the normal ventricles. The effect was less pronounced during acute coronary occlusion, and the mean fibrillation threshold increased from 8 to 13 ma (63 percent increase) at therapeutic procainamide blood levels. In addition, procainamide failed to produce complete reversion of the decreased fibrillation threshold to the normal value during acute myocardial ischemia.

The major cause of death in patients with acute myocardial infarction is ventricular fibrillation. Ventricular premature beats are the most common arrhythmia observed during acute myocardial infarction and are a precursor of ventricular fibrillation. Lidocaine and procainamide have been extensively used in the management of patients in the coronary care unit and have proved effective in suppressing ventricular premature beats and reducing the incidence of ventricular fibrillation. It has recently been shown[1] that lidocaine decreases ventricular vulnerability to fibrillation by increasing the threshold for fibrillation during acute myocardial ischemia. This study was undertaken to investigate the effect of procainamide on the fibrillation threshold of normal and ischemic dog ventricles.

Methods

Experiments were performed in mongrel dogs anesthetized by an intravenous injection of sodium pentobarbital (30 to 35 mg/kg). Under artificial respiration, the chest was opened at the midline, and the heart was cradled in the opened pericardium. The sinoatrial node was crushed to permit pacing the heart at a constant rate by applying electrical stimuli to the ventricle. For reversible occlusion of the anterior descending branch of the left coronary artery, the artery was dissected free for a few millimeters near its origin and a snare was applied around the vessel. Procainamide was administered through a cannulated femoral vein. A femoral artery was also cannulated to obtain arterial samples for determination of blood procainamide levels and blood gas, and to record arterial pressure. Arterial blood gas and pH were frequently

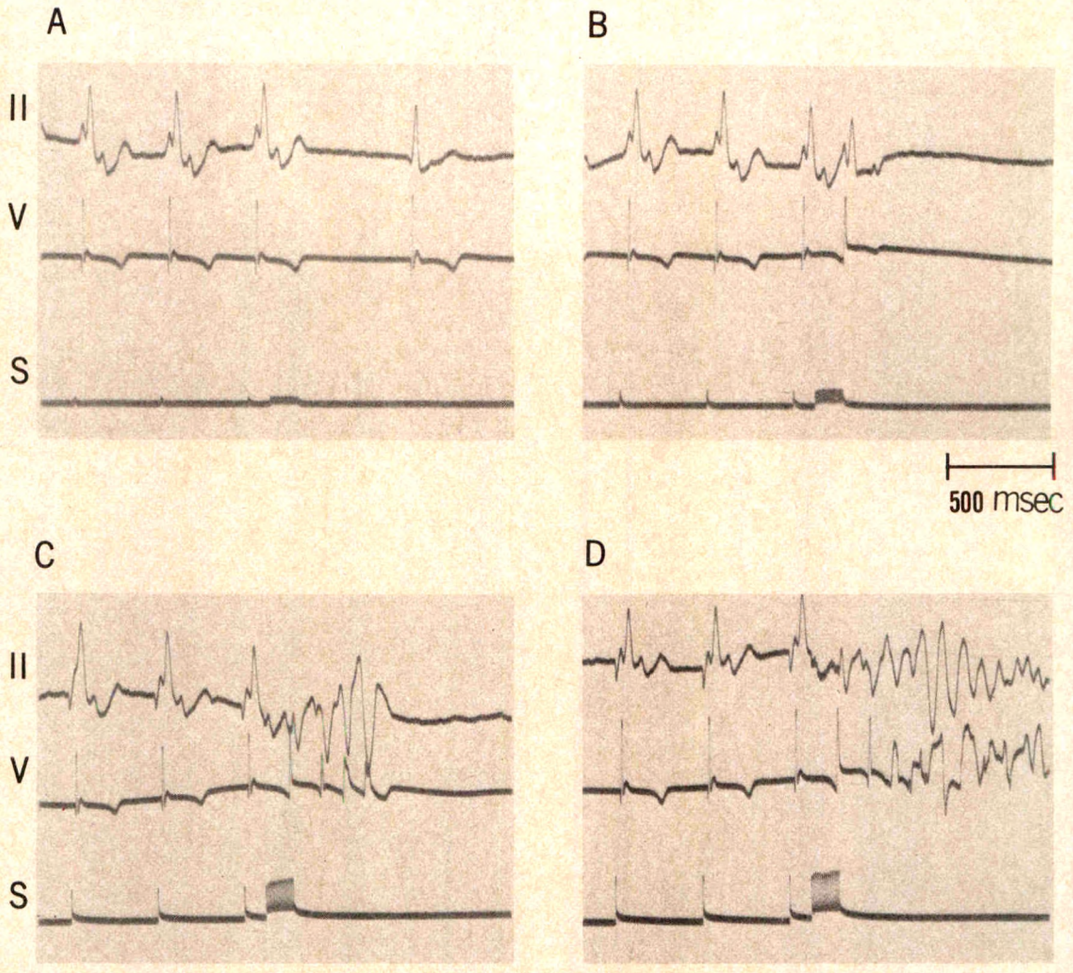

FIGURE 1. Determination of ventricular fibrillation threshold by applying the train of rapid rectangular pulses (100/sec) during the vulnerable period. II indicates lead II electrocardiogram; V, local electrogram recorded from a site close to the stimulating electrodes; and S, the artifact of stimuli applied through the bipolar stimulating electrodes attached to the anterior septal margin of the right ventricle. The intensity of the rapid pulses was gradually increased from **A** to **D.** A subthreshold intensity of the rapid stimuli produced no premature beat in **A.** Stronger rapid stimuli produced one premature beat in **B** and four premature beats in **C.** Further increase in the intensity of the stimuli resulted in fibrillation in **D.**

checked and were corrected when necessary to prevent respiratory or metabolic imbalance.

The bipolar stimulating and recording electrodes were small steel hooks with an interelectrode distance of 3 to 4 mm. The stimulating electrodes were attached to the anterior septal margin of the right ventricle about 10 mm from the edge of the area of expected ischemia. The recording electrodes were attached to a site close to the stimulating electrodes in the potentially intact area, and to another site within the area of potential ischemia at some distance from the site of stimulation. Local electrograms of the potentially intact and ischemic sites, a lead II electrocardiogram and the artifact of stimuli delivered to the stimulating electrodes were all monitored on an Electronics for Medicine recorder. The stimuli were also displayed on an oscilloscope and calibrated by use of a Tektronix current probe amplifier.

The patterns of pacing and test stimuli delivered to the ventricle were programmed by using a variable interval generator and a series of Tektronix wave form and pulse generators. The output of the pulse generator triggered a Grass stimulator which delivered 3 msec pulses to the stimulating electrodes. Ventricular fibrillation threshold was determined by delivering a train of rapid rectangular pulses across the vulnerable period. The method, which was first used by one of us,[2] is depicted in Figure 1. The ventricle was paced by basic stimuli at a cycle length of 400 msec, and the train of rapid pulses was delivered after every 12th basic ventricular response. The pulses were 3 msec in duration and occurred at 10 msec intervals (100/sec). The train was started at about 100 msec after the basic response, and its duration did not extend beyond the absolute refractory period of the premature response evoked by the train. The intensity of the rapid pulses was gradually increased until fibrillation resulted. The fibrillation threshold was then defined as the minimal current in milliamperes that induced fibrillation. Defibrillation was accomplished by direct-current countershock, and 10 to 15 minutes was allowed for recovery before further observations were made.

Results

Figure 2 shows procainamide blood levels plotted against time after a single intravenous injection of the drug in a dose of 10 or 20 mg/kg in five dogs. Only one dog received 20 mg/kg, and the uppermost line indicates the blood levels achieved in this animal.

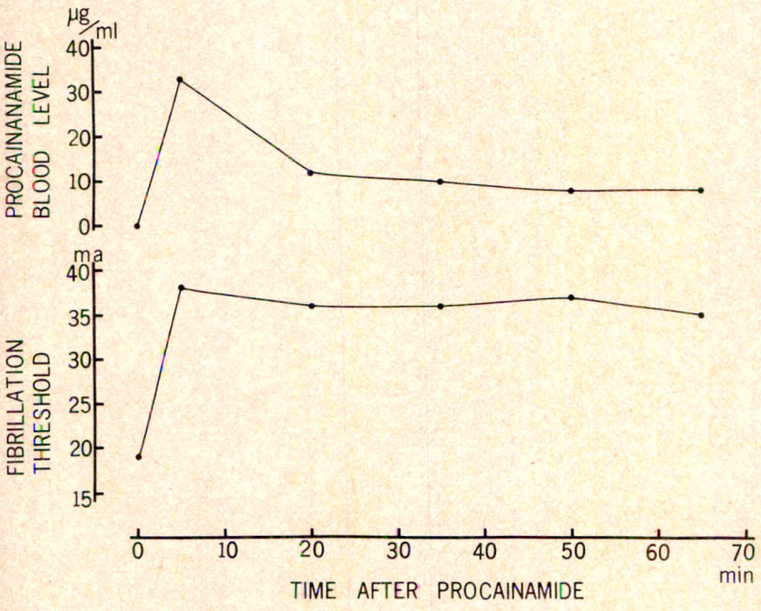

FIGURE 3. Comparison of the time course of changes in procainamide blood concentration and ventricular fibrillation threshold in a dog after an intravenous injection of 10 mg/kg of procainamide.

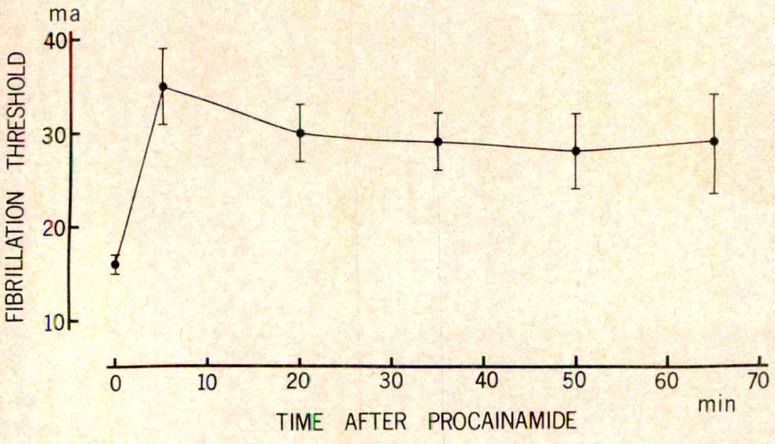

FIGURE 4. Effect of procainamide on the ventricular fibrillation threshold of 12 dogs without acute myocardial ischemia. The values are expressed as means ± standard error at zero time before injection of procainamide and at various times after injection.

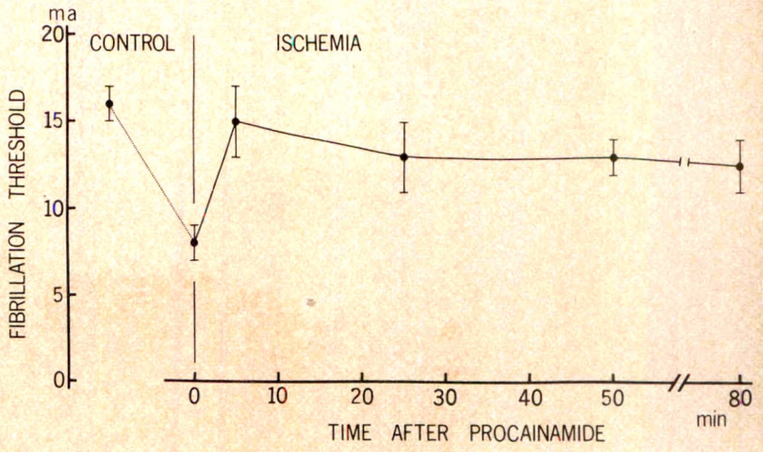

FIGURE 5. Effect of procainamide on the ventricular fibrillation threshold of 11 dogs during acute myocardial ischemia. The control fibrillation threshold is shown at the left. The value at time zero is the fibrillation threshold during acute coronary occlusion before injection of procainamide. The fibrillation thresholds during acute myocardial ischemia are also shown at various times after the injection. The values are expressed as means ± standard error.

The remaining four animals received the drug in a dose of 10 mg/kg. The blood levels were initially high, ranging from 20 to 43 μg/ml 5 minutes after the injection. They fell to therapeutic levels (5 to 10 μg/ml) in 20 to 35 minutes and remained reasonably constant up to 80 minutes after the injection. Procainamide was given in a dose of 10 mg/kg in most of the experiments.

Studies without coronary occlusion: The effect of procainamide on ventricular fibrillation threshold was first studied in 12 dogs without acute coronary ligation. Figure 3 illustrates the results of a representative experiment showing the relation of ventricular fibrillation thresholds to procainamide blood levels. The time course of changes in the fibrillation threshold correlated with changes in procainamide blood levels. The maximal increase in fibrillation threshold occurred at the time of the highest procainamide blood level, 5 minutes after the injection, and an increase in the fibrillation threshold was later maintained at lower values as the procainamide blood concentration remained at therapeutic levels. Figure 4 shows the time course of changes in the mean fibrillation threshold after an injection of procainamide in the 12 dogs without acute coronary occlusion. The mean fibrillation threshold was 16 ma before injection and increased to the maximum of 35 ma 5 minutes after injection ($P < 0.01$). It decreased slightly at 20 minutes, and then remained elevated at 29 to 30 ma up to 65 minutes after the injection ($P < 0.01$). The results indicate that the therapeutic blood concentration of procainamide increased the fibrillation threshold by 14 ma (88 percent) in the ventricles without acute myocardial ischemia.

Studies during acute coronary occlusion: The effect of procainamide on ventricular fibrillation threshold was studied in a group of 11 dogs during acute myocardial ischemia. In these animals, fibrillation thresholds were determined before and during acute ligation of the left anterior descending coronary artery. Procainamide was then injected and the fibrillation thresholds were determined during the coronary occlusion at different intervals from the time of injection. The coronary arterial occlusion lasted for only about 5 minutes before each determination of ventricular fibrillation threshold during acute myocardial ischemia. Figure 5 shows the time course of changes in the mean fibrillation threshold after an injection of procainamide in the 11 dogs during acute occlusion. The mean fibrillation threshold was 16 ma in the control state and decreased to 8 ma during acute occlusion ($P < 0.01$). The mean fibrillation threshold during occlusion was increased to the maximum of 15 ma 5 minutes after injection ($P < 0.01$). It decreased slightly at 25 minutes and then remained elevated at 12 to 13 ma up to 80 minutes after injection ($P < 0.05$). The results indicate that the effect of therapeutic blood levels of procainamide was less pronounced in the ventricles with acute myocardial ischemia than in the control ventricles. The mean increase in ventricular fibrillation threshold in the occlusion studies was only 5 ma (63 percent). In addition, procainamide failed to produce complete reversion of the decreased fibrillation threshold accompanying myocardial ischemia to the control value (16 ma).

Discussion

Procainamide was administered as a bolus injection of 10 mg/kg in most animals in our study. Blood levels of the drug reached their peak immediately, fell to therapeutic levels within about 30 minutes and then remained at those levels as long as the experiment lasted, up to 80 minutes after injection. The dose of procainamide was 20 mg/kg for an initial few experiments, and it resulted in higher therapeutic blood levels of procainamide in these animals. The effect of procainamide on the fibrillation threshold correlated well with procainamide blood levels. The increase, peak and decrease in procainamide blood concentration were paralleled by changes in fibrillation threshold. At therapeutic procainamide blood levels, the mean fibrillation threshold increased markedly from the control value of 16 to 30 ma (88 percent increase) in the normal ventricles.

It has been shown[2,3] that ventricular vulnerability to fibrillation reaches the maximal level at about 5 minutes after occlusion of a coronary artery. We therefore occluded the left anterior descending artery 5 minutes before each determination of ventricular fibrillation threshold. The mean fibrillation threshold decreased markedly from the control value of 16 to 8 ma during acute coronary occlusion (50 percent reduction). The time course of the effect of procainamide on ventricular fibrillation threshold during acute myocardial ischemia was similar to that observed in the normal ventricle. However, the effect was much less pronounced in the ischemic ventricle, and the mean fibrillation threshold increased from 8 to only 13 ma (63 percent increase) at the therapeutic blood concentration of procainamide. Furthermore, procainamide failed to increase the fibrillation threshold above the normal value (16 ma) in the ischemic ventricles at any time after an injection was administered.

Procainamide decreases excitability and responsiveness and increases the effective refractory period of the ventricular muscle.[4] Recent microelectrode studies[5,6] have shown that procainamide decreases automaticity by decreasing the slope of phase 4, decreases conduction velocity by decreasing the rate of phase 0 depolarization, and increases the action potential duration and effective refractory period in the Purkinje tissue. Antiarrhythmic effects of procainamide may be attributed to a decrease in automaticity, a decrease in excitability and an increase in the effective refractory period of the cardiac tissues. The decreased conduction rate may eliminate reentrant beats by the production of bidirectional block in reentrant circuits.[6] The observed increase in ventricular fibrillation threshold may be due to the decreased excitability and prolonged refractory period of the ventricular tissues.

The majority of patients who die of acute myocardial infarction do so suddenly of ventricular fibrillation.[7] Ventricular premature beats are the most frequent arrhythmia observed in patients with acute myocardial infarction, and these premature beats are more likely to initiate ventricular fibrillation during acute myocardial infarction.[7,8] It has been shown[2,9] that ventricular fibrillation threshold is decreased during acute myocardial ischemia in experimental animals, and this was again demonstrated in our study. Procainamide has proved useful in reducing the frequency of ventricular premature beats and fibrillation in patients with acute myocardial infarction. A recent study[7] reported that the drug offers significant protection against ventricular fibrillation in dogs during coronary occlusion.

Our study indicates that procainamide decreases ventricular vulnerability to fibrillation in the ventricle with acute myocardial ischemia, but the effect is relatively less pronounced in comparison with its effect on the normal ventricle. Procainamide was not able to revert the decreased fibrillation threshold accompanying acute myocardial ischemia above the normal value. This is in contrast to the study[1] demonstrating that lidocaine was able to revert the decreased fibrillation threshold well above the normal value during coronary occlusion. In our recent study[10] on the swine model of coronary atherosclerosis produced by the combination of an atherogenic diet and precordial X-irradiation, lidocaine infusion resulted in a four-fold increase in the fibrillation threshold of the ventricles with acute myocardial infarction. These results suggest that lidocaine should offer more effective protection against ventricular fibrillation than procainamide during acute myocardial infarction. The superiority of lidocaine over procainamide in decreasing ventricular vulnerability to fibrillation cannot be clearly explained, but it is possible that lidocaine improves depressed conduction in the Purkinje and ventricular muscle tissues and reduces the likelihood of conduction block and reentry in the ventricle.[11]

Ventricular Defibrillation in the Dog Using Implanted and Partially Implanted Electrode Systems

JOHN C. SCHUDER, PhD
HARRY STOECKLE, MD
JERRY H. GOLD, MSEE
JOE A. WEST, MSEE
JAMES A. HOLLAND, BSEE

Columbia, Missouri

Two totally implanted and two partially implanted electrode systems were studied in 2,100 fibrillation-defibrillation episodes in large anesthetized dogs. In one of the totally implanted systems, two metal disks, 7.6 cm in diameter, were implanted between the pectoralis major muscle and the rib cage, with the right electrode high on the chest and slightly to the right of midline and the left electrode over the apex of the heart. In the other totally implanted system, a unipolar catheter electrode positioned in the right atrium and superior vena cava was used together with a 7.6 cm disk electrode over the apex of the heart. In the partially implanted systems, a unipolar catheter electrode in the right atrium and superior vena cava was used together with either a 7.6 cm disk electrode or a 6.3 by 20.3 cm rectangular sheet electrode placed on the surface of the chest over the apex of the heart. Four types of unidirectional shocks were used in evaluating the twin disk system. Nine types of shocks were used with systems involving the catheter electrode. Derived curves indicate that the 90 percent level of successful defibrillation is achieved with 38 joules on the day of implantation and 54 joules 32 weeks after implantation for the twin disk system, 12 joules on the day of implantation and 19 joules 33 weeks after implantation for the catheter-internal disk system, 15 joules for the catheter-external disk system and 24 joules for the catheter-external sheet system.

The possibility of reducing the incidence of sudden cardiac death by means of automatic standby defibrillation systems that could be implanted in selected patients has been suggested by our own and other groups. Our initial experimental system used electrodes implanted in the chest wall.[1] Mirowski et al.[2] originally visualized a system in which one electrode was incorporated into the tip of a catheter and positioned in the right ventricle and the other electrode was placed under the skin of the anterior chest wall. Later, Mirowski et al.[3] and Denniston et al.[4] proposed an arrangement in which both electrodes were located on a catheter positioned so that one electrode was in the apex of the right ventricle and the other in the superior vena cava. Rubin et al.[5] have suggested a similar scheme. Lown and Axelrod[6] have questioned the validity of pursuing further study of the concept of totally implanted standby defibrillation systems.

Patient and physician acceptance of an automatic standby defibrillator will be dependent upon achieving satisfactory performance with a suitably sized unit. Since the size of the implanted unit is a very strong function of the energy required to achieve defibrillation, we have undertaken detailed studies of the energy requirements for various implanted electrode systems. Previous animal studies by our group have involved bielectrode intravascular catheters in which one electrode is in the right ventricle and the other in the superior vena cava or external jugular vein, or both.[7–9] Our experience has shown

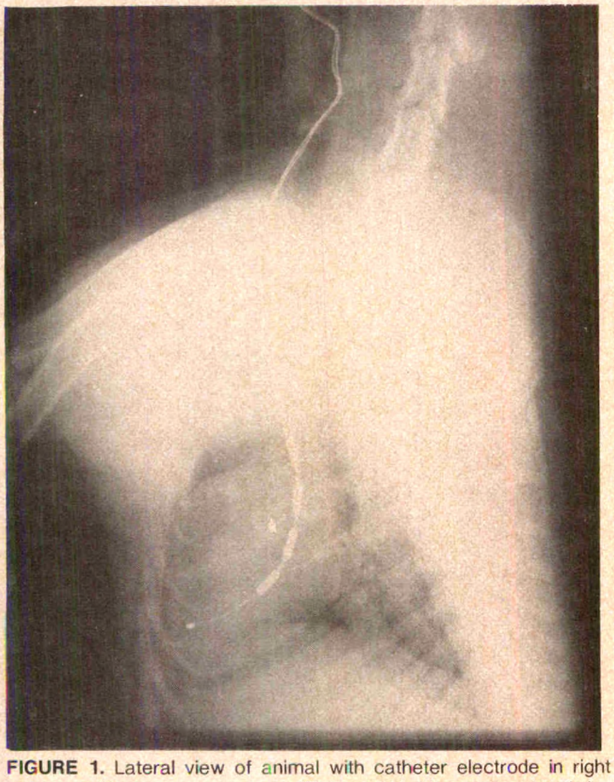

FIGURE 1. Lateral view of animal with catheter electrode in right atrium and superior vena cava. The marker slug at the tip of the catheter is insulated and not a part of the electrode system.

that the effectiveness of such bielectrode catheters in achieving defibrillation is critically dependent upon the tip of the distal electrode remaining well positioned in the apex of the right ventricle. Mirowski et al.[10] have had limited clinical experience with bielectrode catheters having one electrode in the apex of the right ventricle and the other in the superior vena cava.

This paper reports an extensive study of the energy required to achieve defibrillation with two additional types of totally implanted electrode systems. In the first of these systems, two disk electrodes are implanted in the anterior chest wall. In the second system, a catheter having an electrode in the right atrium and superior vena cava is used in conjunction with a disk implanted in the anterior chest wall over the apex of the heart. In addition, two partially implanted systems are considered.

Methods

Implanted Disks

Three dogs ranging in weight from 27 to 31 kg were used. Initially, each animal was subjected to a series of 20 transthoracic fibrillation-defibrillation episodes. An animal was anesthetized with pentobarbital sodium, 27.5 mg/kg body weight, and placed on a thick Plexiglas® table top. Disk electrodes, measuring 7.6 cm in diameter, were covered with Redux paste and taped to the anterior portion of the shaved chest. One electrode was placed over the apex of the heart and the other was positioned slightly to the right of the midline and higher on the chest.

Ventricular fibrillation was then induced by a low current shock and 30 seconds later an effort was made to defibrillate with the wave form being studied. If defibrillation was achieved on the initial trial, the episode was recorded as a success. Otherwise, the event was recorded as a failure and a shock of known high effectiveness was used to salvage the animal. In either event, the procedure was repeated with not less than 3 minutes elapsing between the start of successive episodes. Unidirectional, rectangular wave shocks, 4 msec in duration, were evaluated. In the first group of five episodes, the current amplitude was fixed at 7 amperes. In the second, third and fourth groups of five episodes, the current amplitude was 10, 14 and 20 amperes, respectively. This portion of our study involved 60 fibrillation-defibrillation episodes.

A high power vacuum tube defibrillator, which has previously been described[11] was used to supply all of the shocks. The wave forms of both the current and the voltage associated with the defibrillatory shocks were observed on a Tektronix model 5031 dual beam storage oscilloscope. The electrocardiograms of the animals were observed on a Hewlett-Packard model 130C oscilloscope.

After the initial transthoracic study, stainless steel electrodes 7.6 cm in diameter, polished on one face and insulated with epoxy and silastic on the other face, were implanted between the pectoralis major muscle and the rib cage with the conducting surface toward the rib cage. The right electrode was high on the chest and to the right of the midline. The left electrode was over the apex of the heart. Connections to the disks were made by leads whose proximal ends were externalized at remote locations during each period of evaluation and then reburied.

Using the same test procedure as outlined for our initial transthoracic study, we evaluated the resistance levels and effectiveness of the electrode system in reversing fibrillation in each of the three animals on the day of implantation and 1, 4, 8, 12, 16, 20, 24, 28 and 32 weeks after implantation. A total of 600 fibrillation-defibrillation episodes were used in this portion of our study.

Catheter-Implanted Disk

In two animals with implanted disks, catheters were inserted 33 weeks after the implantation of the disks, first through the right jugular vein and then on another day through the left jugular vein, so as to position an electrode in the right atrium and superior vena cava. The silastic catheter used in our study employed four stainless steel sleeves that were electrically connected together to constitute one electrode. The sleeves were 4 mm in diameter and 15 mm in length and were separated from each other by 10 mm. The most distal sleeve was 50 mm from the tip of the catheter.

In each of our four studies with these two animals, the catheter was inserted through a jugular vein and the tip, as visualized by a marker slug, positioned under fluoroscopy in the apex of the right ventricle. Ties around the vein and catheter, proximal and distal to the site of insertion, served to keep the catheter in position. The same insertion procedure was used in all of our work involving catheters. A typical view, from our catheter-external disk series, is shown in Figure 1.

Nine types of unidirectional rectangular wave shocks were used (5 amperes at 4, 8 and 16 msec, 7 amperes at 2, 4 and 8 msec and 10 amperes at 1, 2 and 4 msec). On a given day, this group of nine shocks was repeated five times. Thus, a given animal on a given day was subjected to 45 fibrillation-defibrillation episodes. The defibrillatory shocks being evaluated were delivered by our vacuum tube defi-

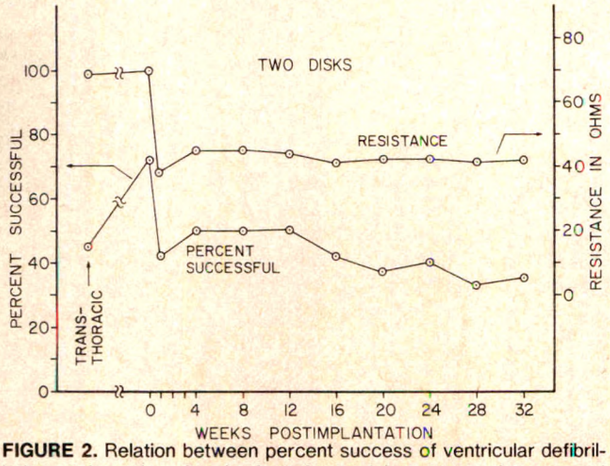

FIGURE 2. Relation between percent success of ventricular defibrillation and weeks after implantation and between resistance and weeks after implantation for implanted disk system when evaluated with set of shocks as specified in text.

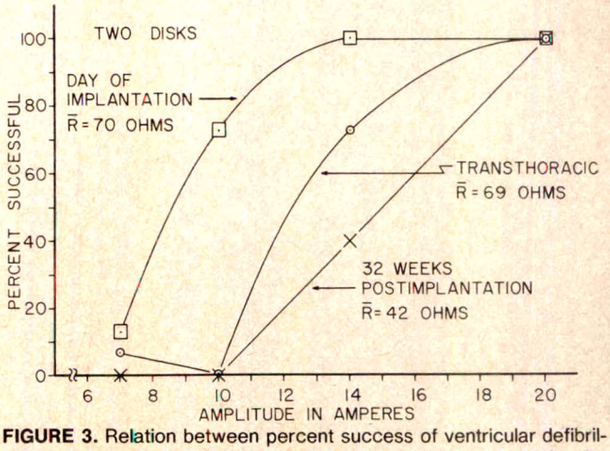

FIGURE 3. Relation between percent success of ventricular defibrillation and amplitude of 4 msec unidirectional rectangular pulse for the twin disk system as evaluated on a transthoracic basis, on the day of implantation and 32 weeks after implantation.

brillator to the electrode system consisting of the catheter electrode in the right atrium and superior vena cava and the disk electrode implanted over the apex of the heart. Shocks for inducing fibrillation and for salvaging the animal in the event the experimental shock was unsuccessful were delivered by another defibrillator[12] to the electrode system consisting of the two implanted disks. The waiting period between the induction of fibrillation and the application of the test shock and the time interval between the start of successive episodes were the same as those in our work with the implanted disks. A total of 180 fibrillation-defibrillation episodes were used in this portion of our study.

In four animals, ranging in weight from 24 to 29 kg, a study of the catheter-implanted disk system was conducted on the same day that a single disk was surgically implanted in the chest wall over the apex of the heart of each of the animals. In this part of the study, the defibrillatory wave forms being evaluated were again delivered to the electrode system consisting of the catheter electrode in the right atrium and superior vena cava and the disk electrode implanted over the apex of the heart. Shocks for inducing fibrillation and for salvaging the animal in the event the experimental shock was unsuccessful were delivered to an electrode system consisting of the implanted disk and an auxiliary disk on the surface of the right side of the chest. Each of these animals was subjected to the same series of 45 fibrillation-defibrillation episodes used in the long-term studies. A total of 180 fibrillation-defibrillation episodes were used in this portion of our study.

Catheter-Surface Disk

The experimental procedure for this portion of our study was substantially the same as that used for our work involving an implanted disk except that external disks were used. The electrode system under study consisted of the catheter electrode in the right atrium and superior vena cava and a 7.6 cm diameter Redux-covered disk electrode taped on the surface of the shaved chest over the apex of the heart. Seven animals ranging in weight from 24 to 29 kg were used. Four of the animals underwent 90 fibrillation-defibrillation episodes each (45 on one day and an additional 45 on another day), and three animals underwent 180 episodes. Thus, the derived data for this portion of our study are based on 540 episodes.

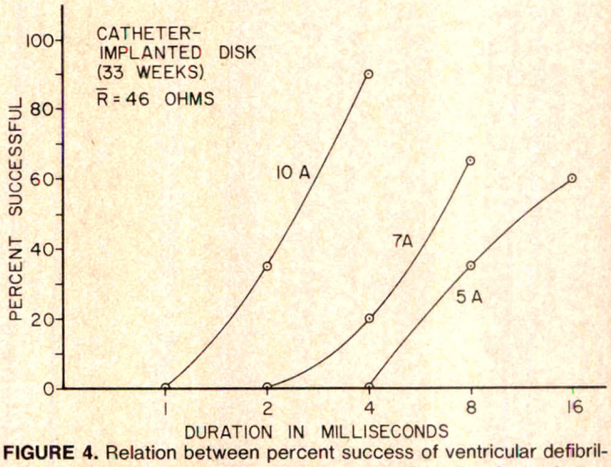

FIGURE 4. Relation between percent success of ventricular defibrillation and duration of unidirectional rectangular pulse for catheter-implanted disk system 33 weeks after implantation.

Catheter-External Sheet

The experimental procedure for this portion of our study was the same as that used in our work involving a surface disk, except that a 6.3 by 20.3 cm rectangular metal sheet was used for the surface electrode. The center of the rectangular sheet was centered over the apex of the heart with the rectangle oriented so that its long axis was perpendicular to the axis of the animal. The seven animals used in 540 episodes ranged in weight from 24 to 28 kg.

Results

The electrode-to-electrode resistance and effectiveness of defibrillation of the implanted disk system are sketched as functions of time and compared to transthoracic results in Figure 2. Each datum point on the resistance curve and each datum point on the percent success curve represents our experience with the complete given set of 20 shocks in each of three animals. Thus, the resistance value and the percent success figure represent the average determined from 60 shocks. Figure 3 shows the relations

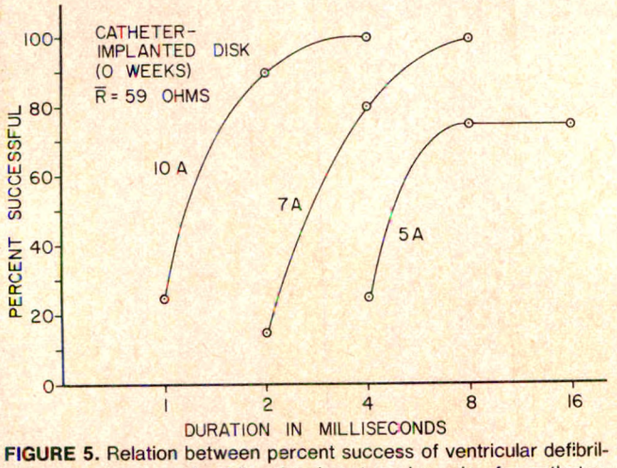

FIGURE 5. Relation between percent success of ventricular defibrillation and duration of unidirectional rectangular pulse for catheter-implanted disk system on day of disk implantation.

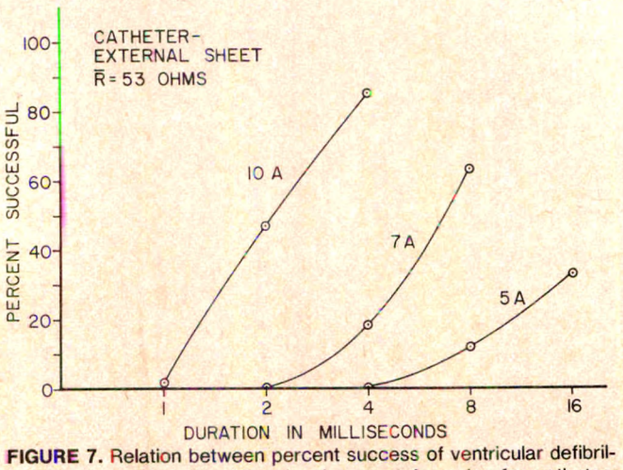

FIGURE 7. Relation between percent success of ventricular defibrillation and duration of unidirectional rectangular pulse for catheter-external sheet system.

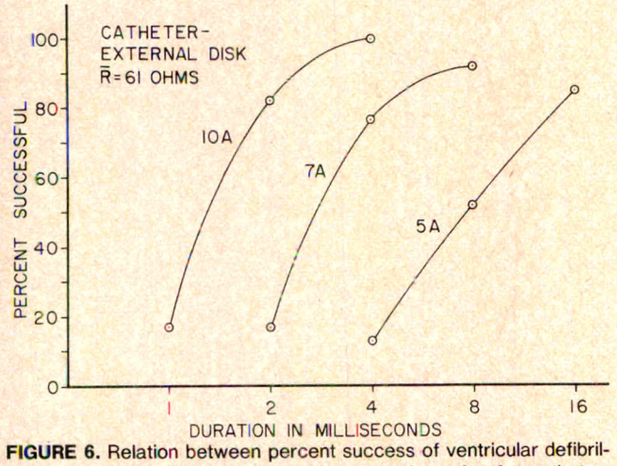

FIGURE 6. Relation between percent success of ventricular defibrillation and duration of unidirectional rectangular pulse for catheter-external disk system.

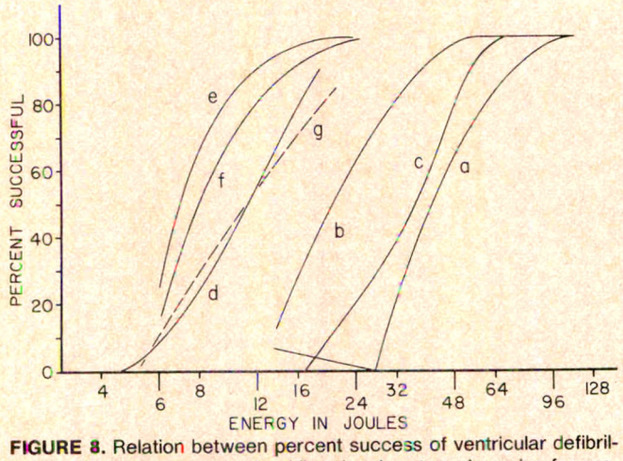

FIGURE 8. Relation between percent success of ventricular defibrillation and energy content of unidirectional rectangular pulse for systems consisting of two disks on surface of chest **(a)**, two implanted disks as evaluated on the day of implantation **(b)**, two implanted disks as evaluated 32 weeks after implantation **(c)**, catheter-implanted disk as evaluated 33 weeks after implantation **(d)**, catheter-implanted disk as evaluated on day of disk implantation **(e)**, catheter-surface disk **(f)** and catheter-surface sheet **(g)**.

between percent effectiveness and amplitude of the 4 msec shocks on a transthoracic basis, just after implantation and 32 weeks after implantation. Each datum point is based on 15 episodes, 5 in each of three animals. The average resistance associated with each of the three curves is also indicated.

Figures 4 through 7 summarize our results for the systems that involve an electrode in the right atrium and superior vena cava in conjunction with implanted or surface disks or a surface sheet electrode. In Figures 4 and 5, each datum point reflects our experience in 20 fibrillation-defibrillation episodes. In Figures 6 and 7, each datum point is based on 60 episodes. Average resistance values are indicated on each figure.

The energy content in joules of a unidirectional rectangular wave shock is given by the equation $U = I^2RT$, where I is the current in amperes, R the resistance in ohms and T the duration of the shock in seconds. Using this relation, we replotted in Figure 8 the three curves of Figure 3 and the 10 ampere members of each of the families of curves of Figures 4 through 7 so as to show the percent success as a function of the energy content of the shock.

Discussion

It is apparent from the data of Figure 2 that the effectiveness of defibrillation increases significantly as the disk electrodes are moved from the surface of the chest to the rib cage. We consider that this initial increase in effectiveness is probably due to an improvement in the flow pattern of the current, with a larger portion of the total current passing through the heart when the disks are on the rib cage. During the first week the disks are implanted, there is a very significant reduction in both resistance and defibrillation

effectiveness. We hypothesize that the decrease in resistance is due to the development of a high conductivity region in the biological material immediately surrounding each disk and that this in turn causes a more diffused flow pattern of current. The data presented in Figures 2 and 3 indicate that the effectiveness of defibrillation 32 weeks after implantation is somewhat less than that 1 week after implantation and much less than that on the day of implantation.

For the catheter-disk systems, the data in Figures 4 through 6 show a significant increase in system effectiveness as the disk is moved from the surface of the chest to the rib cage and then a marked decrease in effectiveness 33 weeks after implantation compared to effectiveness on the day of implantation. The average resistance of the catheter-disk systems decreases very slightly as the disk is moved from the external surface of the chest to the rib cage and then decreases significantly 33 weeks after implantation. This sequence of events is the same as that observed for the twin disk system, and we attribute it to the same factors. Our hypothesis concerning the relation between effectiveness and the flow pattern of the current is further strengthened by the observation that the results for the catheter-external sheet system (Fig. 7) are very nearly the same as for the catheter-implanted disk system 33 weeks after implantation (Fig. 4). With use of the equation cited previously, it is evident that on an energy content basis, the 10 ampere members of each of the families of curves in Figures 4 through 7 are superior to the 7 and 5 ampere members of the same family. This is the reason why these curves were selected for replotting on an energy basis in Figure 8.

The most significant single feature of the family of curves shown in Figure 8 is that any given percent success level can be achieved with significantly less energy in systems involving the right atrium—superior vena cava electrode (curves d, e, f and g) than with twin disk systems (curves a, b and c).

Although exactly comparable data are not available for the bielectrode catheter having one electrode in the apex of the right ventricle and the other in the superior vena cava or jugular vein, or both, available data [7–9] suggest that the energy requirements for the right atrium and superior vena cava-implanted disk system (curves d and e, Fig. 8) compare favorably with the requirements for the bielectrode catheter.

Accelerated Cardiac Escape Rhythms Caused by Ouabain Intoxication

DOUGLAS P. ZIPES, MD, FACC*
EMANUEL ARBEL, MD†
RUSSEL F. KNOPE, MD‡
GORDON K. MOE, MD, PhD

Utica, New York
Indianapolis, Indiana

In anesthetized dogs treated with ouabain, the ventricular escape intervals were measured after (1) vagally induced atrioventricular block, (2) ventricular premature stimulation, or (3) cessation of a period of regular pacing at various cycle lengths. The escape intervals were a direct function of the basic cycle length and were significantly influenced by the last cycle length, whether premature or postmature. Postpacing acceleration of atrial ectopic responses was also demonstrated. When compared with results obtained in isolated Purkinje tissue, ectopic activity associated with early ouabain toxicity appears to be caused by frequency-related transient depolarizations rather than "true" phase 4 depolarization.

Ectopic ventricular activity accompanying digitalis intoxication is usually attributed to the development of pacemaker activity within the specialized conduction system of the ventricles. So long as the intrinsic frequency of the ectopic focus remains slower than that of the sinoatrial node, its pacemaker potentiality remains silent. During the "silent" period, ectopic activity may be exposed by vagal stimulation.[1] The ventricular "escape" interval during vagal stimulation has often been used as an indicator of developing digitalis intoxication in experimental preparations.[2]

If an accelerated ectopic pacemaker can be exposed during the pause induced by vagal stimulation, it should also escape during the compensatory pause after a premature ventricular contraction; and this, too, has been demonstrated. Castellanos et al.[3] observed repetitive responses to single pacemaker stimuli applied to the ventricle during diastole. Lown et al.[4] applied the term repetitive ventricular response ("RVR") to this phenomenon and suggested that it might be used as a sensitive indicator of digitalis intoxication. In their experiments, it seemed clear that a ventricular ectopic focus emerged during the compensatory pause after a premature beat and that, depending upon the relative frequencies of the normal and ectopic pacemakers, "interference dissociation" could permit a series of extrasystoles to appear. If this explanation were valid, one would expect reduction of the sinoatrial nodal frequency by vagal stimulation to expose the same ectopic pacemaker at the same escape interval and frequency. However, Vassalle et al.[5] observed that ventricular extrasystoles appearing during ouabain intoxication were suppressed when the sinus rate was slowed, whereas acceleration resulted in runs of extrasystoles. Wittenberg et al.[6,7] also demonstrated that a period of rapid pacing enhanced the idioventricular frequency.

In preliminary studies, we observed that (1) the escape intervals characteristic of the repetitive ventricular response phenomenon were briefer than those that occurred during vagal stimulation, and (2) the site of origin of the ectopic activity was very often different. These observations were obviously incompatible with the idea that an occult pacemaker will escape whenever a long enough interval is pro-

vided. Our findings suggested that the effects of vagal stimulation and premature ventricular stimulation are at least quantitatively different.

During the course of our preliminary studies, Ferrier et al.,[8] examining the effects of acetylstrophanthidin on isolated Purkinje fibers, observed the development of frequency-dependent transient depolarizations during a pause after a series of driven responses. These depolarizations could reach threshold levels and cause one or more automatic responses. Ferrier et al. concluded that the transient depolarizations, rather than "true" phase 4 depolarization, were responsible for early ectopic activity induced by the cardiac glycosides.

The in vitro observations in isolated Purkinje tissue appeared to fit the characteristics of several phenomena: repetitive ventricular response, frequency-dependent extrasystolic activity and vagally induced escape beats under the influence of cardiac glycosides. The studies reported here were undertaken to analyze these phenomena and to relate them to the in vitro observations of Ferrier et al.[8]

Methods

The study was performed in 36 adult mongrel dogs of both sexes, anesthetized with pentobarbital sodium, 30 mg/kg, and ventilated with a Harvard respirator. The chest was opened in the midline and the pericardium was used to support the heart. In some experiments the sinus node was crushed to achieve a slower spontaneous heart rate. The vagi were isolated and cut in the neck, and the distal ends were used for stimulation. Stimulating and recording bipolar hook electrodes with an interelectrode distance of 1 to 2 mm were placed on the atria and ventricles. Stimuli of 2 msec duration were delivered through an isolated circuit by a Tektronix pulse generator, triggered by a digitally controlled interval generator, at an intensity of 1 1/2 times the diastolic threshold. After demonstration of failure of accelerated ventricular escape beats to emerge during the control period, 25 μg/kg of ouabain was administered intravenously and testing was repeated. If necessary, subsequent injections of ouabain (10 μg/kg at 1/2 to 1 hour intervals) were made until escape beats occurred. Testing for escape beats was begun about 5 minutes after each dose; more extensive series of observations were made when escape intervals were stable, 20 to 30 minutes after injection of ouabain.

During continuous atrial pacing, accelerated ventricular escape beats were elicited by two methods. Premature stimuli were delivered to the ventricles as in the studies of Lown et al.;[4] this maneuver allowed an accelerated ventricular escape beat to occur during the compensatory pause after the premature ventricular complex (Fig. 1, A and B). The second method employed vagal stimulation for 50 msec with square wave pulses of 1 to 2 msec duration at a frequency of 40 to 80 Hz delivered 150 msec before the next atrial stimulus (Fig. 1C). The voltage was adjusted to cause atrioventricular block of a single atrial paced impulse without affecting atrioventricular conduction of succeeding responses. On occasion, combinations of premature ventricular stimulation and vagal stimulation were employed. In some experiments, regular pacing and premature stimuli were applied to the ventricle; vagal stimulation was continuous to prevent interference from supraventricular pacemakers. Ventricular escape intervals were measured from

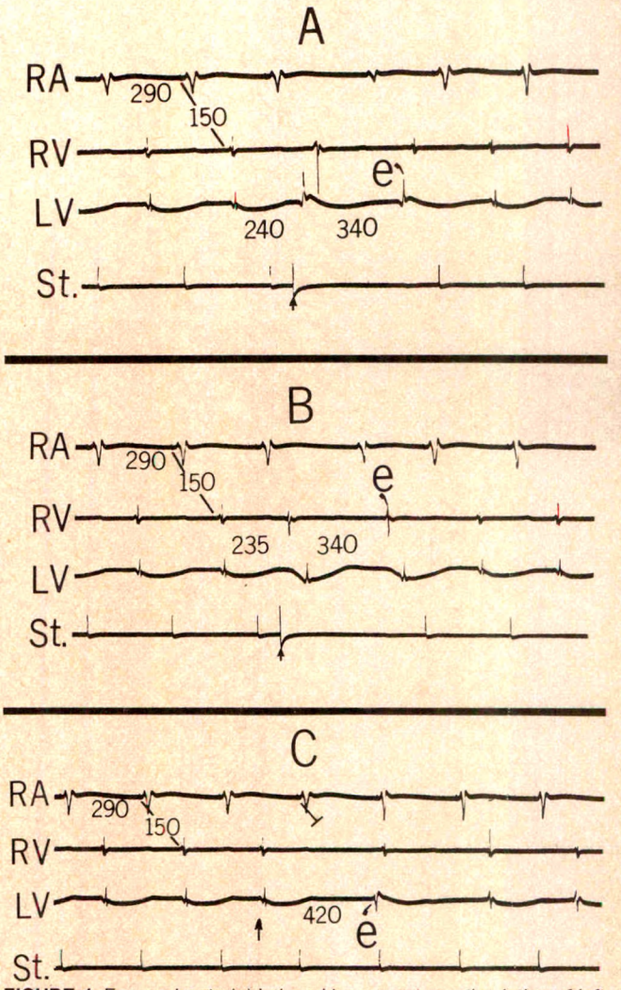

FIGURE 1. Escape beats (e) induced by premature stimulation of left ventricle **(A)**, right ventricle **(B)** and vagus **(C)**. The right atrium is driven at a basic cycle length of 290 msec in all panels. Tracings, top to bottom: right atrial (RA), right ventricular (RV) and left ventricular (LV) electrograms and stimulus artifact (St). The coupling interval of the left ventricular premature response in **A** is 240 msec; that of the right ventricular premature response in **B** is 235 msec. Escape intervals in **A** and **B** are 340 msec; the escape beat originates in the stimulated ventricle in each case. In **C**, a brief burst of vagal stimuli (at **arrow**) blocks transmission of next atrial response, permitting a left ventricular escape beat at 420 msec.

the local electrograms of the ventricular escape beats, recorded at a paper speed of 100 mm/sec on a multichannel oscillograph.

The effects of rapid atrial pacing upon atrial rhythm were evaluated by driving the atrium rapidly at different frequencies for 30 seconds and suddenly terminating pacing. These experiments were performed in animals with a crushed sinoatrial node. The initial escape interval was determined by measuring the interval between the electrogram of the atrial escape beats and the electrogram from the last atrial paced beat.

Results

General Nature of the Escape Beats

Ventricular escape beats could be demonstrated as early as 20 minutes after the intravenous administra-

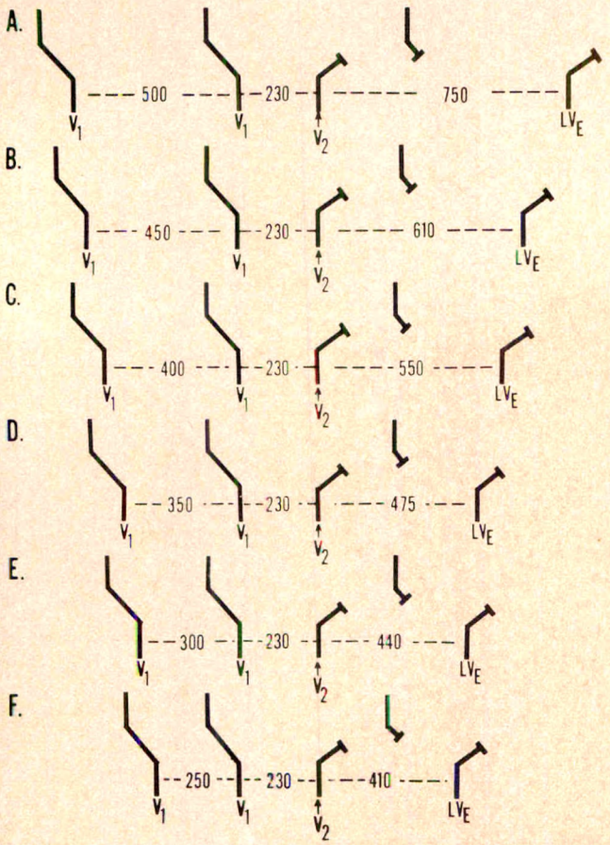

FIGURE 2. Effect of basic cycle length on escape intervals after premature stimulation of the left ventricle. The atrium was paced at the cycle lengths (in milliseconds) indicated in the column at **left;** the V_1–V_2 interval is fixed at 230 msec. LV_E = left ventricular escape beats at the intervals listed in the column at **right.**

tion of 25 μg/kg of ouabain, at a time when there were no overt signs of ectopic activity. In 3 of 14 dogs, premature ventricular stimulation resulted in coupled ventricular responses (repetitive ventricular response) at a stage when vagal stimulation failed to elicit an escape beat within the interval provided; the reverse situation occurred in 2 dogs. In nine dogs, ventricular escape beats could be produced at the same level of ouabain intoxication by either premature ventricular stimulation or vagal stimulation; however, shorter driving cycle lengths were frequently necessary to produce vagally induced escape beats.

Figure 1 illustrates the testing procedure. The atria were driven at a cycle length of 290 msec for 8 to 10 basic cycles. Early premature stimuli applied to the left or right ventricle resulted in coupled beats at an escape interval of 340 msec (Fig. 1, A and B). Vagal stimulation (Fig. 1C, arrow) blocked a single P wave; in the ensuing pause, a left ventricular escape beat occurred at a cycle length of 420 msec.

Mechanism of vagally induced escape beats and repetitive ventricular response: Two features of this experiment suggested that the vagally induced escape beat and the repetitive ventricular response might represent two different mechanisms. The repetitive ventricular response appeared at a shorter interval than the vagally induced escape beat, and in each case originated within the ventricle that was stimulated. If the ectopic responses represented the activity of a latent pacemaker permitted to emerge by the compensatory pause (Fig. 1,A and B) or by the vagally induced atrioventricular block (Fig. 1C), the same escape interval and the same configuration of the ectopic response should have occurred in each case.

At this stage in the study, it was considered possible that a latent pacemaker within the more proximal distribution of the conduction system might be temporarily inhibited by vagal stimulation. However, vagal stimulation sufficient to block atrioventricular transmission during atrial pacing resulted in escape intervals similar to those that followed simple cessation of atrial stimulation. We concluded that the vagus nerve did not significantly influence discharge of the ectopic pacemaker.

Effect of Heart Rate

Experiments were devised to test the influence of basic frequency on the escape interval. In one set of observations, the V_1–V_2 response interval for the premature response was held constant while the basic cycle length was altered; in the other set, the driving frequency was constant while the V_1–V_2 interval was altered.

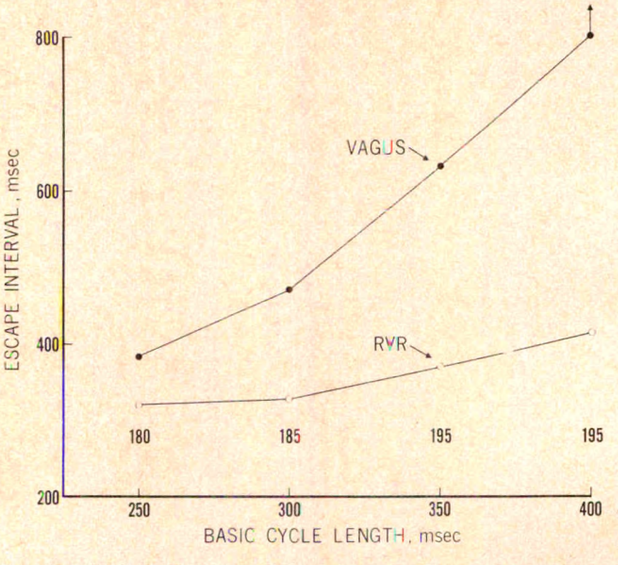

FIGURE 3. Left ventricular escape intervals exposed by vagal stimulation **(solid circles)** and by early premature stimulation of the left ventricle (**open circles,** RVR, "repetitive ventricular response") as a function of basic cycle length. The heart is driven by atrial stimuli. V_1–V_2 intervals are shown at each basic cycle length indicated by the row of figures at bottom. **Upright arrow** at basic cycle length = 400: no escape occurs within the 800 msec interval provided.

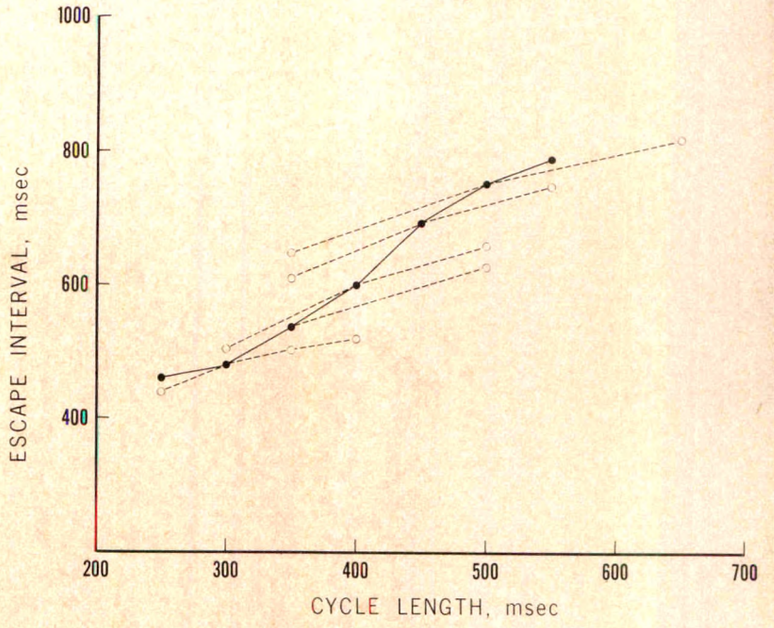

FIGURE 4. Cumulative effect of cycle length on escape interval. The **solid line** connects points recorded after interruption of the train of driving stimuli, at indicated cycle lengths. **Broken lines** indicate premature and postmature stimuli at various basic cycle lengths.

The escape interval after a premature ventricular stimulus at a fixed V_1–V_2 interval is, like the vagally induced escape interval, a function of the basic cycle length preceding the V_2 stimulus. In the experiment illustrated in Figure 2 the V_1–V_2 interval was fixed at 230 msec, and the premature stimulus was applied to the right ventricle. The escape beat, originating in the left ventricle, occurred progressively earlier as the basic cycle length was reduced from 500 to 250 msec.

In the other set of experiments, the basic cycle length was fixed as the V_1–V_2 interval was increased. The escape interval increased progressively as a function of the V_1–V_2 interval.

Comparison of escape intervals resulting from premature and vagal stimulation: Figure 3 compares the escape intervals resulting from premature stimulation and those exposed by vagal stimulation. Both sets of data were obtained from the same animal at approximately the same time. The heart was driven by rhythmic stimuli applied to the right atrium at cycle lengths of 400 to 250 msec. Premature stimuli were applied to the left ventricle at the end of the functional refractory period. At the same basic cycle lengths, atrioventricular block of a single atrial response was induced by brief bursts of stimuli applied to the vagus nerves 150 msec before the subsequent atrial discharge. At the slowest frequency no vagally induced escape beat appeared within the 800 msec pause allowed, but premature ventricular stimulation induced a left ventricular escape beat at 415 msec. At faster driving rates, the vagally induced escape interval was always longer than the repetitive ventricular response interval. Similar relations were observed in other experiments.

If the escaping focus is the same whether exposed by vagal or premature ventricular stimulation, and if its intrinsic rate is not altered by vagal discharge, then the vagally induced escape interval represents the cumulative effect of the driving frequency, and the downward displacement of the repetitive ventricular response curve represents the additional influence of the last (premature) cycle length.

Effect of basic driving frequency on escape interval: The cumulative effect of the basic driving frequency is defined in Figure 4. In this experiment, the heart was driven by stimuli applied at various frequencies to the right ventricle. Interference from supraventricular pacemakers was suppressed by vagal stimulation. After each train of 10 driving stimuli, the stimulator was interrupted long enough to define the relation between basic cycle and escape interval. At each driving rate, an early premature stimulus was delivered through the same stimulating electrodes, and the now briefer escape interval was recorded. Similarly, the response to postmature stimuli ($S_1S_2 > S_1S_1$) was recorded.

The data in Figure 4 describe a kind of hysteresis loop; there is a cumulative effect of the basic driving frequency on the escape interval, but the last cycle, whether briefer or longer than the basic cycle, exerts a major influence.

Atrial Escape Rhythms

The effect of ouabain on ectopic activity in the atria was evaluated by using the technique of "overdrive" pacing in animals with a crushed sinus node. The atrium was driven at various frequencies for a period of 30 seconds, and the subsequent escape interval was recorded. It was established in each case that the first spontaneous response was not a ventricular escape beat propagated back to the atrium, but its precise site of origin was not determined. Figure 5

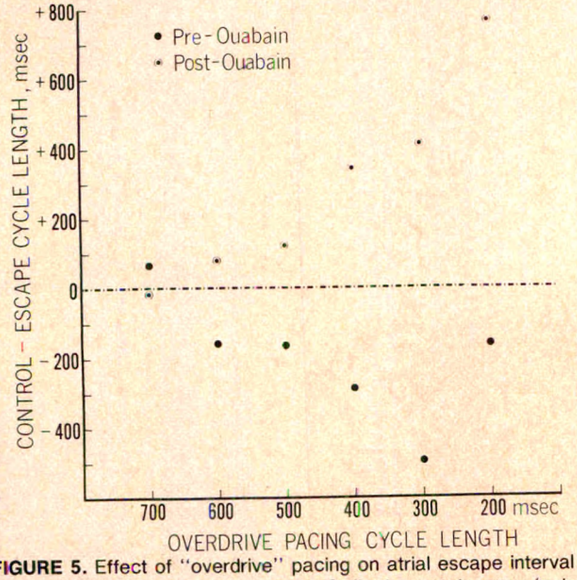

FIGURE 5. Effect of "overdrive" pacing on atrial escape interval in an animal with a crushed sinus node. **Ordinate:** spontaneous (ectopic) atrial cycle length minus escape interval. **Abscissa:** cycle length of overdrive pacing of the atrium for 30 second periods. The upward "displacement" of the control data point at the 200 msec cycle length probably represents a 2:1 response of the ectopic pacemaker site to the pacing stimuli.

illustrates one such experiment. Before administration of ouabain, the spontaneous prepacing cycle lengths ranged from 700 to 1,100 msec. After administration of ouabain, the spontaneous frequency was slightly depressed; the cycle lengths ranged from 950 to 1,200 msec. To "normalize" the escape intervals, the data are plotted as the difference between the spontaneous prepacing cycle length and the first escape interval at each of six driving frequencies. The difference was positive if postpacing acceleration occurred; it was negative if depression resulted. During the control period, the expected postpacing depression of automaticity occurred (filled circles). After the administration of ouabain (45 μg/kg, given intravenously as an initial dose of 25 μg/kg followed by two 10 μg/kg injections at 40 to 60 minute intervals), postpacing acceleration of the atrial escape rhythm was demonstrated.

Discussion

Our experiments confirm the observations of other investigators[3,4,6], who established that an increase in pacing rate accelerated the rate of the postpacing ventricular rhythm and shortened both the first escape cycle length and the escape interval after premature ventricular stimulation. In addition to the basic heart rate, the coupling interval at which a premature stimulus is delivered affects the subsequent ventricular escape interval. Lengthening the coupling interval lengthened the ventricular escape interval until a ventricular escape beat was prevented by the next response of supraventricular origin. A ventricular escape beat could be exposed once again if the spontaneous atrial systole was blocked or delayed. Postmature ventricular stimulation significantly delayed the ventricular escape interval.

At similar basic cycle lengths, ventricular escape intervals that followed vagal stimulation were almost always longer than those that followed premature ventricular stimulation; often, ventricular escape beats followed premature ventricular stimulation, but not vagal stimulation, within the time intervals allotted. The short cycle produced by premature ventricular stimulation, which was not present after vagal stimulation, accounts for these differences. Hagemeijer and Lown[9] also noted that the minimal heart rate necessary to produce ventricular escape beats after premature ventricular stimulation was less than that required to produce escape beats after a pause in pacing.

Mechanisms of Ectopic Activity Associated with Ouabain Toxicity

Kastor et al.[10] suggested that ouabain preferentially enhances automaticity of canine Purkinje fibers in the left ventricle. Rothberger and Winterberg[1] drew a similar conclusion. Our data in part support this conclusion by demonstrating left ventricular escape beats after vagal stimulation in 9 of 14 animals. However, after premature ventricular stimulation, the escape impulse most often arose on the stimulated side. The explanation for this apparent discrepancy is obvious. When a premature response is evoked by a stimulus applied to the right ventricle, any potential ectopic focus within the conducting system on the right will be discharged earlier than a comparable focus on the left. Accordingly, the response will be more premature on the right side, and the coupling interval of the ectopic response within the right ventricle should be correspondingly more abbreviated than in any potential focus on the left side.

Reentry?: The ectopic responses initiated by premature stimulation of the ventricles have usually been considered manifestations of pacemaker activity accelerated by digitalis; closely coupled responses have been ascribed to reentry. However, coupled activity is an early manifestation of digitalis toxicity; it can be demonstrated shortly after the injection of 25 percent of the lethal dose of ouabain, before any significant depression of conductivity in the atrium, atrioventricular node or ventricles. It is unlikely, therefore, that the spontaneous discharge is due to reentry.

Phase 4 depolarization?: It is also unlikely that the ectopic activity results from enhanced phase 4 depolarization, unless that term is broadened to include all automatic activity not due to reentry. In some of the experiments described by Vassalle et al.,[5] the vagal escape interval was prolonged by digitalis, although coupled responses could still be elicited. In the in vitro studies of Ferrier et al.,[8] the "pacemaker" potential of isolated Purkinje fibers was regularly de-

pressed by acetylstrophanthidin at a time when transient depolarizations were coupled to an antecedent driven response. The coupling interval of the transient depolarizations (or ectopic responses generated by them) was abbreviated by acceleration of the driving rate or by the interpolation of premature responses. These events were also described in specialized atrial fibers, identified by the phase 2 plateau configuration of their action potentials.[11]

Rate-dependent depolarizations?: Our results do not permit the conclusion that ectopic activity exposed by vagal stimulation or premature stimulation of the ventricles, or accelerated by increasing the driving rate of the atria or ventricles, is—or is not—due to enhanced phase 4 depolarization. They do not permit arbitrary rejection of reentry as the cause. However, the similarity of the behavior of the ectopic activity with that described by Ferrier et al.[8] and Hashimoto and Moe[11] suggests that the escape responses in the atria and ventricles may be manifestations of rate-dependent transient depolarizations rather than of reentry or "true" pacemaker activity.

Predominant Right Ventricular Dysfunction After Right Ventricular Destruction in the Dog

NABIL H. GUIHA, MD*
CONSTANTINOS J. LIMAS, MD
JAY N. COHN, MD, FACC

Washington, D. C.

Right and left ventricular function was assessed by observing the response to rapid blood volume expansion before and after extensive cauterization of the right ventricle in open chest dogs. In the control period, left ventricular end-diastolic pressure surpassed right ventricular end-diastolic pressure by an average of 11.5 mm Hg after volume expansion whereas, after destruction of the right ventricle, pressure in this chamber surpassed pressure in the left ventricle by an average of 4 mm Hg. In contrast, after left ventricular damage, left ventricular end-diastolic pressure averaged 25 mm Hg more than right ventricular end-diastolic pressure. Despite extensive damage to the right ventricular free wall, the right ventricle continued to generate a near normal pressure and aortic flow could be increased above control levels by volume expansion. We conclude that, in contrast to previous evidence, damage to the right ventricle produces a syndrome of predominant right ventricular dysfunction. However, cauterization of the entire free wall of the right ventricle does not reproduce the more profound right ventricular dysfunction noted in infarction of the right ventricle in man.

Since the original observations of Starr et al.[1] in 1943 that right ventricular damage did not lead to increased venous pressure, it has generally been held that normal right ventricular myocardial function is not necessary for circulatory stability when the pulmonary vascular bed is normal. This thesis has not been reexplored in recent years, nor has it previously been tested clinically because the isolated case reports of right ventricular infarction have not included pertinent hemodynamic observations.

Our recent observation of six patients with apparent right ventricular infarction associated with evidence of predominant right ventricular dysfunction[2] led us to return to the experimental model used by previous workers[1,3,4] in order to define changes in ventricular function more carefully than was possible in the earlier studies. Our findings confirm clinical observations that right ventricular damage may lead to a syndrome of predominant dysfunction of the right ventricle. However, they demonstrate that isolated right ventricular damage should not precipitate a low output state so long as intravascular volume is adequately expanded.

Methods

Eight mongrel dogs were anesthetized with pentobarbital sodium; pulmonary ventilation was maintained by an intermittent positive pressure respirator. The chest was opened by a midsternal incision and the pericardium cut to expose the heart. Catheters were introduced in the femoral artery for continuous monitoring of pressure and in the femoral vein for volume loading and blood withdrawal. The right and left ventricles were catheterized and right and left ventricular end-diastolic pressures were measured from the mid-chest using Statham P23Db strain gage transducers amplified and recorded on a multichannel Hewlett Packard recorder. Aortic flow was mea-

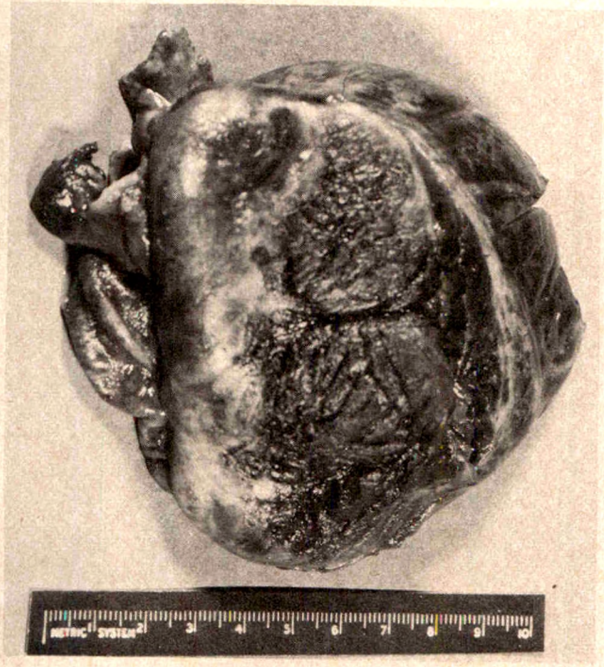

FIGURE 1. Right ventricular free wall after extensive cauterization. Damage extends through entire ventricular wall.

sured by means of an electromagnetic flow probe (Statham) placed around the ascending aorta. Flow was not calculated in absolute terms but was reported as percent change from control levels.

Ventricular damage was produced in seven dogs by application of a heat cautery to the entire free wall of the right ventricle in six dogs and to the anterolateral wall of the left ventricle in one dog. The desired degree of transmural damage—approximately 75 percent of the right ventricular surface (Fig. 1) or 50 percent of the left ventricular surface—was produced by repeated application of the cauterization over approximately 45 minutes until the integrity of the ventricular wall appeared threatened. In the eighth dog left ventricular damage was accomplished by injection of 0.2 ml of mercury into the left circumflex coronary artery. Two dogs died of ventricular fibrillation during the procedure; five other dogs manifested ventricular fibrillation that was promptly reverted by electrical countershock. After the right ventricle had been cauterized, the chamber was noted to be dilated. No systolic contraction of the free wall of the ventricle could be detected visually.

Ventricular function was assessed before and after myocardial damage by monitoring the response to rapid volume expansion. In the control period 500 to 1,000 ml of dextran and saline solution was administered intravenously over a period of 5 to 10 minutes or until left and right ventricular filling pressures were significantly increased. Blood was then withdrawn until ventricular end-diastolic pressures were restored to control levels. Immediately after satisfactory myocardial damage had been produced, the withdrawn blood was rapidly reinfused and additional dextran and saline administered if necessary to raise ventricular end-diastolic pressures to high levels. In two dogs volume expansion was carried out only after right ventricular damage had been produced in order to rule out any possible influence of the precautery volume expansion on the results noted after right ventricular damage. In one dog the circulating blood volume was allowed to equilibrate with a dextran-filled 500 ml reservoir connected in series to the femoral vein before the control studies. Volume loading could then be accomplished without altering the hematocrit by compressing the reservoir to empty its contents into the vascular system.

Results

Ventricular Filling Pressures

After instrumentation of these open chest dogs left ventricular end-diastolic pressure averaged 6.5 mm Hg and right ventricular end-diastolic pressure 2.6 mm Hg (Table I). During rapid volume expansion both pressures increased progressively, with end-diastolic pressure in the left ventricle increasing at a greater rate than that in the right. At the end of the volume infusion left ventricular end-diastolic pressure remained more than double the simultaneously measured right-sided pressure. The response to whole blood expansion from a reservoir was identical to the response to dextran infusion and the data were therefore pooled.

After cauterization of the right ventricle, both right and left ventricular end-diastolic pressures remained normal. However, that in the right ventricle had increased slightly to 5.3 mm Hg and now was slightly greater than that in the left ventricle, which had decreased to an average of 5.0 mm Hg. During rapid volume expansion after right ventricular damage, right ventricular end-diastolic pressure increased at a greater rate than left ventricular end-diastolic pressure (Fig. 2 and 3). At the end of the infusion of blood and dextran, right surpassed left ventricular end-diastolic pressure by an average of 4 mm Hg. The response to the infusion was similar whether the animals had or had not received a volume challenge before cauterization.

Calculation of right ventricular peak systolic minus end-diastolic pressure provided an index of the pres-

sure generated by the right ventricle. Pressure generation averaged 18 mm Hg in the control period and increased to 31 mm Hg during volume expansion. After right ventricular damage, pressure generation was 19 mm Hg, but no significant increase occurred during volume expansion and pressure generation averaged only 20 mm Hg at the end of the infusion period.

Left ventricular damage led to a sharply increased left ventricular end-diastolic pressure and a slightly increased right ventricular end-diastolic pressure. During volume loading, the former pressure increased markedly to an average of 40 mm Hg and surpassed the latter by an average of 25 mm Hg (Fig. 2 and 3).

Aortic Flow

After right ventricular damage, aortic flow was reduced by an average of 20 percent. This reduction in right ventricular output despite a slight increase in right ventricular end-diastolic pressure indicates a considerable shift downward and to the right of the right ventricular function curve (Fig. 4). In contrast, the reduction in left ventricular output was accompanied by a reduction in left ventricular filling pressure consistent with little or no change in left ventricular function. During progressive volume expansion, aortic flow rose to levels more than 50 percent higher than control flow levels but at the expense of a sharp increase in right ventricular end-diastolic pressure and a relatively smaller increase in left ventricular end-diastolic pressure. Therefore, right ventricular damage resulted in a marked shift to the right of the right ventricular function curve so that it then moved to the right of the left ventricular function curve.

Discussion

The right ventricle serves to propel blood through the lungs and to provide an adequate left ventricular filling pressure while maintaining a low central venous pressure. It is therefore the performance of the right ventricle that should account for the fact that left atrial pressure normally is higher than right atrial pressure. The observations of Starr et al.,[1] Bakos[3] and Kagan[4] that damaging the right ventricle did not raise venous pressure requires further scrutiny. If right ventricular function were completely abolished, then left atrial filling might still be maintained if there was an adequate pressure gradient from the right atrium to the left atrium allowing passive flow through a low resistance pulmonary vascular bed. This phenomenon is exemplified in the studies of Rodbard and Wagner,[5] who demonstrated that pulmonary blood flow could be maintained when the right ventricle was excluded from the circulation.

However, right ventricular function persisted in our studies as well as in the catheterization studies of Bakos[3] and Kagan,[4] since the right ventricle generated normal pressures after it had been damaged. The source of systolic pressure in the right ventricle after

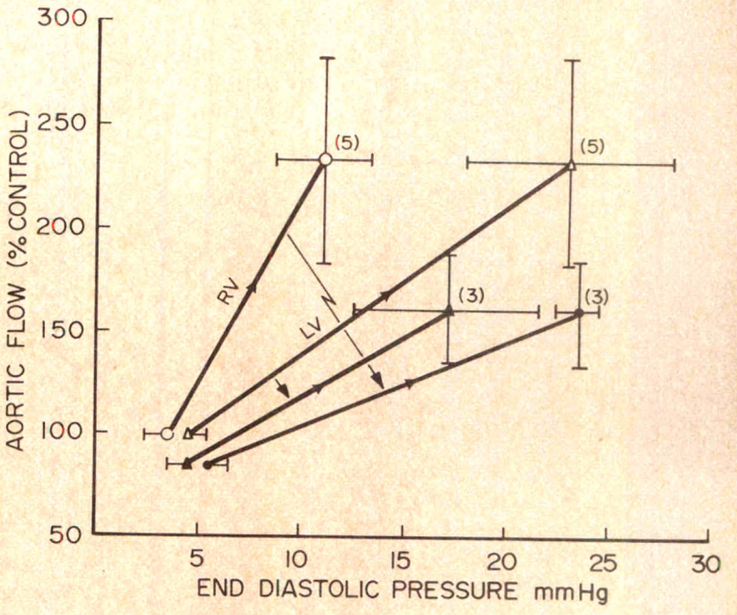

FIGURE 4. Mean relation between aortic flow and left (LV) and right (RV) ventricular end-diastolic pressure during volume expansion before and after right ventricular cauterization. In control period **(open symbols)**, the left ventricular function curve is normally situated to the right of the right ventricular function curve. After cauterization **(closed symbols)** the right ventricular function curve is shifted markedly to the right of the left ventricular function curve. Note that after right ventricular damage, volume flow before volume expansion has been reduced to an average of 70 percent of control flow level. However, flow can still be increased to more than 150 percent of the control level during volume loading.

destruction of this chamber has never been satisfactorily resolved. Since many of the bands of myocardial muscle encircle both ventricles,[6] Bakos[3] suggested that contraction of left ventricular fibers could also generate pressure in the right ventricle. However, the absence of contraction of the free wall of the right ventricle noted both visually and myographically[4] does not support this hypothesis. A more likely explanation is that residual functioning right ventricular fibers, either in the deeper layers of the myocardium less severely damaged by cauterization or in the interventricular septum, are capable of shortening adequately to generate a normal level of resting pressure.[4,7] Since right ventricular contraction involves primarily apex to base shortening rather than a change in transverse diameter, as in the left ventricle,[8] effective pressure generation would not necessarily be abolished by destruction of the right ventricular free wall. Noncompliance of the cauterized portion of the chamber might contribute to the pressure increase when the residual fibers shorten.

Even though the damaged right ventricle exhibited only a slight increase in end-diastolic pressure and was capable of generating a normal systolic pressure, it is clear that right ventricular function was considerably impaired. The pressure gradient between the left and right atria was reduced, and during progressive volume loading a paradoxical right to left ventricular end-diastolic pressure gradient of 1 to 5 mm Hg was maintained. The right ventricular peak pressure generation, which increased during volume expansion in the control period, was unchanged during loading after right ventricular damage. In contrast, left ventricular damage resulted in a disproportionate rise in left ventricular end-diastolic pressure and the gradient between left and right ventricular end-diastolic pressures increased progressively during infusion. It is likely that the increase in right ventricular output that accompanied volume expansion after right ventricular damage was due both to an increase in end-diastolic stretch of the residual functioning fibers and to a passive increase in pulmonary flow resulting from the right atrial–left atrial pressure gradient. Since normal and abnormal cardiac function curves tend to converge at reduced filling pressures,[9] the severity of ventricular dysfunction may become apparent only when the ventricle is challenged with an acute increase in preload. It is also possible that tricuspid regurgitation contributed to the rightward shift of the right ventricular function curve at greater filling pressures.

Clinical implications: The aortic flow measured in these studies is of particular importance in relating these experimental studies to the clinical syndrome of pump failure after myocardial infarction. Although flow was reduced after right ventricular damage it could always be restored to values above control levels by increasing right ventricular end-diastolic pressure. Therefore, low output failure or shock should not complicate this type of experimental right ventricular destruction so long as blood volume is expanded and pulmonary vascular resistance is not increased. The explanation for low cardiac output despite increased right ventricular end-diastolic pressure in patients with right ventricular infarction thus must be attributed to differences in the nature of the damage to the right ventricle or to coexisting left ventricular damage, or both. In contrast to these findings in experimental right ventricular destruction, patients with right ventricular infarction may demonstrate almost complete absence of right ventricular pressure generation. This difference in response probably reflects a difference in the distribution of the myocardial injury, which in patients with ischemic heart disease is likely to involve the septum as well as the free wall and therefore may abolish apex to base shortening. As in clinical acute myocardial infarction,[10] experimental infarction of the left

ventricle resulted in a sharp increase in left ventricular end-diastolic pressure. Support of pulmonary blood flow in this circumstance can be maintained with a near normal right ventricular end-diastolic pressure by virtue of the pumping ability of the right ventricle. When this is impaired by right ventricular myocardial damage, end-diastolic pressure in the right ventricle rises to levels as high or higher than those in the left ventricle and the syndrome of predominant right ventricular dysfunction occurs.

In summary, right ventricular damage produces disproportionate right ventricular dysfunction, but isolated right ventricular damage should not in itself lead to irretrievable circulatory impairment. Nonetheless, right ventricular damage accompanied by left ventricular damage should produce a specific hemodynamic derangement in which predominant right ventricular dysfunction may be accompanied by a low output state. An understanding of the mechanism of the heart failure in this syndrome is a necessary prerequisite to rational management. An increase in cardiac output in this setting probably can be accomplished only if the pressure gradient from the right to the left atrium is increased. This could be accomplished either by volume expansion (Fig. 2) or by a reduction of left atrial pressure.[2]

The Gordon/DonMichael Esophageal Obturator Airway*

A new resuscitation concept, the Esophageal Obturator Airway developed by Dr. Archer S. Gordon and Dr. T. A. Don Michael* offers an effective but simpler method than endotracheal intubation for establishing a patent airway during resuscitation procedures. The Esophageal Obturator Airway is introduced into the esophagus rather than the trachea, and has the following advantages:

- Does not require use of a laryngoscope or other instrumentation.
- Does not require visualization of the larynx or esophagus.
- Does not require any interruption of CPR.

When the airway is inserted and the mask is seated on the face, the obturator tip and inflatable cuff lie in the esophagus below the bifurcation of the trachea. The tip and inflated cuff occlude the esophagus and:

- Prevent gastric distension during resuscitation.
- Prevent regurgitation which leads to aspiration of gastric contents.

Mouth-to-mask, bag-valve-mask, or mechanical ventilation at the mask orifice inflates the lungs via the multiple openings in the portion of the airway which lies in the pharynx.

Contraindications: 1. children; 2. conscious or semi-conscious patients; 3. cases of caustic poisoning; 4. patients with known esophageal disease; 5. rescuers without adequate manikin and/or clinical training and practice.

Five good reasons why Brush biomedical recording systems are your best buy.

1. Brush has a complete line of biomedical signal conditioners and recording systems.

We make a recorder/signal conditioner system to meet any biomedical recording need you may have.

For research monitoring OR, and Cath Lab you can choose from 1 to 8 channels on high performance direct writing recorders, XY recorders, 4 and 8 channel monitoring oscilloscopes, a light beam oscillograph with up to 16 channels.

Our engineered systems include all transducers, interconnecting cables, signal conditioning, recorders and direct display readouts.

2. The Brush pressurized inking system gives you the highest quality traces.

Brush traces are the standard of the industry. Our pressurized inking system eliminates smudges, smears, skips and puddles because the traces are actually forced into the paper. The record you get is crisp, clear and permanent.

3. Brush guarantees better than 99.5% linearity.

There are two reasons why we can guarantee such a high degree of accuracy. First, our Metrisite® non-contact servo-loop feedback device moves freely in an enclosed air gap. Second, our recorders have a rectilinear presentation rather than a curvilinear one. This eliminates geometric errors inherent with the conventional system.

4. Brush biomedical recording systems give you trouble free operation.

All of our instruments require minimal maintenance. For example, our disposable ink cartridge provides for a year's worth of recording. Our Metrisite tracing system eliminates slide wires and all the problems that go with them. And all of our electronics are solid state.

5. A Brush system is one of the easiest to operate.

All systems are self calibrating. Our controls are conveniently placed to give you maximum flexibility. Chart paper can be replaced in seconds. Switching signal conditioners is a snap. And Brush service technicians and engineers are readily available when and if you do need assistance.

Send for our free full color catalog. Write Gould Inc., Instrument Systems Division, 3631 Perkins Avenue, Cleveland, Ohio 44114. Or Kouterveldstraat Z/N, B 1920 Diegem, Belgium.

Contraindications: There are no absolute contraindications to digitalis. However, in ventricular paroxysmal tachycardia or ventricular fibrillation, it should be used *only* in refractory cases not induced by digitalis intoxication and if heart failure has developed.

Precautions: If the patient has been given digoxin during the previous week or any other less rapidly excreted drug of the digitalis group during the previous two weeks, the dose of Lanoxin brand Digoxin must be reduced accordingly. Because of impaired renal function and excretion in elderly patients, they frequently require lower than recommended doses.

Potassium loss in patients sensitizes the heart to digitalis intoxication even with recommended doses. The diuretic agents as well as electrolyte manipulations by the physician are major causes of potassium depletion in cardiac patients. Under these conditions, it may be necessary to reduce the usual dosages of Lanoxin brand Digoxin during digitalization and maintenance.

Digoxin is usually ineffective in cases of cardiac failure due to mechanical causes which are independent of myocardial diseases, e.g., cardiac tamponade, or to disorders not primarily of cardiac origin, as severe anemia. Despite a variable or poor response to digoxin in the presence of active rheumatic carditis, the development of cardiac failure is an indication for its use.

Effects of Overdosage and Treatment: The symptoms of overdosage with digoxin are quite similar to those occurring with other digitalis preparations. The most common toxic manifestations are anorexia, nausea, vomiting and various cardiac arrhythmias, including ventricular extrasystoles and paroxysmal supraventricular tachycardia or fibrillation with A-V block. In general, the gastrointestinal manifestations of toxicity with digoxin precede the cardiac arrhythmias occurring from overdosage. Furthermore, because of the rapid dissipation of digoxin, manifestations of toxicity are of short duration, usually lasting from a few hours to one or two days.

If necessary, potassium chloride may be administered as an intravenous infusion containing (adult dosage) 40 milliequivalents in 500 cc. of 5% dextrose in water, given over the course of 1 hour and repeated, if required, until a total of 120 milliequivalents have been given (1 mEq. KCl = 74.5 mg.). Electrocardiographic monitoring should be conducted and the infusion halted immediately upon the appearance of peaking of the T-waves. For children, the intravenous infusion dosage of potassium chloride would be 5 to 10 milliequivalents in 100 cc. of 5% dextrose in water given over the course of 1 hour, repeated if required, to a total of 15 to 30 milliequivalents. For more serious intoxication with abnormal cardiac rhythms, potassium chloride may be given orally in divided doses totalling 4 to 6 grams per day (adults) or 1 to 2 grams (children) provided renal failure is not present.

LANOXIN® digoxin TABLETS. **0.125 mg.** (yellow) in bottles of 100 and 1,000. **0.25 mg.** (white) scored, in bottles of 100, 500, 1,000 and 5,000; also Unit Dose Pack, strips of 10 tablets, 10 boxes of 100 tablets (1,000). **0.5 mg.** (green) scored, in bottles of 100 and 1,000.

Complications of Percutaneous Femoral Arterial Catheterization

Prospective Evaluation with the Doppler Ultrasonic Velocity Detector

ROBERT W. BARNES, MD*
JOHN L. PETERSEN, MD
RICHARD B. KRUGMIRE, Jr.
D. EUGENE STRANDNESS, Jr., MD

Seattle, Washington

Prospective evaluation of vascular complications of 160 percutaneous femoral arterial catheterizations was carried out in 142 adult patients undergoing cardiac catheterization at two affiliated hospitals of the University of Washington. Arterial velocity signals and blood pressure in the limbs were monitored with the Doppler ultrasonic velocity detector before and after each procedure. The rate of complications (14 percent) was similar at each hospital; they included one accidental dissection of the iliac artery and 22 arterial thromboemboli. The location of thromboemboli appeared to be related to the duration of use of an indwelling arterial catheter. Complications were more common in patients, especially female, with mitral valve disease and in patients with coexisting peripheral arterial occlusive disease. Two thirds of the patients with thromboembolic complications had no symptoms. All but one patient with femoral thrombosis had operative thrombectomy; no patient with distal occlusion underwent operation. The Doppler ultrasonic velocity detector is a simple, rapid noninvasive technique for assessing limb hemodynamics in patients undergoing arterial catheterization.

Arterial catheterization has become a valuable technique for diagnosis of cardiac and peripheral vascular diseases, but it continues to have serious consequences for some patients. Although reports indicate that complications after arterial catheterization occur infrequently in experienced centers, several studies suggest that their true incidence may be underestimated. Differences in the reported frequency of catheterization accidents may reflect differences in investigator experience, catheterization methods, patient selection, diagnostic criteria and techniques for detecting complications. The reported rate of such complications increases when the techniques of oscillometry,[1] balloon catheter thrombectomy[2] or withdrawal angiography[3] are routinely used after catheterization.

To evaluate the efficacy of improved catheterization techniques, material modifications or pharmacologic prophylaxis in preventing catheterization accidents, accurate methods for diagnosing these complications must be developed. Because the results of pulse detection by different observers are variable, this method of assessing arterial circulation is an unreliable guide to the presence of occlusion after catheterization. The recent development of the Doppler ultrasonic velocity detector and methods for measuring segmental limb blood pressures have permitted accurate, objective noninvasive assessment of circulatory hemodynamics in peripheral arterial disease.[4] Our investigation therefore used these techniques to assess prospectively complications of cardiac catheterization by the percutaneous femoral arterial route.

TABLE I

Vascular Complications of Femoral Arterial Catheterization

Hospital	Catheterizations (no.)	Complications	
		no.	%
University Hospital	99	15	15
Veterans Administration Hospital	61	8	13
Total	160	23	14

Methods and Materials

From June 1 through December 31, 1971, a total of 142 adult patients undergoing cardiac catheterization by percutaneous femoral arterial cannulation were studied at the University Hospital and the Veterans Administration Hospital of the University of Washington. The Seldinger technique of femoral arterial catheterization was similar at the two hospitals. Catheters were wiped and frequently flushed with heparinized saline solution. Systemic heparinization was not used. Coronary arteriography by the femoral route was performed by the Judkins technique.

Patient assessment before and after catheterization included recording of peripheral pulses, arm and ankle systolic pressures detected by Doppler ultrasound[5] and evaluation of the quality of arterial signals[6] by the ultrasonic velocity detector (Parks Electronics Laboratory, Beaverton, Ore.). For measurement of systolic blood pressure, pneumatic cuffs with 8 by 40 cm inflatable bladders (Statham Instruments, Oxnard, Calif.) to encircle the limb completely were placed on an arm and both ankles. With the ultrasonic probe positioned over a distal limb artery (radial, posterior tibial or dorsalis pedis) the corresponding limb cuff was inflated so that cuff pressure exceeded the patient's systolic pressure, thus obliterating the Doppler arterial signal. The cuff was then slowly deflated until the level of systolic pressure was reached at the point of return of an audible Doppler arterial velocity signal. The values for systolic pressure measured by the Doppler technique correspond closely with direct intraarterial pressure measurements (reported correlation coefficient 0.991).[7]

Systolic blood pressure in the ankle, as determined by ultrasound, is normally equal to or greater than that of the arm.[4] Criteria for thromboembolic complications in our study were systolic pressure in the ankle more than 20 mm Hg less than that in the arm and abnormalities of the arterial velocity signals. The normal arterial velocity signal is multiphasic, with a prominent systolic component and one or more distinct diastolic components. Distal to an obstruction the arterial velocity signal may become attenuated, with loss of the separate diastolic sound components. A loss of peripheral pulses usually coexists, but this sign was not used as a sole criterion of arterial complication because of the recognized variability of pulse detection by different observers.

Patients with coexisting peripheral arterial occlusive disease demonstrated before catheterization both a lower level of systolic pressure in the ankle than in the arms and abnormalities in the arterial velocity signal distal to the obstruction. Thromboembolic complications after catheterization in these patients were manifested by a further reduction in ankle systolic pressure in relation to pressure in the arm.

The anatomic location of the arterial occlusion was defined by segmental limb blood pressures measured at the proximal thigh, above and below knee and ankle levels.[8] A pressure gradient greater than the normal 20 to 30 mm Hg between two adjacent levels of measurement indicated arterial obstruction between those sites. The level of abnormal arterial signals detected with the ultrasonic velocity detector was a further indication of the site of thromboembolic occlusion. Arteriographic studies to identify thromboembolic occlusion were not performed.

Veterans Administration Hospital	0	0	8

Results

There were 92 male and 50 female patients aged 14 to 77 years (mean age 48 ± 10 [1 standard deviation]). They underwent a total of 160 percutaneous femoral arterial catheterizations, 99 performed at the University Hospital and 61 at the Veterans Administration Hospital. The prevalence of arterial complications after catheterization (14 percent) was similar at each hospital (Table I). Three deaths occurred, all secondary to myocardial infarction associated with the procedure.

Except for a single instance of dissection of the iliac artery by a catheter, the arterial complications in this study were thromboembolic (Table II). There was no instance of major hemorrhage, false aneurysm or arteriovenous fistula. The pattern of location of the arterial occlusion differed at the two hospitals. At the University Hospital half of the thromboemboli involved the femoral artery and half occurred below the knee; at the Veterans Administration Hospital all arterial occlusions were distal to the femoral artery. These differences may be related to the mean duration of use of an indwelling arterial catheter at each institution. At the University Hospital, where about half of the procedures are performed for valvular heart disease, the mean duration of use of an indwelling arterial catheter (53 ± 23 minutes) was significantly longer ($P < 0.001$) than at the Veterans Administration Hospital (35 ± 22 minutes) where more than three quarters of the studies involved selective coronary arterial catheterization. The mean duration of use of an indwelling arterial catheter in patients with femoral thromboemboli (53 ± 22 minutes), was

significantly longer than the duration in patients with distal occlusions (34 ± 20 minutes) (P <0.001). There was no significant difference between the duration of use of an indwelling catheter in patients with thromboemboli and in those with no complications.

The frequency of complications did not correlate significantly with age, body surface area or cardiac index. However, patients with mitral valve disease (stenosis, regurgitation or combined lesions) had a significantly higher rate of complications (32 percent, Table III) than patients with other forms of cardiac disease (12 percent) (P <0.01). The significantly greater frequency of complications in female than in male patients (P <0.05) may be explained by the fact that mitral valve disease appeared predominantly in the former. An attempt to assess the factor of sex in each diagnostic group revealed no statistically significant differences, perhaps because of insufficient numbers in each sample.

Precatheterization screening studies with the Doppler ultrasonic velocity detector revealed 18 patients (13 percent of all patients studied) with coexisting peripheral arterial occlusive disease in one or both legs. Eleven limbs with diseased vessels were catheterized, and complications occurred in 8, representing 33 percent of all complications in our study. Each hospital demonstrated this high risk of vascular accidents after catheterization of atherosclerotic arteries.

Symptoms: Only one third of the patients with thromboembolic complications had symptoms of ischemia such as pain, subjective coldness, paresthesia or muscle weakness (Table IV). This low frequency of symptoms occurred in patients with femoral arterial occlusion as well as those with distal thromboemboli. Although peripheral pulse deficits were documented by at least one observer in all but one of these patients, there was considerable variability in the pulses recorded by different observers. Pulse detection was thus not considered a reliable guide to the presence or location of thromboembolic complications in our study.

Treatment and results: Operative thrombectomy with successful restoration of circulation was carried out in all but one of the patients with femoral arterial occlusion. In all patients operated on, fresh clot was retrieved from the femoral artery. There was no instance of intimal flap or other vascular injury associated with the obstruction. The single patient with femoral arterial occlusion who did not undergo operation never had significant ischemia and had excellent collateral circulation as evaluated with the ultrasonic velocity detector. Patients with distal thromboemboli did not undergo operation, and all but one had excellent recovery of distal perfusion by collateral circulation or spontaneous lysis of the occlusions. One patient with preexisting peripheral arterial occlusive disease had significant ischemia after occlusion of the single remaining patent below-the-knee vessel of the catheterized limb. Although this patient's leg remained viable, he succumbed to severe generalized coronary artery disease 6 weeks after catheterization. None of the remaining patients with arterial complications died during the study.

TABLE III

Prevalence of Arterial Complications in Patients With and Without Mitral Valve Disease

	Male	Female	Male	Female
None	9	12	72	26
Present	2	8	9	4
Total	11	20	81	30

Discussion

Although the information afforded by cardiac catheterization more than justifies its inherent risks, efforts to reduce these risks deserve continued attention. The prevalence of arterial vascular accidents after catheterization is generally reported to be less than 5 percent.[9–11] However, most studies are retrospective and document only more serious symptomatic complications. Thromboembolic accidents are usually detected only by the presence of pulse deficits. The recognized fallibility of pulse detection by various observers, again demonstrated in our study, makes palpability of pulses an unreliable criterion for assessment of peripheral circulation. Because thromboembolic complications are frequently asymptomatic—as in two thirds of our patients—it is important to develop more objective techniques for assessing the peripheral circulation in patients undergoing cardiac catheterization.

Several investigators have documented an increased frequency of observed complications after arterial catheterization when more sensitive criteria are utilized for diagnostic assessment. Jacobsson et al.[1] noted a greater accuracy in detecting thromboembolic complications when oscillometry was routinely used before and after catheterization. Although many of their patients with detected abnormalities had minimal symptoms and often had pulses, thromboemboli were always retrieved at operative exploration. Formanek et al.[3] described frequent detection

TABLE IV

of thrombotic material on arterial catheters when withdrawal angiography was employed. Local or distal embolization of such thrombotic material after catheter removal was likewise demonstrated arteriographically. Baker et al.[2] documented retrieval of thrombus in more than 50 percent of patients subjected to routine balloon catheter embolectomy at the time of brachial arterial catheterization. These experiences have led to efforts to minimize such complications by improving techniques, catheter materials and pharmacologic prophylaxis. However, these measures can be properly evaluated only if the existence of thromboembolic accidents can be defined accurately and objectively.

The Doppler ultrasonic velocity detector has been of established utility in the physiologic assessment of patients with peripheral arterial occlusive disease. Because its use is simple, rapid and noninvasive, this instrument lends itself well to screening and follow-up studies of the peripheral circulation. The characteristic multiphasic pattern of the normal arterial velocity signal is lost distal to an arterial occlusion, thus permitting localization of an obstructive process. The determination of arm, ankle and segmental limb pressures permits a fairly reliable quantitative estimate of the severity of the arterial occlusion.

Our study documents the relatively greater frequency of arterial thromboembolic accidents after catheterization when a sensitive objective technique is used for diagnosis. The prevalence of complications was similar at the two hospitals, but the distribution of thromboembolic occlusions differed. The lack of more proximal, and presumably larger, emboli at the Veterans Administration Hospital may have been related to the shorter average period of use of an indwelling arterial catheter at that hospital. Other factors, such as the type of catheter used and the patients' sex (all but two patients at the Veterans Administration Hospital were male) may have been contributory. Despite the differences in duration of the catheterization procedure at the two hospitals, there were no differences in the period of use of an indwelling catheter in patients with and without complications at either institution.

The significantly greater frequency of complications in female patients and in patients with mitral valve disease has been noted by other investigators.[12] There were too few patients in our study to permit statistical analysis of the independent contribution of these variables.

Prevention: Routine assessment of the peripheral circulation of patients before catheterization revealed a significant number of patients (13 percent) with coexisting peripheral arterial occlusive disease. Many of these patients had no prior history of claudication, although their underlying cardiac disease may have restricted their activity sufficiently to mask symptoms of arteriosclerosis obliterans. The importance of recognizing peripheral arterial disease is reflected in the high frequency of complications (73 percent) in patients catheterized by way of an atherosclerotic artery.

If preexisting arterial occlusive disease is discovered in a limb with the ultrasonic velocity detector, every effort should be made to use another limb as a route for arterial catheterization. This dictum is important regardless of the location of disease in the affected limb. Proximal obstructions may cause difficulty in catheter passage and increase the risk of arterial dissection or thrombotic occlusion. Distal disease limits arterial runoff, making the limb more susceptible to ischemia after the occurrence of distal thromboemboli that might be well tolerated in the normal limb. This phenomenon was manifested by the patient in this series who had severe ischemia after distal embolic occlusion of the left anterior tibial artery, his only patent vessel below-the-knee before catheterization. In limbs with preexisting arterial disease, thrombectomy may be difficult or even unsuccessful unless more extensive reconstructive techniques are used.

Diagnosis of thromboembolic complications: Our data indicate that as many as two thirds of patients with thromboembolic complications after catheterization may be asymptomatic, whether they have occlusion of the femoral artery or distal obstruction. The maintenance of limb blood flow through collateral circulation accounts for the lack of symptoms, especially in patients at bed rest after the catheterization procedure. Such patients have no symptoms until their activity increases upon discharge from the hospital. With development of adequate collateral circulation or dissolution of thromboemboli, symptoms may never develop. Measurement of the resting ankle blood pressure with the Doppler ultrasonic velocity detector provides a reliable guide to the adequacy of peripheral circulation. Furthermore, the level of ankle systolic blood pressure correlates well with limb blood flow during exercise and the period of postexercise reactive hyperemia.[13] This physiologic information may be a valuable guide to management of patients with thromboembolic complications after catheterization.

Operative thrombectomy: In our study all but one patient with occlusion of the femoral artery underwent operative thrombectomy with successful restoration of circulation. Although all but two patients were asymptomatic, operative management seemed indicated because of the possibility of future claudication and the fact that removal of thrombus from a major vessel can be simply performed with a great chance of success. One patient with a femoral arterial thrombus had excellent collateral circulation and operation was not performed in light of his severe cardiac disease.

No patient with thromboembolic occlusion of arteries below the knee underwent operation. Except for the aforementioned patient with coexisting severe arteriosclerosis obliterans, no patient had significant ischemia and all had excellent peripheral circulation as determined with the ultrasonic velocity detector. Since distal emboli may be difficult to remove with the balloon catheter and complications may occur with repeated attempts at thrombectomy, operation

may be justifiably avoided in such patients when adequate distal perfusion can be objectively established.

Clinical implications: The results of our study suggest the value of objective physiologic monitoring of the peripheral circulation in patients undergoing arterial catheterization. This principle can be applied not only to percutaneous femoral arterial catheterization but also to translumbar angiography and brachial arterial cutdown techniques.[14] The Doppler ultrasonic velocity detector is a simple noninvasive instrument and is well accepted by patients. The quality of arterial velocity signals and the segmental measurement of limb blood pressure may be readily determined. These hemodynamic evaluations permit rapid screening for preexisting vascular disease, monitoring for thromboembolic complications and physiologic guidance in the management of such catheterization accidents. Finally, the ability to assess more accurately the status of the peripheral circulation will enhance future evaluation of various prophylactic measures to reduce the frequency of complications of cardiac catheterization.

New Instrument for Transvenous Cardiac Biopsy

PHILIP K. CAVES, FRCS

EUGENE DONG, Jr., MD
EDWARD B. STINSON, MD
NORMAN E. SHUMWAY, MD, FACC

Stanford, California

A new forceps is described for obtaining serial endomyocardial biopsy specimens from the human heart. The instrument is introduced percutaneously into the right internal jugular vein and used to obtain tissue from the apex of the right ventricle. Eighty-five biopsy procedures have been performed in 19 patients after cardiac transplantation. The technique used was 100 percent successful in obtaining endomyocardial biopsy specimens, and there were no significant complications. A biopsy procedure may be performed within 5 minutes. Serial percutaneous transvenous endomyocardial biopsies are now routinely performed with this instrument in new heart transplant recipients and in patients with primary cardiomyopathy.

Although biopsy of the kidney, liver and many other organs is routine in clinical medicine, biopsy of the heart is infrequently performed. Consequently, knowledge is limited about serial histologic changes that occur in myocardial disease. Reported techniques for obtaining myocardial biopsy specimens have included percutaneous needle biopsy of the left ventricle,[1] catheter needle biopsy of the interventricular septum[2] and open thoracotomy.[3] The morbidity and mortality associated with these methods have precluded their widespread acceptance.

Transvenous biopsy of the endomyocardium of the right or left ventricle was first described 11 years ago by Sakakibara and Konno.[4] However, despite the availability of the Konno-Sakakibara bioptome in this country, there have been few reports[5,6] of its use outside Japan. The potential value of serial biopsy of the orthotopically transplanted canine heart in the diagnosis of acute cardiac allograft rejection encouraged us to develop a technique in our laboratory[7] for repeated cardiac biopsy in the dog by way of the external jugular vein. Subsequently, development of a technique[8] for percutaneous introduction of the biopsy forceps into the internal jugular vein in man provided a means for obtaining serial endomyocardial biopsy specimens from the human heart.

Our initial clinical experience[9] with cardiac biopsy using the Konno-Sakakibara bioptome was unsatisfactory. This instrument has many small moving parts, and the poor mechanical advantage of the jaws results in frequent failure to remove a satisfactory specimen from the right ventricular endocardial surface. We therefore designed the new cardiac biopsy forceps described in this report. Using this instrument, we have now performed 85 cardiac biopsy procedures with uniform success and without significant complication in 19 patients after cardiac transplantation.

The Instrument

The cardiac biopsy forceps is an integral unit with three main parts (Fig. 1A). The handle is similar to that on most surgical instruments and includes a ratchet so that the jaws may be locked. A flexible spiral wire catheter cov-

ered with Kynar® shrink tubing is attached to one end of the handle, and a stiff, flexible wire that passes through the catheter is attached to the other end. Opening and closing the handle controls the jaws, which are welded to the other ends of the catheter and wire. The jaws consist of one fixed and one mobile part, each ending in a hollow cup 1.5 mm in diameter. The edges of the cups are sufficiently sharp to permit removal of the specimen by a cutting action rather than avulsion. When the jaws are closed and locked, the instrument has a smooth rounded tip that passes through a no. 9F catheter sheath (Fig. 1B); when they are open, the jaws have a span of 2.5 mm (Fig. 1C). The catheter is 50 cm long. Sliding on the catheter is a rubber plug that fits into the Luerlok connection on the sheath and prevents escape of blood around the catheter. In addition, Teflon® seals are present at both ends of the catheter to prevent penetration of blood beneath the catheter tubing.

Immediately before use, the biopsy catheter is bent at a right angle 7 cm from the tip (Fig. 1A). This bend is then stiffened by brief immersion in ice-cold saline solution. After the catheter is inserted through the sheath, the right angle of the bend is reduced to approximately 30°, which is usually ideal for passage of the catheter through the tricuspid valve.

Biopsy Technique

There has been little change in our biopsy technique described for use with the Konno-Sakakibara bioptome.[8] Under local anesthesia, a no. 16 Medicut cannula is inserted directly into the right internal jugular vein. A flexible guide wire is then inserted through the cannula and a no. 9F Desilets-Hoffman false catheter and sheath are passed over the guide wire into the vein. The biopsy forceps are introduced through the sheath and the rubber plug is inserted into the Luerlok connection of the sheath to prevent leakage of blood. The forceps are then advanced to the apex of the right ventricle under fluoroscopic control (Fig. 2). The open jaws of the instrument can easily be pressed against the endocardium from this approach, since the catheter has only a gentle curve in the region of the tricuspid valve. The jaws are then closed and the instrument is withdrawn steadily. A jerk occurs as the specimen is removed from the endomyocardium. After retrieval of the biopsy specimen from the jaws of the forceps, the instrument may be reintroduced to obtain additional specimens. Finally, the sheath is removed from the vein, and pressure is applied over the puncture site with the patient sitting up-

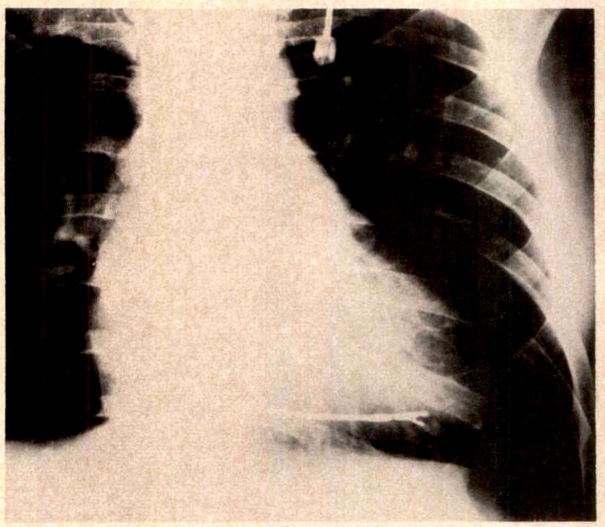

FIGURE 2. Plain chest X-ray film showing the biopsy forceps in the right ventricle.

right. Bleeding is immediately controlled and the vein remains patent for subsequent use.

The biopsy procedure can usually be completed within 5 minutes and requires less than 1 minute of fluoroscopy. The electrocardiogram is monitored throughout the procedure, and a chest X-ray film is obtained afterward.

Results

One hundred and sixty-three biopsy specimens have been obtained from 19 transplanted human hearts during 85 biopsy procedures (Table I). On most occasions two specimens were removed, but in some cases as many as four separate specimens were obtained by repeated introduction of the catheter. The majority of biopsies were performed in transplant recipients during the early postoperative period, and were utilized for direct histologic assessment of acute graft rejection (Fig. 3) and the response to immunosuppressive treatment.[10] In eight long-term survivors biopsy specimens were obtained either dur-

ing episodes of suspected late acute rejection or during routine late postoperative evaluation.

We have never failed to obtain tissue during a biopsy procedure with the new forceps described in this report. Minor complications were encountered in two patients, but they could not be related directly to the use of the forceps. In one patient a small pneumothorax was produced during introduction of the Medicut cannula. In another patient, who had previously had repeated episodes of atrial fibrillation, the arrhythmia recurred during performance of the biopsy procedure.

Discussion

Serial cardiac biopsy may offer new insight into the pathogenesis and clinical management of cardiac disease. The transplanted heart is perhaps uniquely accessible to this technique since striking and readily observed changes in endomyocardial histologic features evolve rapidly during acute episodes of graft rejection. Thus, the value of serial cardiac biopsy with the new instrument described here was readily demonstrated in our population of transplant recipients.

Features we considered essential in the design of our biopsy forceps and its use in patients receiving immunosuppression therapy were safety, efficiency and patient acceptance. Our experience to date has confirmed that these criteria have been satisfied, and frequent cardiac biopsy is now a routine aspect of clinical management during the first 2 months after transplantation. Percutaneous insertion of the forceps under local anesthesia into the right internal jugular vein provides rapid and direct access to the region of the right ventricle. The stiffness of the catheter and wire permits controlled manipulation and firm application of the jaws to the endocardial surface. The strength and cutting action of the jaws result in easy removal of the specimen, whose size is

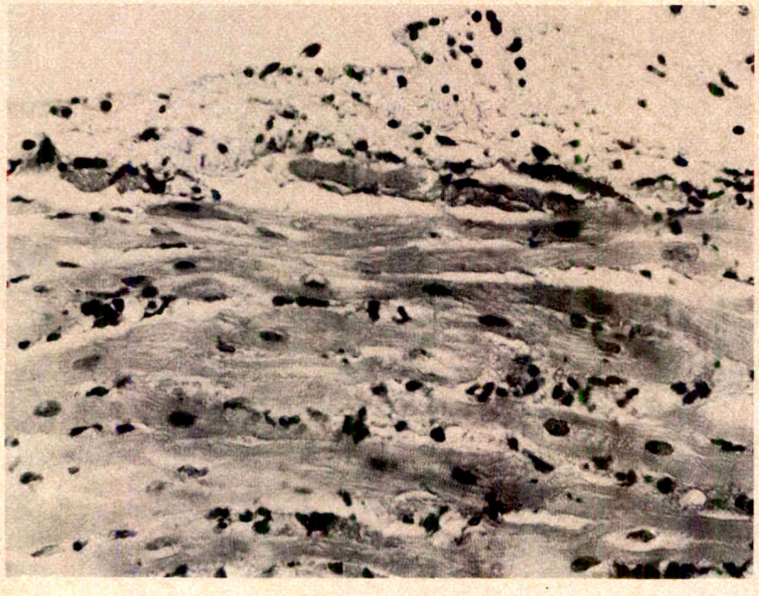

FIGURE 3. Biopsy specimen from a cardiac transplant recipient. The histologic detail is excellent and shows severe acute cardiac allograft rejection with edema of the endocardium and myocardium, lymphocytic cell infiltration and fibrinous exudate. (Hematoxylin-eosin ×320, reduced by 25 percent.)

limited by the dimensions of the jaws. Multiple specimens can be obtained by repeated introduction of the forceps through the indwelling catheter sheath in the internal jugular vein. After removal of the sheath, the vein remains patent and available for subsequent cannulation, and the skin puncture site heals to an imperceptible scar without suturing. The entire procedure can be completed within several minutes.

Our experience with 163 biopsies during 85 procedures without significant complications testifies to the safety of our biopsy technique. The risk of this procedure is similar to that of right heart catheterization by way of a central vein, and thus would appear to be substantially less than that associated with left ventricular needle biopsy by percutaneous puncture (hemorrhage, cardiac tamponade, ventricular fibrillation).[1] The technical difficulties encountered in transvenous biopsy by way of peripheral veins, as previously described,[5,6] are avoided. On the basis of our favorable experience with cardiac transplant recipients, we have extended this technique to the study of patients with primary myocardial disorders.

Julius Cohnheim's Experiments on Heart Valves

SAUL JARCHO, MD

New York, New York

Surgical operations on the valves of the human heart have attracted the attention and aroused the admiration of many persons who are not directly concerned with surgery or even with any branch of medicine. Not long ago these procedures were a spectacular rarity. If nowadays they are no longer rare, they have nevertheless not ceased to excite wonder.

It has been difficult to determine exactly and reliably who first performed these operations. The trail obviously leads back to the European experimental physiologists of the second half of the 19th century. A previous article in the present historical series contained excerpts from one of the earliest contributions, an essay by Edwin Klebs (1834–1913), "On Operative Wounds of the Heart Valves and Their Consequences." This appeared originally in the *Prager Medicinische Wochenschrift*, volume 1, pages 29–36, 1876.[1] Not long after, Ottomar Rosenbach (1851–1907) issued a thesis, "Ueber artificielle Herzklappenfehler, Eine experimentellpathologische Abhandlung" (On Artificial Insufficiency of the Heart Valves, a Treatise on Experimental Pathology, Breslau, 1878, 39 pages[2,3]).

Rosenbach was a pupil of Julius Cohnheim (1839–1884), one of the great geniuses of experimental pathology.* Cohnheim's statement, which follows, indicates that his experiments preceded those of Rosenbach. The excerpts from Cohnheim have been taken, with slight modification, from his Lectures on General Pathology,[5] translated from the second German edition by Alexander B. McKee.[5] The original appeared in 1877 to 1880.

Excerpts from Cohnheim

. . . Now, should one of the morbid conditions just described be established in connection with the heart, it follows as a direct conclusion from our recent discussions that the work done by the organ must be augmented to correspond with the increased demands upon it; and this will occur whether the entire heart or only single parts are concerned. At any rate this is the result to which we have been led by our reflections. But in order to determine whether this increase really takes place, we shall again have recourse to the experimental method. If one of the lesions described above be produced artificially in a healthy animal, a simultaneous examination of the arterial and venous circulation, on the one hand, and of the intracardiac pressure, on the other, must afford reliable information on the point at issue. With this object a very simple, but it is true imperfect, method of demonstration may be resorted to. Nothing more is necessary than the production of artifical aortic insufficiency by perforating the aortic valves of an animal.† The experiment can almost always be carried out successfully in the rabbit, and with still greater certainty in the dog. A thin metallic sound, furnished at its distal end with a button, is introduced into the carotid in the direction of the heart, and if carefully manipulated, may quite easily be made to perforate at least one, sometimes two, or perhaps all three segments; or one may even succeed in partially tearing them from their attachment to the aorta. That laceration of the valves has been successfully effected is not merely apparent to the operator as he guides the instrument; as a rule, a loud, mostly whistling murmur, audible over the base of the heart, at once affords proof of positive success. Most unmistakable information is, however, derived from the arterial pressure-curve, where the peculiar characters of the pulse of aortic insufficiency, shortly to be discussed, immediately make their appearance. But although there is no doubt that the aortic valves are perforated, and no longer able to effect complete closure of the orifice during the ventricular diastole, *the mean arterial pressure continues at precisely its former level*, nor is the venous pressure in the least influenced by the operation. This result, while making it extremely probable that the work done by the left ventricle has increased in consequence of the insufficiency, does not, however, directly prove it. There is, moreover, in the experiment the inherent drawback that the amount of insufficiency is not under control, since the number of segments perforated and the size of the perforations are more or less matters of chance, and there is no possibility of determining the extent of the injury *intra vitam*. Much more instructive therefore, although more complicated, is another experimental procedure, by which *stenosis*, and not insufficiency, of the arterial ostia is produced artificially.

This experiment, like that on positive pericardial tension, is carried out on a curarized dog, whose respiration is maintained artificially, the first step being the formation of a large window in the left half of the thorax by an ample re-

This study was based on research assisted by the National Institutes of Health (Grant HL-10948).

Address for reprints: Saul Jarcho, MD, 35 East 85th St., New York, N. Y. 10028.

* Cohnheim laid the basis for our knowledge of the mechanism of inflammation. I have discussed his contributions to this subject in previous issues.[4]

† This experiment was first communicated in the first edition of these lectures, vol. i, p. 38; described more in detail, as well as supplemented and developed especially in the clinical direction, by Rosenbach in his inaugural thesis, 'Ueber artificielle Herzfehler,' Breslau, 1878, and 'Arch. f. experiment. Path.,' ix, p. 1; since wrongfully called in question by J. Goddard, 'Kunstmatig opgewekte gebreken van het ostium aortae,' J. D. Leiden, 1879.

section of the ribs. The pericardium is then opened at its upper end, in the neighborhood of its reflection, and the cellular and adipose tissues binding together the aorta and pulmonary artery immediately above their origins are divided by means of two pairs of forceps. The greatest caution must be exercised here, since the thin-walled pulmonary artery is extremely susceptible of injury. A strong thread is then passed round the artery of which it is desired to produce stenosis, and the ligature is secured in a loop-knot, such as is employed in surgery under the name of "Graefean." The lumen of the aorta or of the pulmonary artery can now be more or less constricted at discretion by means of the ligature. The curve of the *arteria femoralis* (this vessel being connected with the kymograph) and a soda-manometer in connection with the *vena jugul. sin.* simultaneously supply us with information as to the pressure relations in the systemic vessels. The intracardiac pressure is registered by one of the manometers of the kymograph, connected with a comparatively wide glass tube introduced into the corresponding ventricle. The glass tubes employed for this purpose are closed at the cardiac end and provided with a lateral aperture; they should be filled with a 0.6 per cent solution of common salt and introduced into the heart; the introduction being carried out, on the right side, from the *v. jugul. ext. dextra,* and on the left, from left auricular appendage, which is then secured by a ligature round the tube. The tube may be most conveniently connected with the manometer of the kymograph, after the method of Goltz and Gaule,* by means of another forked one, the two limbs of which serve as manometers. One limb is provided with a valve allowing the ascent, but not the descent, of the column of mercury, and acts as a maximum manometer, while the other forms a manometer of the ordinary kind.

The animal being thus prepared, let us begin with the production of *stenosis of the pulmonary artery,* regulating its severity by the amount of twist communicated to the ligature-rod. Now, you may increase the twist either slowly and gradually but continuously, or intermittently, and carry it to such a pitch that a very marked constriction of the pulmonary artery becomes apparent not only to the examining finger, but to the naked eye—for all that, *you cannot detect the slightest change in the femoral curve or in the manometer in the jugular;* mean pressure, pulse, and respiratory undulations, everything remains exactly as before. A change occurs only when the stenosis is carried beyond a certain point. *The arterial pressure then undergoes a steep and sudden descent,* while at the same time the level of the venous manometer rapidly rises; the femoral curve approaches to within 10–15 mm. of the abscissa, the respiratory undulations cease, the pulsations become extremely small, their rhythm considerably retarded and quite irregular; and, if the ligature is not loosened, life is in extreme danger. As soon, however, as the ligature is untwisted and the passage through the pulmonary artery thus opened up, the arterial pressure-curve reascends (its pulsations succeeding each other at first slowly, but by degrees more rapidly) till it, as a rule, reaches, and for a short time maintains, a level higher even than the original, while at the same time the level of the soda-manometer falls almost to the zero point.

You see, the last part, the conclusion of this experiment, harmonizes perfectly with the pericardial one, while the first part presents a complete contrast. For, while in the pericardial experiment, the lowering of arterial and the elevation of venous pressure were from the commencement exactly proportional to the increase of tension in the sac, stenosis of the pulmonary artery has, for a long time, no influence whatever on the circulation through the systemic vessels. An examination of the intracardiac curve affords an explanation of this striking difference. The moment the pulmonary ligature is tightened even slightly, *you observe an immediate rise of intracardiac pressure on the right side;* and the more the stenosis is increased, the higher is the ascent of the pressure-curve of the right heart. This is expressed most elegantly by the curve obtained from the maximum manometer; every turn of the rod, even the gentlest, is here at once responded to by a step upward. The manometer of ordinary construction also represents this appearance quite clearly. Indeed, it reveals another interesting phenomenon not observable in the maximum curve, namely, an extension of the systolic excursions of the mercurial column, keeping pace with the gradually increasing constriction. True, in the case of the right heart this extension is not very striking; yet, where the narrowing was extreme, I have sometimes seen the distance between the systolic summit and the diastolic depression almost doubled. The rise of intracardiac mean pressure, if one may use the expression, or the maximum values attained by the single systoles, is still more considerable; in severe narrowing they very commonly exceed the original maximum by two or three times its value. The intracardiac pressure reaches its greatest elevation at the moment when the arterial curve rapidly falls. At this point the ventricle makes what may be described as a series of desperate efforts, marked by long excursions corresponding with the heart-beats, which are now slow and rapidly become irregular. This does not last long, it is true; for the intracardiac pressure falls after a very short time whether the ligature be relaxed or not. If an extreme degree of stenosis be maintained, the intervals between the heart-beats become longer and longer, and the curve acquires the closest resemblance to the last part of the curve of asphyxia. If, on the other hand, the passage through the pulmonary be freed, a fall of pressure in the right heart takes place *pari passu* with a reascent of the femoral pressure, whereby the systolic excursions continue large at first, but quickly regain their original size and frequency.

If, instead of the pulmonary artery, the aorta ascendens be ligatured, the course of the experiment is in all essential particulars the same. Here also, the arterial and venous pressures are wont to remain a very long time completely unchanged, despite the steadily increasing narrowing of the aortic lumen, till at last the sudden and steep descent of the arterial curve and rapid ascent of the venous pressure ensue. Henceforward the femoral curve proceeds in a straight line, uninterrupted by respiratory- or pulse-elevations, and steadily approaches the abscissa, while the level of the venous manometer rises slowly but continuously. But when the aortic ligature is relaxed, the femoral pressure instantly shoots up, almost always in the first instance above its original level, which it, however, resumes after the lapse of about five to ten seconds; while the venous pressure is restored in a very short time to normal. Nevertheless, as compared with stenosis of the pulmonary artery, there are some peculiarities in the details which are worthy of being recorded. In the first place, there may occasionally be seen, sometimes preceding, sometimes following, the abrupt fall, an equally abrupt ascent of the arterial curve, never lasting long, it is true, but very soon giving place to the final descent already described—without doubt the effect of acute anaemia of the brain, which produces, as you are aware, intense excitement of the vasomotor centre. Moreover, in the aorta the earliest beginning of the gradual

* Goltz and Gaule, 'Pflüg. Arch.,' xvii. p. 100.

stenosis does not manifest itself, as was the case in the pulmonary artery, by an increase of intracardiac pressure; the twist given to the ligature-rod must be somewhat more ample before the heart reacts to it—to be explained, I think, by the circumstance that a slight diminution of the lumen of the aorta is of no importance when compared with the sum of the resistances normally opposed to the emptying of the left ventricle. But when once the heart's action is affected, the increase in intracardiac pressure is much more considerable, not only absolutely but relatively, than on the right side; so that I have repeatedly observed an ascent of maximum pressure to four times the value of that obtaining with a free aortic channel. Of surpassing interest, however, is the influence of the stenosis of the aorta on the character of the individual cardiac contractions, and thereby on the arterial pulse. The narrower the aortic lumen and the higher the intracardiac pressure, *the more ample do the single contractions become,* and the greater, consequently, the distance between the systolic summit and the diastolic depression of each pulsation. At first no more time is consumed by these enlarged cardiac contractions than formerly; but when they exceed certain limits, they cannot possibly be carried out unless more time be expended on the single contractions; or, in other words, as soon as the stenosis has attained a certain pitch, the heart-beats become considerably more ample, but also *slower, less frequent*. A change of this kind must naturally have its effect on the arterial curve, and it may in fact be observed that, after a certain amount of twist has been given to the ligature, the systolic elevations of the femoral artery become fewer, and, to compensate for this, a good deal larger and less steep in their ascent; *there is an infrequent and sluggish, but mostly elevated pulse* . . .

But however remarkable this feature may be, for us the chief interest of experimental stenosis lies in the circumstance that it affords the key to the comprehension of cardiac pathology. For you will certainly have no hesitation in utilizing the experiences gained here, not merely in artificial insufficiency of the aorta, but also in the natural valvular and other lesions which impose an abnormal amount of work on the heart. If, in the previously normal aortic valves of individuals advanced in life, or in younger individuals, after an inflammatory process leading to adhesion of the valvular segments has run its course, a pure, uncomplicated aortic stenosis be developed as the result of a high degree of calcification of the segments, the condition produced is not to be distinguished in any essential particular from our artificial narrowing except by its much more gradual establishment, its chronic character; this, however, is a circumstance, which certainly cannot be anything but serviceable to the discharge of the work of the heart. Yet we are not left to infer from experimental evidence alone that the human heart reacts to the pathological valvular lesions simply by increasing the work done; we have, in addition, an infallible proof of this in *the increased bulk, the hypertrophy* of the heart, or of that portion of its musculature at least, on which the lesion in question throws a larger amount of work . . .

Comment on Cohnheim's Experiments

The foregoing excerpts are part of a treatise on pathology significantly titled *Lectures.* The arrangement of this work is of interest. Its first two major subdivisions are titled, respectively, "Circulation" and "Nutrition." Whereas "Circulation," as a modern reader might expect, discusses the heart, peripheral resistance, thrombosis, embolism, dropsy, and the like, "Nutrition" includes necrosis, atrophy, hypertrophy and tumors.

In his introductory chapter, not included in the present excerpts, Cohnhein says, "We speak of disease only when we have an *occurring,* a *progression,* a *process* in mind . . . This consideration, it is evident, leads us logically to define disease as a *deviation from the normal or healthy vital processes.*" The emphasis is clearly dynamic; hence, the importance of experiments on the living animal. From the large number of experiments Cohnheim performed I have selected a few examples dealing with the valves and chambers of the heart, since these lead directly to the work of MacCallum and others which will be considered later in the present series.

Cohnheim produced aortic insufficiency by lacerating the aortic valves with a metallic sound introduced by way of the carotid artery. The results were studied by auscultation and determinations of arterial pressure. Finding this blind procedure inadequately controllable, Cohnheim turned to operations on the pulmonary artery and aorta. In curarized dogs maintained under artificial respiration he placed ligatures loosely about both of these vessels while keeping manometric surveillance of arterial, venous and intracardiac pressures. Occlusion of the pulmonary artery had no effect on jugular or femoral pressures until stenosis had been carried beyond a certain degree. After this the level of arterial pressure fell steeply while venous pressure increased. These events contrasted sharply with what happened after aortic occlusion.

Apart from the obvious importance of Cohnheim's work—with which we must include that of his many pupils—Cohnheim has special importance for us as Americans, since he was a teacher of William Welch and was influential in Welch's appointment to the professorship at Johns Hopkins. Since Welch may be regarded as the father of experimental pathology in the United States, Cohnheim may be designated its grandfather.

Cohnheim's influence on American pathology did not end with Welch. His writings influenced MacCallum, in a manner that will be discussed later in the present series.

Principles and Pitfalls in Establishing Normal Electrocardiographic Limits

ERNST SIMONSON, MD

Minneapolis, Minnesota

The three main prerequisites for determination of valid normal limits are adequate sample size, sample composition representative of the average healthy population, and adequate statistical evaluation. In a substantial number of publications, even recent publications, one or the other of these principles (and occasionally all three) have been disregarded. The most common error is inadequate sample size. The minimal sample size of a male adult population for determination of normal limits should exceed 500, and approach 1,000 for a mixed sample of men and women. Constitutional variables affecting the electrocardiogram (relative body weight, age, sex and race) must be considered. In view of the skewed distribution of most electrocardiographic items, 95 or 98 percentiles should be used for determination of valid normal limits. Use of standard deviations (usually ±2 SD) may result in erroneous limits. The extreme values of the distribution of a sample of healthy persons are not acceptable because they include values from a substantial number of abnormal persons, thus resulting in a large number of false normal diagnoses.

There are three prerequisites for determination of normal limits, (1) adequate sample size, (2) composition of the sample to be representative of average healthy population, and (3) adequate statistical evaluation.

Adequate Statistical Evaluation

Actual extreme values of a sample: The following statistical methods have been used for determination of normal electrocardiographic limits: (1) actual extreme values of a given sample (for instance, in the widely quoted limits of Sokolow and Friedlander[1]). This is the poorest method for the establishment of normal limits; the limits will expand with the size of the sample. In numerically adequate samples they are so wide that they include an appreciable number of patients with false normal diagnoses. On the other hand, extreme values in small samples may not include 95 percent of the normal population and thus may result in false diagnoses of abnormality. Extreme stray values in a large sample may well be due to unrecognized pathologic changes; these values should be excluded rather than included when normal limits are established. Therefore, the *total* normal distribution is not suitable. The limits should include the large majority of the normal healthy population, cutting off a small percentage of healthy people. Cutoff points of 2 or 2.5 percent at the low and high ends of the normal distribution, used in most investigations, include 95 or 96 percent of the normal population. Hence, a small percentage of healthy subjects (2 to 2.5 percent at each end) will fall, by definition, outside of the normal limits. If the distance from the 95 percent limits is still small, such subjects may be classified as "borderline," provided that only one item is concerned. If more than one item slightly exceeds the normal limits, the proba-

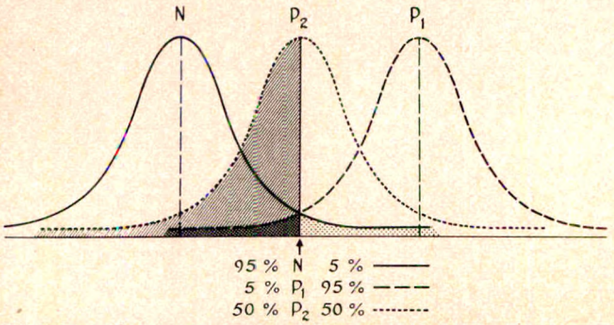

FIGURE 1. Frequency distribution of a hypothetical normal sample (N) and two samples of patients (P_1 and P_2) representing two different types of disease for a hypothetical electrocardiographic item. The dividing line for 5 percent at the upper end of the normal distribution coincides with that for 95 percent of the patients in group P_1 and for 50 percent (median) in group P_2. The areas of overlap are shaded. The diagnostic implications are discussed in the text. (Reprinted by permission from Simonson E: The normal variability of the electrocardiogram as a basis for differentiation between "normal" and "abnormal" in clinical electrocardiography. Am Heart J 55:80–103, 1958.)

bility of abnormality increases.[2] In general, the probability of abnormality increases with the distance of a subject from the mean or median of the distribution inside and, particularly outside, the 95 percentile limits. There is always some overlap in the distribution of diagnostic items in a normal population and in a population of patients limiting the diagnostic separation. The degree of overlap depends on the type of abnormal condition and its severity, and on the diagnostic item. As a rule, more patients will be within the normal 95 percent distribution range than the small number of 4 to 5 percent healthy subjects falling outside.

As an example, the overlap in the distribution of "normal" subjects and patients with left ventricular hypertrophy by QRS scalar or spatial voltage criteria has been a frustrating experience of many investigators.[3] McCaughan et al.,[4] recently investigated the rate of electrocardiographic and vectorcardiographic recognition of left ventricular hypertrophy in 939 patients with arterial hypertension subdivided into three groups progressing in severity of disease (group 1—394 patients; group 2—242 patients; group 3—303 patients). In their study, use of the voltage criterion 3.1 of the Minnesota code[5] for the conventional electrocardiogram provided a correct diagnosis in only 21 percent of cases in the first group, 34 percent of cases in the second group and 43 percent of cases in the third group, with a false positive rate of 6 percent. Conventional Frank lead criteria ($R_x - 1.9$ mv; $R_x + Sy - 2.1$ mv; $R_x + S_z - 3.1$ mv) were somewhat superior with a 24 percent rate of correct recognition of left ventricular hypertrophy in group 1, a 37 percent rate in group 2 and a 44 percent rate in group 3. False normal rates were 76, 63 and 56 percent, respectively, and the false positive rate was 5 percent for all three groups. The differentiation was still unsatisfactory but could be improved by multivariate analysis. The situation is schematically illustrated in Figure 1, which shows the frequency distribution of a hypothetical item in a hypothetical normal sample (N) and two samples of patients (P_1 and P_2) representing two different types of disease. For simplicity, a symmetrical Gaussian distribution has been assumed. The dividing line for 5 percent at the upper end of the normal distribution (marked with an arrow) coincides with that for the lower 5 percent of the patients in group P_1 and with 50 percent (median) in group P_2. The areas of overlap are shaded. The normal limits are the same for comparison of N with P_1 and P_2, but the diagnostic separation is very different: excellent for P_1 and poor for P_2. Unfortunately, the situation in group P_2 is more common, whereas that in group P_1 is quite exceptional, as Weisbart and Simonson[6] demonstrated for various electrocardiographic items in differentiating a normal population from a sample of patients with inferior myocardial infarction.

Figure 2 shows the distribution of the Q_3 interval in a normal sample and in a sample of patients with inferior wall infarction (old, subacute and acute). There is a wide overlap, corresponding approximately to that of groups N and P_2 in Figure 1. The overlap is even greater for Q_3 amplitude (Fig. 3). On the other hand, the separation in the distributions of T_2 (Fig. 4), particularly in subacute inferior infarction, is quite good, approximating the situation of N vs. P_1 in Figure 1. Unfortunately, this is exceptional; overlap as in the distribution of Q_3 is more common.

Standard deviation: Two methods have been used to determine the 95 percent normal limits: (1) more frequent, addition of ±2 standard deviations (S.D.) to the mean, and (2) less frequent, determination from the percentile distribution. Use of the standard deviation for determination of normal limits is convenient, but this method assumes a symmetrical Gaussian distribution. Unfortunately, nearly all single electrocardiographic items as well as ratios (such as Q/R ratios) have highly skewed distributions.[7]

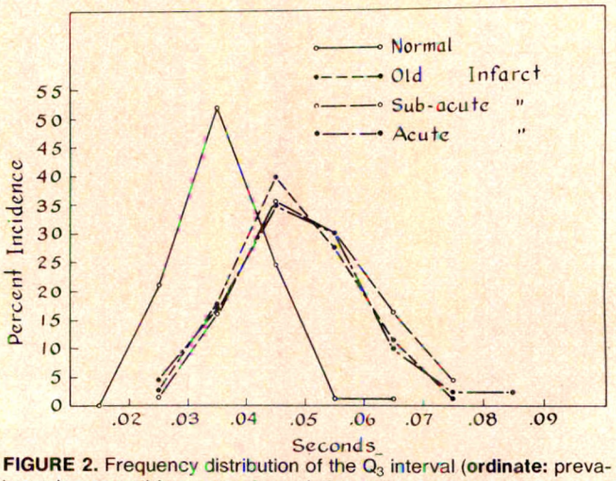

FIGURE 2. Frequency distribution of the Q_3 interval (**ordinate:** prevalence in percent) in a normal population and in patients with myocardial infarction of the posterior wall (acute, subacute and old). (Reprinted by permission from Weisbart and Simonson.[6])

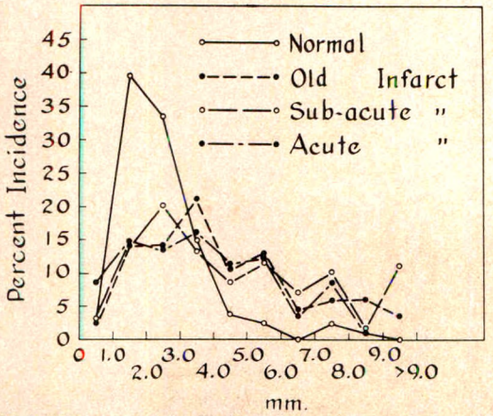

FIGURE 3. Frequency distribution of the Q_3 amplitude (**ordinate:** prevalence in percent) in a normal population and in patients with myocardial infarction of the posterior wall (acute, subacute and old). (Reprinted by permission from Weisbart and Simonson.[6])

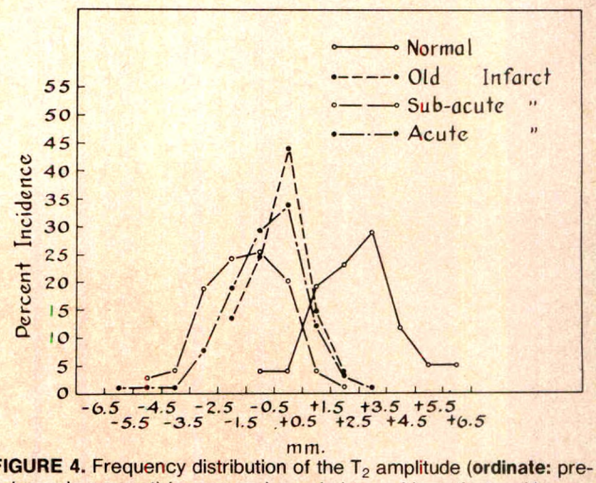

FIGURE 4. Frequency distribution of the T_2 amplitude (**ordinate:** prevalance in percent) in a normal population and in patients with myocardial infarction of the posterior wall (acute, subacute and old). (Reprinted by permission from Weisbart and Simonson.[6])

Therefore, normal limits determined with use of ±2 S.D. are too narrow at the long end of distribution and too wide at the short end, resulting in an appreciable number of false normal diagnoses at the short end and false abnormal diagnoses at the long end of distribution.

Percentile distribution: Determination of normal limits from the percentile distribution is the only reliable method for establishing normal limits. This procedure is facilitated by utilizing electronic computer analysis from punch cards. However, a simple method without aid of computers has been described by Barden (Appendix 1, p 285, in Simonson[7]). I will discuss some more sophisticated aspects of statistical analysis later.

Sample Size

Of the pitfalls in determination of normal limits, inadequate sample size is probably the most frequent.[7] Even in a relatively homogenous sample, such as a sample of young men aged 20 to 30 years with normal body weight, that is, between 95 and 105 percent of predicted body weight (normal = 100), at least 100 subjects are needed for recognition of the percentile distribution, and the normal limits derived would be applicable only to a similar homogenous sample in regard to age, body weight and sex. All constitutional variables—age, body weight, sex, race and, to a lesser degree, chest configuration—are determinants for the normal electrocardiogram.[7–9] Whereas the individual electrocardiograms of older and younger, underweight and overweight, male and female subjects may fall well into generally accepted normal limits, the distribution of the various items and, consequently, the normal limits will be different in samples with different proportions of these constitutional variables. Therefore the sample must be large enough to cancel out or, preferably, permit separate analysis of the effect of the various constitutional variables on the distribution of electrocardiographic or other items in the subgroups thus defined. The purpose of the subdivision into categories of age, relative body weight, sex and race is to provide the normal limits for these subgroups, which are considerably narrower than the limits for the whole population sample and provide a more accurate separation between "normal" and "abnormal." Thus, each individual patient should be evaluated with use of the normal limits for his constitutional category.

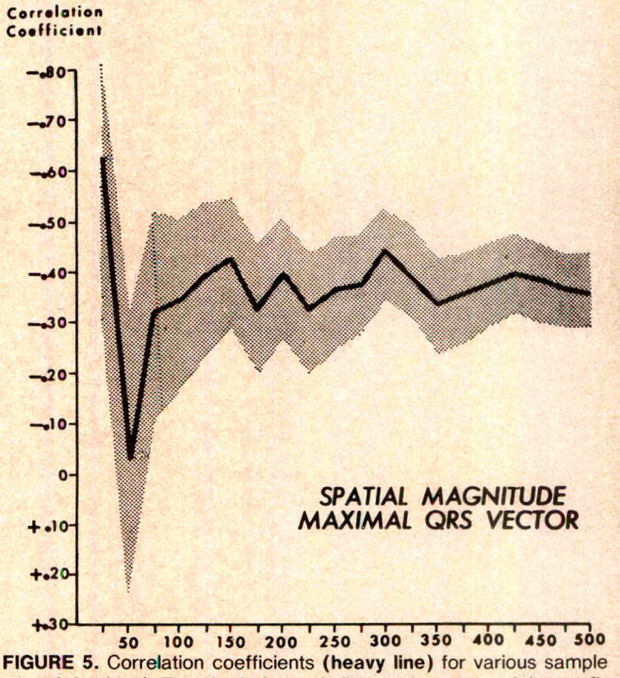

FIGURE 5. Correlation coefficients **(heavy line)** for various sample sizes **(abscissa).** The **shaded area** indicates the extent of the confidence limits. (Reprinted by permission of the American Heart Association, Inc. from Pipberger et al.[10])

The need for a large sample size has been demonstrated by Pipberger et al.[10] Figure 5 shows the variation of the correlation coefficient *(r)* between age and the spatial maximal QRS vector. Small sample sizes, that is, up to 200, show huge variations, and the cor-

relation coefficient stabilized only with sample sizes over 500. It is not surprising that with groups of less than 200, as were frequently used in studies of the effect of age on the electrocardiogram or vectorcardiogram, conflicting results have been obtained.[11] Thus, the minimal sample size for determination of normal limits of the male adult population should exceed 500 and should be closer to 1,000 if the sample includes men and women. Assuming three age and three weight groups of an adult male and female population with 100 in each subgroup, we arrive at a desirable sample size of 1,800. Our sample of 950 adult men and women[7] did not permit subdivision of the female sample and the young male sample into weight groups. Such subdivision is desirable, if not essential, since the effect of age is different in men and women and the effect of relative body weight is greater in older than in younger people. Because of the skewness of distribution, constitutional variables may affect upper and normal limits differently. For example, the left QRS axis shift with age affects much more the lower (2.5 percentile) than the upper normal limits (97.5 percentile). In men, the upper normal limit for ages 20 to 29 years is 95.9° and at ages 40 to 59 it is 87.9°, a difference of 8°. The low normal limits change from 2.9° to −28.4°, respectively, a difference of 30.9°.[7]

The largest sample (6,014 healthy men) with measurement of electrocardiographic items has been collected by Hiss et al.[12] However, clinical application of their data is limited because many of the measurements are unconventional and some items used in clinical routine are not included. Several attempts have been made to arrive at a large sample size by pooling samples.[13–16] This is not a sound procedure. Limits from pooled samples are likely to be determined largely by samples that are least representative of the healthy average population. The most recent example of inadequate sample size is found in the study by Copeland et al.[17] Normal 95 percent limits were calculated for the McFee-Parungao vectorcardiogram from a sample of 120 normal subjects (61 men, 59 women) with an age range of 15 to 64 years. The age distribution was highly skewed and no information about weight and race distribution was given. It is unlikely that the values can be reproduced in another normal sample with a different distribution of age, sex, weight and race.

Sample Composition

The sample shold be representative of the healthy, average American population. Obviously, even a large sample, such as that collected by Hiss et al.,[12] is a very small portion of the total population. Several precautions are needed to assure reasonably adequate sample composition. For male populations aged 20 to 60 years, the sample should be drawn from a working population since this is the large majority and its use facilitates collection. The civilian female labor force in the United States is about 50 percent of the adult female population and therefore should be fairly representative.

Electrocardiographic screening process: To obtain a sample representative of the average *healthy* population, the sample must be screened for elimination of all subjects with chronic diseases that could even remotely affect the electrocardiogram; fourteen such conditions have been listed.[7] The screening should be done independently; that is, it should not involve the electrocardiogram. This leads to a dilemma, because the electrocardiogram is a more sensitive method for detecting myocardial disease than most other routine methods. According to the Framingham study, about 30 percent of myocardial infarctions are silent. Bundle branch block, particularly right bundle branch block, may be clinically asymptomatic. For detection of arrhythmias the electrocardiogram is the only available objective method. Coronary arteriography is obviously not suitable for collection of a large normal sample. Therefore, it has been an accepted and justifiable procedure to exclude from normal samples all subjects with gross electrocardiographic abnormalities. The Minnesota code,[5] which is being widely used on an international scale, is a useful tool for this purpose. For data on prevalence of electrocardiographic abnormalities in a large asymptomatic population we refer to Averill and Lamb's study[18] on 63,375 Air Force personnel, and to the large epidemiologic series of Keys.[19]

Clinical screening process: The definition of health is a difficult problem because it is based on a negative criterion: the absence of recognizable disease. A person should be considered healthy when results of all clinical tests that may reveal disorders potentially affecting the electrocardiogram are negative. The distribution of the various items in a group thus selected could then be taken as representative for a healthy population. Unfortunately, the clinical screening procedure has not been standardized; its reliability depends on the methods used, as well as on the thoroughness and experience of the clinical investigator. The examination should include a thorough history, which may be facilitated by questionnaires such as those prepared by members of the Laboratory of Physiological Hygiene. The individual electrocardiogram in many pulmonary, hormonal, infectious, central nervous system and even cardiac diseases may be within the normal range of limits, but in all these conditions electrocardiographic abnormalities have been reported. Therefore, inclusion of such patients will invalidate the "normal" limits.

Pitfalls in sample selection: A common pitfall is the use of "cardiovascular normal" hospitalized patients. Hospitalized patients, whatever the reasons for hospitalization, are not representative of the healthy average population. Bed rest alone produces a deterioration of cardiovascular regulations in young, healthy men.[20,21]

Similarly, electrocardiograms obtained before death from hospital patients with a normal heart at

autopsy are not a suitable source for a normal sample, unless obtained from accident victims. Absence of detectable cardiac disease does not rule out functional ST–T segment changes or arrhythmias. The sample of Myers et al.,[22] used for normal electrocardiographic standards, consisted of moribund patients with a normal heart at autopsy. It is hard to conceive of a sample more remote from the healthy average population.

We found significant differences between the means of various electrocardiographic items in Vaquero's sample[23] and our sample of 950 adults in the United States. Therefore, the normal limits from the Mexican sample are not applicable to the American white adult population, but were utilized in the pooled samples.[13–15] We also found significant differences between various electrocardiographic items in American and Italian populations[24] and Japanese population.[2] Therefore, standards obtained in one country may not be applicable for populations of other countries. For large countries such as the United States, wide geographical distribution of the sample is desirable. This was achieved in our sample.[7] Reservations must also be made about samples obtained from a population preselected for physical fitness, such as athletes and (to a lesser degree) military personnel.

Nearly every conceivable pitfall can be found in the sample of Sokolow and Friedlander.[1] In view of the extreme heterogeneity of the sample (including psychiatric patients, aviation personnel and even some infants), its size (150) is much too small. The use of actual extreme values for the normal limits is not acceptable, as discussed earlier. The limits are most likely determined by extremes in the sample.

Even a large sample collected with an attempt to avoid all pitfalls may not be truly representative of a general healthy population because it is rarely possible to obtain a truly random sample of the total population. Comparison with other samples of healthy persons collected independently by other investigators in different regions would be important for generalization. There is excellent agreement between the limits in our sample of young men and those in the original sample of 1,000 young men of Graybiel et al.,[25] and between the longitudinal electrocardiographic age trends of the 17 year follow-up study[26] of their original sample and the cross-sectional age differences in our male sample of 649 men. This agreement gives assurance that both samples are fairly representative of the healthy, male adult American population.

Separation of "normal" and "abnormal": In view of the overlap in the distribution of single electrocardiographic items in healthy populations and various populations of patients, the relation between two or more electrocardiographic items has been used to improve the separation between "normal" and "abnormal." The simplest relations are ratios such as R/S, Q/R, R/T and P/R ratios. Frontal plane QRS, T and P axes also reflect the relation between two variables. Utilization of these ratios for normal limits has considerably improved the correct recognition of various abnormalities. The percentage in patients of Q/R ratios exceeding 95 percent of normal limits exceeded that of Q wave amplitudes or duration in Frank leads Y and Z.[27] With use of a more sophisticated statistical method, sets of Q/R ratio limits were prepared for three Frank leads on the basis of the respective probability density function for a population of healthy men and 114 patients with myocardial infarction. The combined use of normal limits for a Q/R ratio of 0 to 0.19 mv in lead X, 0 to 0.24 mv in lead Y and 0.1 to 1.64 mv in lead Z resulted in correct recognition of 77.2 percent of patients with infarction, independent of site of the infarct and with a false abnormal rate of only 0.2 percent. Q wave amplitude contributed practically nothing to the separation obtained by means of Q/R ratios.

Normal 95 percent limits determined by bivariate analysis, utilizing the initial frontal plane 20 msec QRS and maximal QRS vectors, increased the recognition of myocardial infarction from insignificant (17.5 percent) for the single vectors to clinically useful (71.1 percent).[28]

Multivariate analyses: One of the first attempts to use multivariate analysis was undertaken by Shapiro et al.[29] In 649 healthy men and 516 asymptomatic men with hypertension and a normal electrocardiogram, the Hotteling T^2 test was used to provide more sophisticated definition of normal limits and improved separation of these two groups. With a matrix of only five electrocardiographic items, 13 percent of the hypertensive group were outside the 95 percent limits for normal. With 20 electrocardiographic items as a matrix, 40 percent of the hypertensive patients were outside these limits. The results were encouraging for systematic use of internal consistency among various electrocardiographic items to gain a more precise definition of normality. Recently, Pipberger and co-workers[4,30,31] did pioneering work in using multivariate analysis with the aid of electronic computers. The improved definition of normality greatly reduced the overlap in various abnormal conditions. We also have been working in this direction, and recently provided[32] a demonstration of the diagnostic power of this approach in the differentiation between anterior myocardial infarction and cor pulmonale. It is well known that the electrocardiogram in patients with cor pulmonale may simulate that of patients with myocardial infarction. Separation of these groups is far more difficult than separation of either group from normal subjects. By means of multivariate analysis the combination of five manually measured items—sum of R waves in leads X and Z, QRS interval, Z component of the 25 msec QRS vector, and the ratio $S_x/R_x + S_x$—resulted in correct identification of 89 percent of patients with cor pulmonale and 91 percent of patients with myocardial infarction. This recognition rate was far superior to that of single conventional or Frank electrocardiographic items. Kerr et al.[33] obtained similar results.

Echocardiographic Manifestations of Discrete Subaortic Stenosis

RICHARD H. DAVIS, MD
HARVEY FEIGENBAUM, MD, FACC
SONIA CHANG, AB
LEE L. KONECKE, MD
JAMES C. DILLON, MD

Indianapolis, Indiana

The echocardiographic manifestations of discrete membranous subaortic stenosis are described in three cases. The diagnosis was confirmed by cardiac catheterization in all and at operation in two. The characteristic finding in these patients was abnormal movement of the aortic valve leaflets. The leaflets opened rapidly with the onset of systole, then exhibited abrupt premature closure shortly after ventricular ejection. The valve remained partially closed throughout the remainder of systole. This premature leaflet closure is believed to be caused by obstruction to aortic valve flow produced by the band-like fibrous subaortic tissue. The valve leaflets also exhibited a gross fluttering motion possibly caused by a jet stream effect of the turbulent blood hitting the leaflets. In the two patients treated surgically, postoperative echograms continued to show premature leaflet closure but the degree of closure was decreased. The echocardiogram of one patient had the characteristic systolic anterior bulge of the mitral valve observed in muscular subaortic stenosis or idiopathic hypertrophic subaortic stenosis. Our data suggest that the following echocardiographic findings are suggestive if not specific for discrete subaortic stenosis: aortic valve closure early in systole, persistent valve closure throughout the remainder of systole, coarse fluttering of the leaflets, and absence of asymmetric septal hypertrophy.

Subaortic obstruction to left ventricular outflow has been generally classified in two categories: discrete membranous subaortic stenosis and idiopathic hypertrophic subaortic stenosis. Several echocardiographic features of idiopathic hypertrophic subaortic stenosis, sometimes called hypertrophic obstructive cardiomyopathy, have been described.[1–5] These features consist of systolic bulging of the anterior leaflet of the mitral valve and asymmetric hypertrophy of the septum. A few investigators[6] have noted systolic closure of the aortic valve. Discrete membranous subaortic stenosis is typically characterized by a ring-like fibrous band usually located immediately below the aortic valve. This paper describes the echocardiographic findings in a series of three patients with the diagnosis of discrete subaortic stenosis.

Material and Methods

The diagnosis of discrete subaortic stenosis was made in all three patients on the basis of typical findings at cardiac catheterization and cineangiography; in two patients operation confirmed the lesion. The three patients were aged 8, 18 and 18 years, respectively; two were male and one was female. The resting subaortic gradient was 90 and 100 mm Hg, respectively, in the two patients who underwent operation. The third patient had a gradient of 46 mm Hg and was not operated upon. Two patients had associated mild aortic insufficiency.

The echocardiographic examination was performed with an Ekoline 20 echograph combined with an Electronics for Medicine strip chart recorder. A

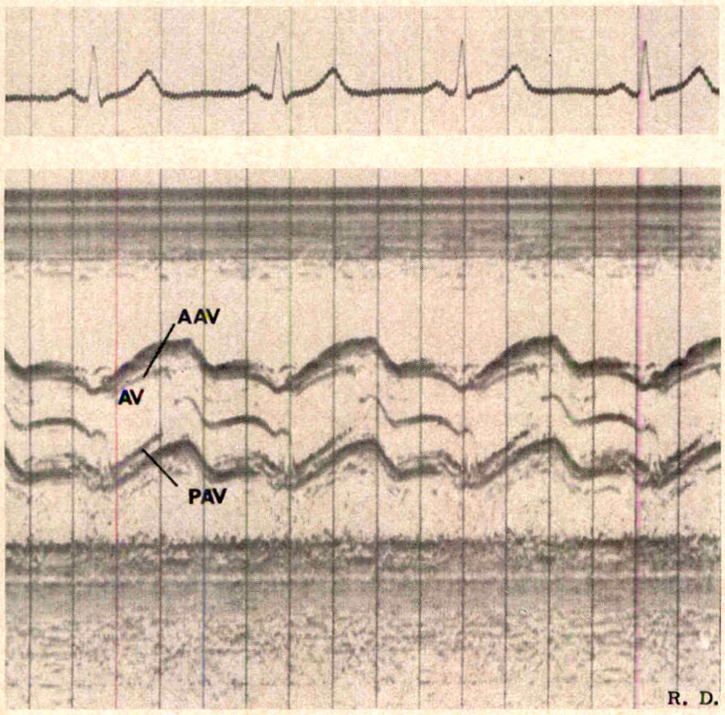

FIGURE 1. Normal aortic valve (AV) echogram showing opening of the valve leaflets with parallel separation throughout systole forming a box-like configuration. AAV = anterior aortic valve leaflet; PAV = posterior aortic valve leaflet.

2.25 megaHertz transducer with an outer diameter of 0.5 inch focused at 7 cm was used. All patients were examined in the recumbent position with the transducer placed in the third or fourth intercostal space along the left sternal border. With the transducer in this location the ultrasonic beam was directed so as to record a complete study of the mitral valve, left ventricle, aortic valve and the outflow tract including the aortic leaflets.

Results

All three patients had a striking abnormality of the aortic valve leaflets. In all, an initial rapid opening was followed by an abrupt closure of at least one leaflet shortly after the onset of ventricular ejection with continued partial closure or limited opening of the valves throughout the remainder of systole. There

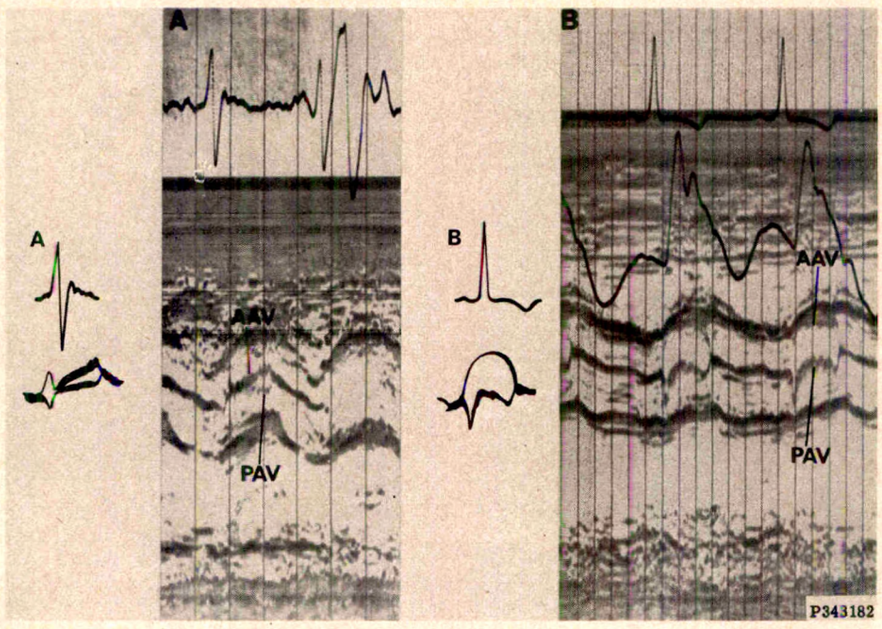

FIGURE 2. Case 1. **A,** preoperative echogram and accompanying diagram of the aortic valve echogram showing closure of the aortic leaflets in systole. **B,** postoperative echogram showing abnormal early closing but greater leaflet separation during systole. was also a distinct fluttering of the aortic leaflets. Figure 1 demonstrates an echogram from a normal aortic valve. Shortly after the electrocardiographic QRS complex, the aortic leaflets open and form a box-like configuration throughout systole. These echoes originate from two of the three leaflets of the aortic valve. During systole they are parallel and then close after the end of ventricular ejection. Upon close inspection one may note a very fine fluttering of the leaflets. Figure 2 demonstrates aortic valve echograms obtained before and after operation in a patient (Case 1) with discrete subaortic stenosis. To the left of the echograms are diagrams indicating the motion of the aortic leaflets. In the preoperative illustration (Fig. 2A) the aortic leaflets open with the onset of systole and then close almost immediately and are in a relatively closed position throughout systole. After surgical relief of the subvalvular obstruction (Fig. 2B), there is marked improvement in the valve motion. The posterior aortic leaflet retains its abnormal motion with mid-systolic closure; however, the anterior leaflet has a more normal appearance so that the distance between these two leaflets is considerably greater in the postoperative record.

Figure 3 presents aortic valve echograms obtained before and after operation in Case 2. Again in the preoperative record (Fig. 3A), the valve closes abruptly after the onset of ventricular ejection and is in a relatively closed position throughout systole. Upon close inspection one can appreciate gross fluttering of the aortic valve during systole. This fluttering is more obvious than that seen in a normal aortic valve. After operation (Fig. 3B), the leaflets again move more normally. Although there is still a small degree of mid-systolic closure, the leaflets are widely separated almost throughout systole. Figure 4 is an

aortic valve echogram taken from Patient 3, who had a gradient of only 46 mm Hg across the subaortic stenosis and was not treated surgically. Again only the anterior aortic valve leaflet is well seen, and one can detect the early systolic closure of the valve (arrow).

Discussion

As mentioned, mid-systolic closure of the aortic valve has been reported in patients with hypertrophic subaortic stenosis.[1–3] In our experience, this finding has occurred in patients with severe obstruction usually characterized by marked anterior bulging of the mitral leaflet to the point of virtually obliterating the outflow tract. Two of our three patients showed no evidence of systolic bulging of the anterior leaflet. We believe that close inspection of the echoes discloses some systolic bulging of the anterior mitral leaflet in one of the surgically treated patients. This bulging was not marked, did not obliterate the outflow tract and was not of the type usually associated with severe obstruction due to muscular hypertrophic subaortic stenosis. However, we cannot exclude the possibility that this patient had combined features of both discrete and muscular subaortic stenosis. After operation, the patient continued to have evidence of systolic bulging of the mitral valve despite a marked change in the aortic valve echogram. None of our patients had the asymmetric hypertrophy of the septum typical of hypertrophic subaortic stenosis.[5] All three patients had some degree of symmetrical hypertrophy of the left ventricle involving both the septum and the posterior left ventricular wall.

Some investigators[7] have mentioned that in this lesion it may be possible to visualize an abnormal echo in the vicinity of the outflow tract presumably originating from the site of obstruction. Although we observed some peculiar echoes in the outflow tract that may have originated from the obstructing lesion, we were not convinced that this was a reproducible finding in all three cases. This subject needs further investigation, and it is possible that we may be able to record the actual obstruction.

The abnormal aortic valve motion with discrete subaortic stenosis can probably be explained by alterations in aortic valve flow. The premature closure may be caused by the physical obstruction to aortic valve flow produced by the band-like fibrous subaortic tissue. Initially there appears to be rapid flow that produces some opening of the passive aortic leaflets. Possibly, as the left ventricle ejects its blood and the cavity decreases in size, the actual amount of obstruction increases and produces further diminution of aortic valve flow during much of systole. This degree of closure of the aortic valve during systole is rarely seen in patients with hypertrophic subaortic stenosis, who usually have only a brief period of closure during mid-systole. The fluttering of the leaflet seen in our patients is probably due to the jet of blood striking the leaflets. Although the normal aortic valve leaflets flutter slightly, the fluttering was far more pronounced in our patients.

Although our series of patients is small, we believe that the findings involving the aortic valve in patients with discrete subaortic stenosis are consistent. Since the abnormality seemed to be partially relieved after operative correction, it must be related to the subaortic obstruction.

Echocardiographic Diagnosis of Left Atrial Myxoma

ENRIQUE C. MARTINEZ, MD
THOMAS D. GILES, MD, FACC
GEORGE E. BURCH, MD, FACC

New Orleans, Louisiana

The presence of a left atrial myxoma in a young woman who presented with mitral valve obstruction was established by echocardiography before surgery. A systematic echocardiographic approach to such a patient is described, by which other diagnostic possibilities, including artifacts, may be eliminated. It is indicated that echocardiography should be performed in patients with suspected obstructive lesions at the mitral valve, unexplained syncope or suspected bacterial endocarditis, as well as in patients who have had atrial myxomas removed since these tumors occasionally recur.

Echocardiography is rapidly becoming established as a reliable and safe technique for the diagnosis of atrial tumors.[1-6] Artifacts, atrial thrombi and mitral valve disease can cause difficulty in diagnosis. Nevertheless, if clinical evidence of mitral valve obstruction exists, a correct diagnosis of left atrial myxoma is possible from ultrasound tracings alone, provided a systematic approach to diagnosis is used. Such an approach is illustrated with echocardiographic recordings from a young woman with a left atrial myxoma.

Case Report

A 30 year old woman was referred to the Tulane Cardiology Service at Charity Hospital of Louisiana at New Orleans for mitral commissurotomy. Dyspnea on exertion, orthopnea and occasional dizziness had begun insidiously 8 years before admission, during the last trimester of her third pregnancy. Steady worsening of her symptoms began approximately 4 months before admission. There was a questionable history of low-grade fever, but there was no history of rheumatic fever. During March 1972, the patient underwent cardiac catheterization at another hospital. The data were considered to show mitral stenosis and pulmonary hypertension, and mitral commissurotomy was recommended.

Physical examination on admission to Charity Hospital showed a blood pressure of 110/70 mm Hg, pulse rate of 68 beats/min and temperature of 98.4° F, orally. Regular sinus rhythm was present, and the apex beat of the heart was located in the fifth intercostal space in the midclavicular line. The first heart sound could be palpated at the apex, and a left parasternal impulse was present. On auscultation, the first heart sound was loud at the apex. The second heart sound at the base was narrowly split and had an accentuated pulmonic component. A low-pitched, early diastolic sound, best heard at the apex, was well separated from the second heart sound and did not have the quality of an opening snap. A grade 2/6 high-pitched systolic murmur that radiated to the axilla and a diastolic rumble with presystolic accentuation were heard at the apex. The diastolic rumble closely followed the early diastolic sound. A firm and nontender splenic tip was palpated.

Upon admission, the hematocrit was 35 percent and the hemoglobin 12.4 g/100 ml of blood. The erythrocyte sedimentation rate was 36 mm in 1 hour. Results of other laboratory examinations were within normal limits.

Teleoroentgenograms of the chest (Fig. 1) showed a heart with a "mitral" configuration. The pulmonary artery, left atrium and right ventricle were enlarged. The electrocardiogram (Fig. 1) was compatible with mild right ventricular hypertrophy and left atrial enlargement. An apex cardiogram

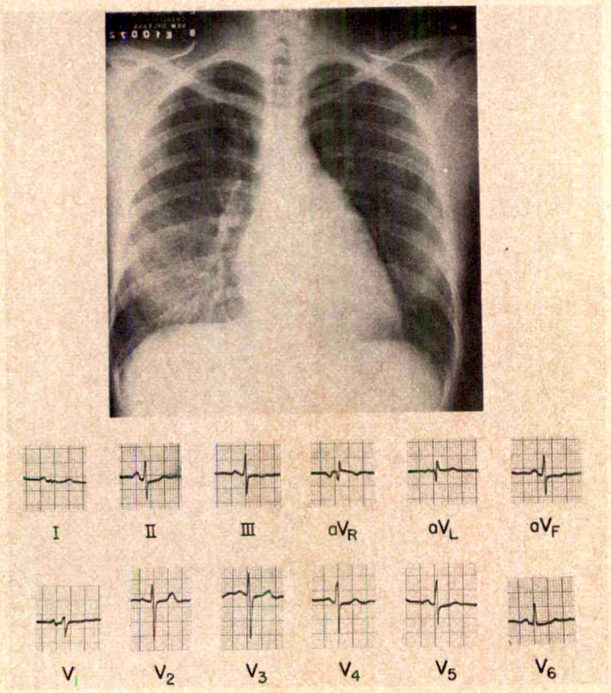

FIGURE 1. Teleoroentgenogram of the chest and electrocardiogram. The teleoroentgenogram shows "mitralization" of the heart. The left heart border is straight, the primary pulmonary arterial segment is enlarged and the vascular pattern is increased in upper lung zones. The electrocardiogram is compatible with left atrial and mild right ventricular hypertrophy.

showed a deep notch in the systolic portion of the tracing, which coincided with the first heart sound.

Echocardiography: On the day after admission to the hospital the patient was examined with a Smith-Kline ultrasonoscope (Ekoline-20A). This instrument has a transducer 1.6 mm in diameter, a frequency of 2.2 megaHz and a repetition rate of 1,000 pulses/sec. A permanent record was obtained using a Honeywell Visicorder. The patient was examined in bed with her head elevated 30°. With the transducer placed over the fifth intercostal space at the left sternal border, and the beam of ultrasound directed posteriorly and slightly inferolaterally, echoes were recorded from both mitral valve leaflets and the posterior wall of the left ventricle (Fig. 2B). Clouds of wavy-lined echoes were recorded posterior to the anterior leaflet of the mitral valve only during ventricular diastole (Fig. 2B). The portion of diastole during which these tumor echoes were recorded varied greatly with both direction of the ultrasound beam and patient position. Echoes from the posterior leaflet of the mitral valve could be recorded only after careful exploratory scanning. Once these echoes were identified, a record could be obtained that showed echoes from both leaflets as well as abnormal tumor echoes (Fig. 2B).

With the transducer placed over the fourth intercostal space and the ultrasound beam directed posteriorly, echoes from the anterior leaflet of the mitral valve and from the posterior wall of the left atrium were recorded. In this position, clouds of wavy-lined echoes could be seen posterior to the anterior leaflet of the mitral valve in the left ventricle during diastole and in the left atrium during ventricular systole (Fig. 2C).

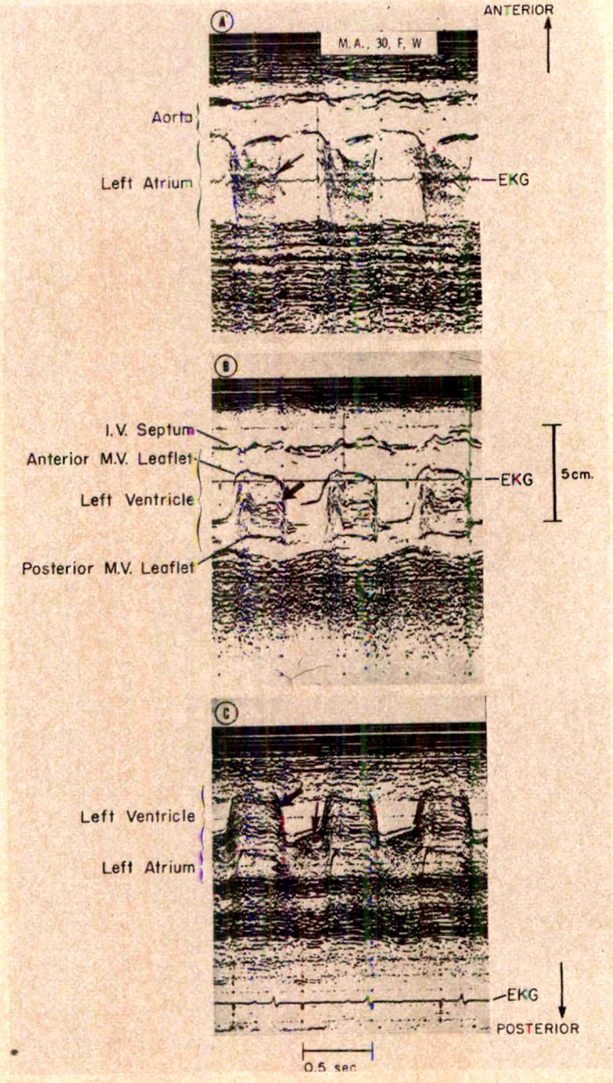

FIGURE 2. Echocardiograms recorded with the ultrasound beam directed **(A)** through the aorta and left atrium, **(B)** through the left ventricle and **(C)** through the left ventricle and left atrium. I.V. = interventricular; M.V. = mitral valve.

Finally, with the transducer still placed over the fourth intercostal space, but with the ultrasound beam directed toward the right shoulder, echoes were obtained from the aorta and left atrium (Fig. 2A). Clouds of abnormal echoes appeared in the left atrium only during ventricular systole. No echocardiographic abnormalities of the interventricular septum or left ventricle were recorded.

Recatheterization and surgery: The patient subsequently underwent a second right heart catheterization, and cineangiocardiograms of the left heart chambers were obtained by injection of contrast material into the pulmonary artery. A large filling defect detected in the left atrium was found to prolapse through the mitral valve orifice into the left ventricle during ventricular diastole (Fig. 3) and return into the left atrium during ventricular systole.

Finally, the patient had a typical myxoma excised from the left atrium (Fig. 4). Since recovery from operation, the patient has been asymptomatic. An echocardiogram recorded postoperatively showed normal findings (Fig. 5).

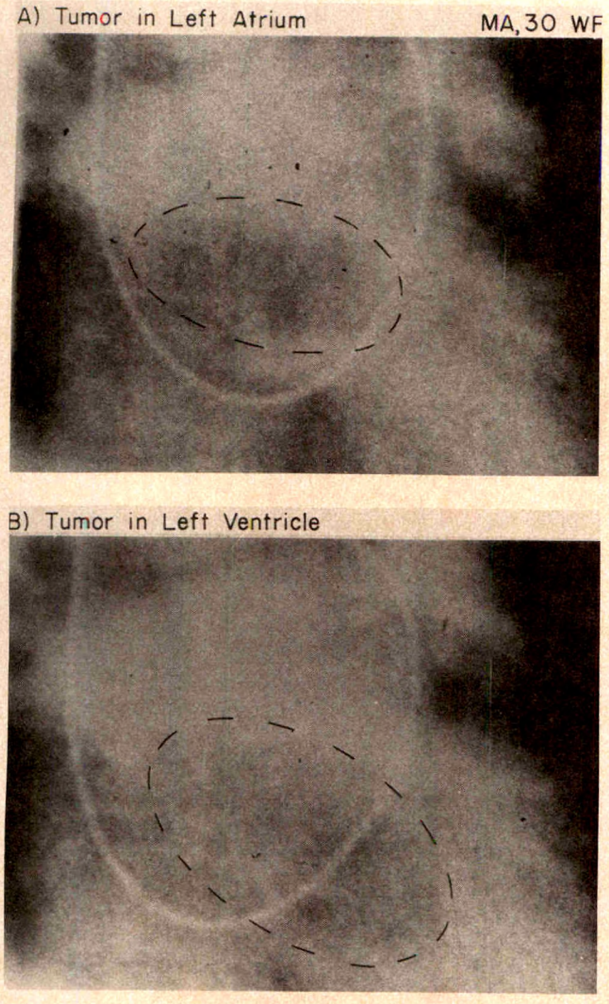

FIGURE 3: Cineangiograms recorded with the patient in the anteroposterior position during ventricular systole **(A)** and diastole **(B).** The "negative filling defect" representing the tumor is outlined.

Discussion

The clinical findings in this patient are familiar. Physical examination revealed ample evidence of pulmonary hypertension and a normal left ventricle. Together with electrocardiographic and roentgenologic evidence of left atrial enlargement, these findings were diagnostic of an obstructing lesion of the mitral valve orifice. The peculiar early diastolic sound and notching of the systolic portion of the apex cardiogram strongly suggested a left atrial myxoma.[5] The echocardiogram established the diagnosis.

Differentiation of left atrial myxoma and mitral stenosis: The echocardiographic examination of such a patient should be systematic. First, the presence or absence of mitral valve stenosis should be determined. The echocardiographic findings establishing the diagnosis of mitral stenosis are diminished C–E amplitude, decreased diastolic slope (E to F) and, in patients with regular sinus rhythm, absence of an *a* wave of the anterior leaflet of the mitral valve, as well as an inability to record echoes from the posterior leaflet of the mitral valve. The posterior leaflet moves concordantly with the anterior leaflet when mitral stenosis is present.[7,8]

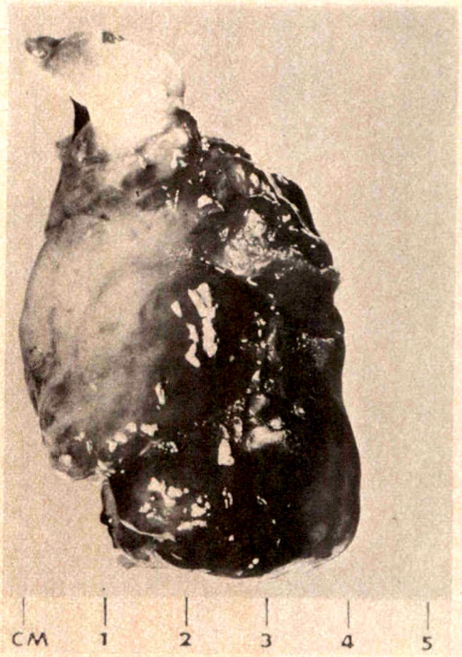

FIGURE 4. Photograph of myxoma removed surgically from the left atrium.

Thus, several features of the echocardiographic tracings obtained from patients with left atrial myxoma are useful in excluding the diagnosis of significant mitral stenosis, as illustrated by the tracings recorded from our patient. The most important echoes in excluding the diagnosis of mitral stenosis are those obtained from the posterior leaflet of the mitral valve.[8] Various planes may have to be explored to obtain clear echoes from the posterior leaflets, a procedure that often taxes the patience of both examiner and patient. However, the diagnosis of significant mitral valve stenosis may be excluded if the mitral valve leaflets can be demonstrated to move far apart during diastole. Additional evidence against the presence of mitral valve stenosis is a normal or greater than normal C–E amplitude. Although an *a* wave was present in the echocardiograms recorded from our patient, this finding does not exclude mitral valve stenosis.

A decreased E to F slope of the anterior leaflet of the mitral valve, as was occasionally recorded in this patient (Fig. 2B), should not by itself influence the examiner to make the diagnosis of mitral stenosis.[8] The flow of blood around the tumor mass and the absence of rapid pressure changes between the left atrium and left ventricle are probably responsible for the finding of a decreased E to F slope in patients with left atrial myxoma.

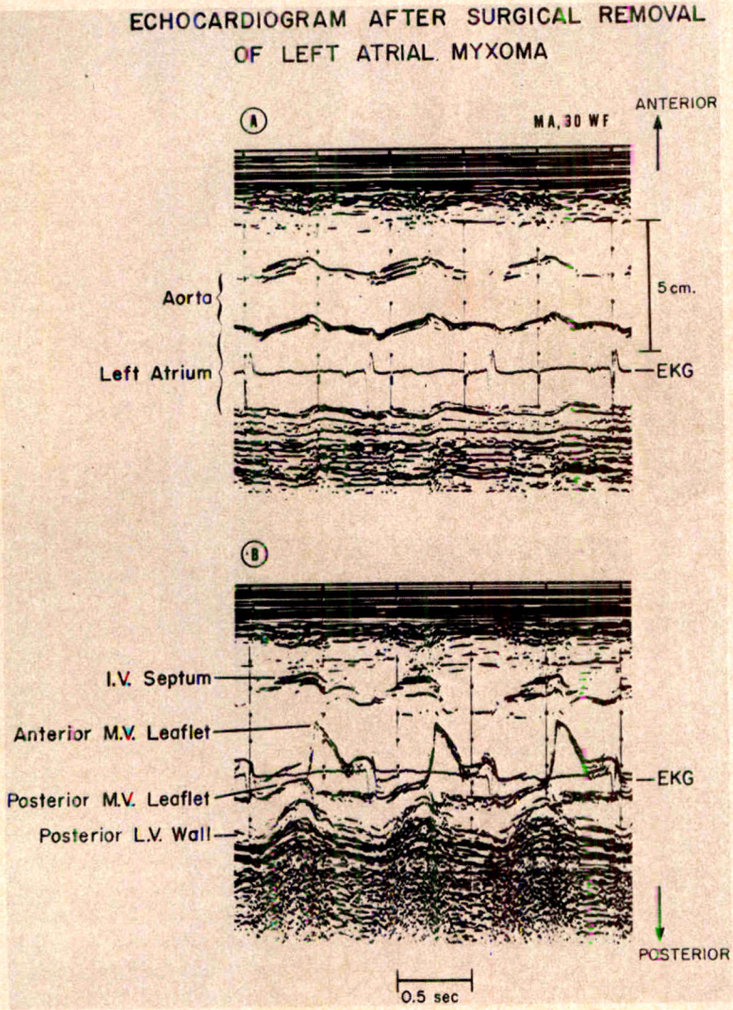

FIGURE 5. Echocardiograms recorded after surgical removal of the left atrial myxoma, with the ultrasound beam directed **(A)** through the aorta and left atrium, and **(B)** through the left ventricle. Compare these recordings with those shown in Figure 2. I.V. = interventricular; L.V. = left ventricular; M.V. = mitral valve.

Echocardiographic differentiation of obstructing mass in mitral orifice: Once the diagnosis of mitral stenosis has been excluded, an exploration with the echocardiograph should be undertaken in search for an obstructing mass in the mitral valve orifice. The recording of abnormal echoes from the region posterior to the anterior leaflet of the mitral valve during ventricular diastole is one of the most reliable manifestations of a tumor. However, such echoes may originate from thrombi in the left atrium or may be artifactual.[1,9]

The pendular motion of a tumor attached to the left atrial wall, produced by differences in pressure between the left atrium and left ventricle during ventricular diastole and systole, can be detected in the echocardiogram. This motion of the tumor in the heart of our patient was demonstrated beautifully at angiocardiography, and the time course of movement was also nicely followed by exploratory scanning with the echocardiograph. The illustrations reveal the tumor in position in the left atrium and then in the left ventricle.

To arrive at a reliable echocardiographic diagnosis, echoes must be obtained through at least three planes, that is, through both leaflets of the mitral valve and left ventricle, through the aorta and left atrium and through an intermediate plane displaying the anterior leaflet of the mitral valve and left atrium[10] (Fig. 2C). This latter plane is difficult to record unless the left atrium is enlarged. Occasionally, all of these planes may be recorded in one continuous rotation in direction of the beam of sound.

If a prolapsing tumor is present, an echocardiogram recorded through the first plane will reveal clouds of echoes behind the anterior leaflet of the mitral valve only during ventricular diastole (Fig. 2B). In the second plane, tumor echoes will be recorded from the left atrium only during ventricular systole (Fig. 2A). A recording from the intermediate plane will reveal tumor echoes in the left ventricle during ventricular diastole and in the left atrium during ventricular systole (Fig. 2C). These recordings provide an explanation for previous tracings considered to show the tumor in the mitral valve orifice, which rested on the anterior leaflet of the mitral valve in the left ventricle throughout the cardiac cycle.[2,11] It is therefore of utmost importance to de-

termine from which portion of the heart the echoes that are most posterior originate.

Collectively, these findings are diagnostic of a mass obstructing the mitral orifice in a ball-valve fashion and exclude the possibility that the echoes are artifacts or the results of a mass attached to the mitral valve leaflets. As indicated, the direction of the ultrasound beam is of paramount importance in determining the period of the cardiac cycle during which tumor echoes will be recorded. The appearance of an echo-free space posterior to the anterior leaflet of the mitral valve early in ventricular diastole with the appearance of abnormal echoes late during ventricular diastole is strong evidence of a tumor prolapsing through the mitral valve orifice. However, such a finding is solely dependent on the time required for the tumor to descend to the level of the ultrasound beam. Thus, in a given patient, the early echo-free space posterior to the anterior leaflet of the mitral valve during ventricular diastole will vary considerably and may therefore be a poor guide to degree of obstruction.

The characteristic configuration of the multiple mass of interrupted echo traces representing echoes from the tumor mass is important in the diagnosis of atrial myxoma. These characteristic echo lines are due to the nonhomogeneity of the tumor mass, as suggested by Effert and Domanig.[1] The motion of the tumor produces a characteristic wavy appearance of the abnormal echoes, as in those recorded from our patient and in previously reported cases.[1-6] Indeed, the lines seem to follow the motion of the normal anterior leaflet of the mitral valve and may well represent related hemodynamic phenomena. Artifacts do not have this wavy appearance, and thrombi have a characteristic dense, layered appearance.[9]

Clinical implications: This is the second case reported in which the diagnosis of left atrial myxoma was missed at routine cardiac catheterization.[6] In both instances, the patients had injection of contrast material into the left ventricle. Injection of contrast material into the pulmonary artery, with cineangiograms of the left heart, is a superior and safe method for demonstrating these tumors. Injection of contrast material directly into the left atrium using the transseptal technique[5] is not without danger.[12]

Thus, the echocardiogram is extremely useful in the diagnosis of obstructive lesions of the mitral valve orifice. Mitral stenosis and obstruction of the mitral orifice by tumor may be ruled in or out by echocardiography. The echocardiographic pattern of cor triatriatum, a lesion that may pose a problem in differential diagnosis, is distinctive.[13] The echocardiogram is most valuable when used in conjunction with history taking, physical examination, electrocardiogram and teleoroentgenograms of the chest.

The diagnosis of left atrial myxoma should be suspected in all patients with obstructive lesions of the mitral valve orifice as well as those with syncope or possible subacute bacterial endocarditis. Echocardiographic examination of such patients should be performed when feasible. Moreover, since atrial myxomas have been reported to recur,[14] periodic echocardiographic examinations should be performed in patients who have had these tumors removed. Finally, echocardiography is useful and reliable only if employed with patience, care and understanding.

Delayed Systolic Peak of the Femoral Pulse from Kinking of the Aortic Arch

KYUHYUN WANG, MD
DONALD HARRINGTON, MD
FREDARICK L. GOBEL, MD, FACC

Minneapolis, Minnesota

In an asymptomatic 38 year old man, an abnormal mediastinal density was due to kinking of the aortic arch. A delay in the systolic peak of the femoral pulse compared to that of the radial pulse aided in making the correct diagnosis. Indirect pulse tracings taken simultaneously from the femoral and the right radial arteries revealed that the delayed femoral pulse was due to a longer systolic build-up time in the femoral artery than in the radial artery. The onset of the upstroke was simultaneous in both arteries as in normal persons. An aortogram demonstrated narrowing of the aortic lumen at the site of the kink. Direct intraaortic pressure measurements revealed identical peak systolic pressures in the aortic arch and in the descending aorta distal to the kink.

An abnormal superior mediastinal density on the chest roentgenogram may, on rare occasion, be due to kinking of the aortic arch. Kinking of the aortic arch has occasionally been mistaken for a mediastinal neoplasm or an aortic aneurysm and patients have been unnecessarily subjected to therapeutic irradiation or exploratory thoracotomy.[1-4] When kinking of the aortic arch coexists in a patient with a documented neoplasm or recent history of chest trauma, a confusing diagnostic problem may arise.[1,5,6] A delay in the systolic peak of the femoral pulse when compared to that of the radial pulse may elucidate this usually benign condition. This is a report of such a case.

Case Report

A 38 year old asymptomatic farmer was referred to the Minneapolis Veterans Administration Hospital because of an abnormal superior mediastinal density suggestive of an aneurysm or tumor noted on a routine chest roentgenogram (Fig. 1). There was no history of cardiac disease or chest trauma. Physical findings included a distended left external jugular vein (Fig. 2), a soft systolic ejection murmur and an ejection click along the right sternal border (Fig. 3). Palpation of the femoral pulse revealed it to be delayed when compared with the radial pulse. In addition to the mass density, the chest X-ray film also revealed a dilated ascending aorta. An aortogram revealed typical kinking of the aortic arch and a bicuspid aortic valve (Fig. 4). The left subclavian artery originated from the area of the acute kinking, and the left carotid artery originated from the aortic arch. Direct intraarterial pressure recordings taken simultaneously from the aorta proximal and distal to the area of acute angulation revealed no peak systolic pressure gradient (Fig. 5). There was no aortic regurgitation or peak systolic pressure gradient across the aortic valve.

Indirect pulse tracings taken simultaneously from the femoral and the right radial arteries revealed the simultaneous onset of the pulse upstroke in both arteries but a 120 msec delay of the systolic peak of the pulse in the femoral artery when compared to that of the radial artery (Fig. 6). Pulse recordings in 12 control subjects demonstrated that the femoral systolic peak appeared either before or simultaneously with the radial systolic peak (Table I).

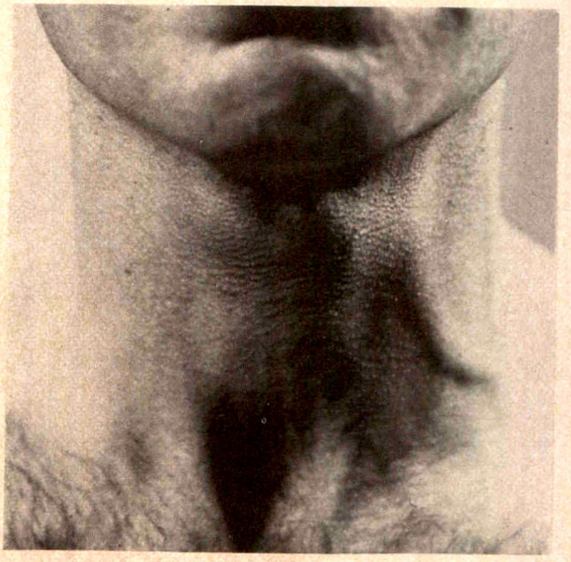

FIGURE 2. Photograph showing unilateral distension of the left jugular vein.

The patient remains asymptomatic and is currently being followed up as an outpatient.

Discussion

Kinking of the aortic arch has been recognized as a distinct roentgenographic entity[1,7] and is usually characterized by two major findings: (1) an abnormally long and redundant aortic arch, and (2) a sharp kink at the anticipated site of the attachment of the ligamentum arteriosum. The aorta proximal to the kink is elongated and rises considerably higher in the mediastinum than the normal aortic arch. The segment of aorta between the origin of the left carotid artery and the left subclavian artery is the portion of the aorta that usually contributes to the redundancy. This segment contributes to the abnormal mediastinal mass density viewed on the posteroanterior chest X-ray film. The aorta distal to the kink may be aneurysmally dilated. The acute angulation at the level of the origin of the left subclavian artery may approach 90°. In coarctation of the aorta and in senescent lengthening of the thoracic aorta, the redundant aortic segment is usually absent and the angulation is much less marked. The term pseudocoarctation has been used to refer to an abnormality of the aortic arch suggestive of either kinking of the aortic arch or mild coarctation of the aorta when no pressure gradient is measurable. This term is misleading and should be discarded.[8] This redundant aortic segment may have compressed the left innominate vein in our patient, thus leading to the unilateral distension of the left external jugular vein.

Differentiation from coarctation of aorta: Since patients with kinking of the aortic arch are usually asymptomatic, pathologic material in such cases is scant.[9-12] Coarctation of the aorta is characterized by an internal ridge composed of aortic media occurring at a point opposite the ductus arteriosus or the

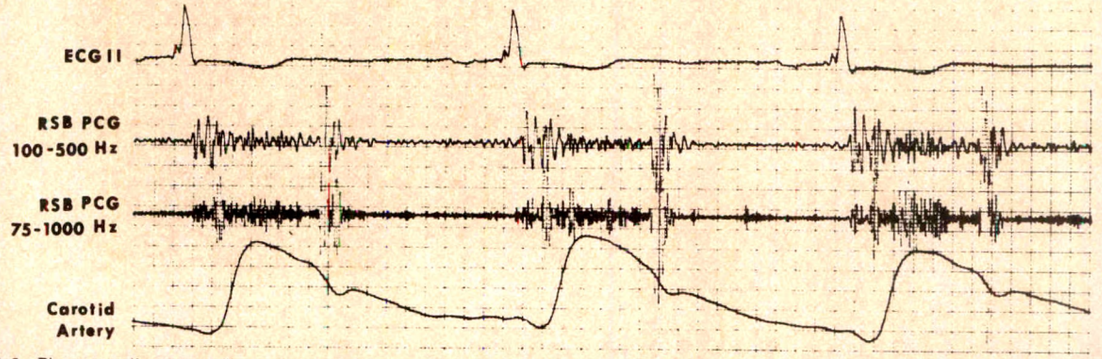

FIGURE 3. Phonocardiogram taken at the right second intercostal space simultaneously with electrocardiographic lead II and carotid arterial pulse tracing. A systolic ejection click is followed by a systolic ejection murmur. The tracing was obtained using a Mingograf 34 direct writing recorder with ink jet galvonometers and a frequency response linear from 0 to 500 Hz. RSB PCG = right sternal border phonocardiogram.

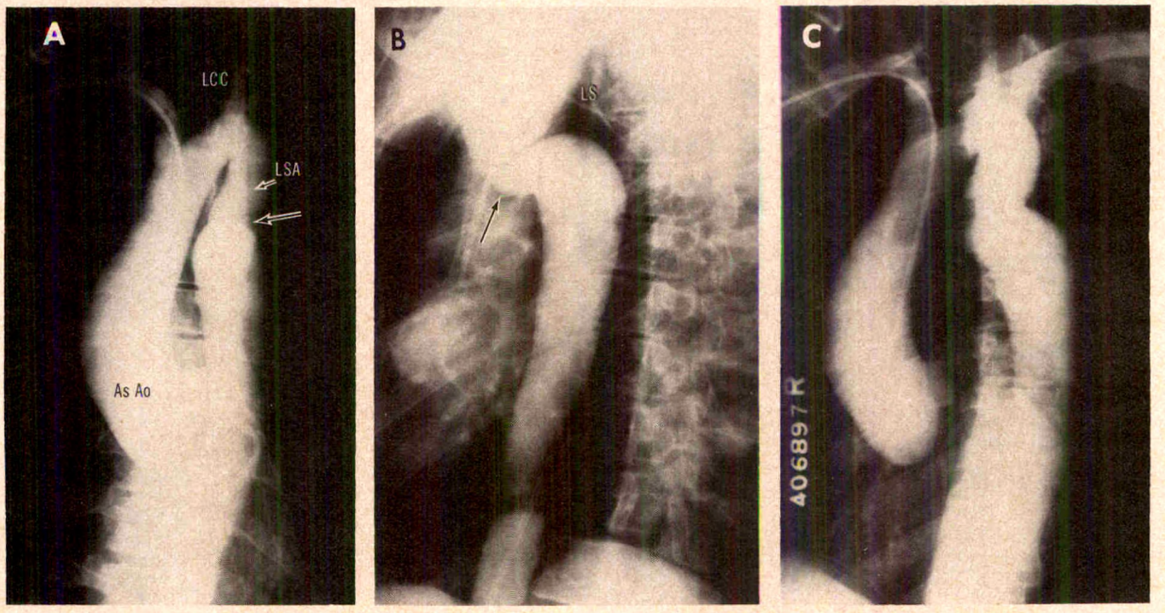

FIGURE 4. Aortograms **A,** taken in the anteroposterior projection. Contrast material was injected into the ascending aorta (AsAo) through a catheter introduced from the right brachial artery. The aortogram demonstrates two aortic valvular cusps and a dilated ascending aorta. The kinked portion of the aorta is indicated by the **lower arrow.** The aorta proximal to the kink is elongated and rises high in the superior mediastinum. The distance from the left common carotid (LCC) artery to the left subclavian artery (LSA) is lengthened. **B,** taken in the steep left anterior oblique projection with the catheter positioned as in **A.** This view demonstrates the kinking at the anticipated site of the ligamentum arteriosum **(arrow).** The left subclavian (LS) artery also arises from the same area. This projection reveals narrowing of the aorta at the site of the kink. There is a moderate degree of aneurysmal dilation of the aorta distal to the kink. **C,** taken 30° in the left anterior oblique projection with the catheter in the same position as in **A** and **B.** The bicuspid nature of the aortic valve is best seen in this view.

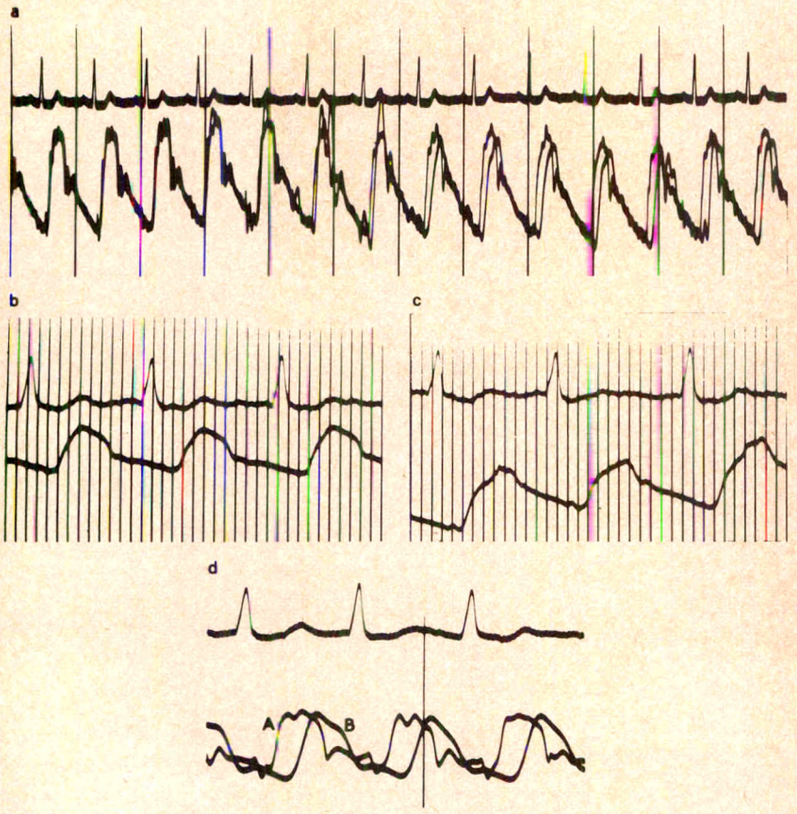

FIGURE 5. Pressure tracings. **a,** intraaortic, recorded from two Teflon® catheters during withdrawal of one catheter from the ascending aorta to a point distal to the kinked segment. The second catheter remained in the ascending aorta. Note the lack of appreciable pressure gradient across the site of kinking. **b,** tracing in the ascending aorta from a catheter-tip transducer. The patient had atrial fibrillation during this and subsequent recordings. **c,** tracing taken in abdominal aorta from the same catheter-tip transducer used in **b.** The systolic upstroke is prolonged compared to that in **b. d,** simultaneous intraaortic pressure tracings taken from two Teflon catheters, one in the ascending aorta (A) and the other in the midabdominal aorta (B). The build-up time is prolonged, and the systolic peak is delayed in the abdominal aorta when compared to that of the ascending aorta.

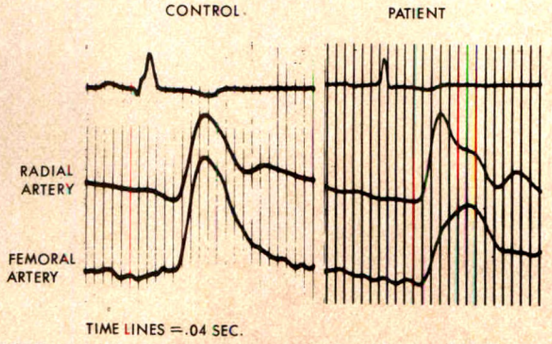

FIGURE 6. Indirect pulse tracings and electrocardiogram taken simultaneously from the right radial artery and the right femoral artery. In a representative normal subject **(left)**, the onset of the systolic upstroke and the systolic peak are simultaneous in both arteries. In contrast, the patient **(right)** has a 120 msec delay of the systolic peak of the femoral artery compared to the radial artery, whereas the onset of the upstroke is simultaneous in both arteries. Pulse tracings were obtained from an Electronics for Medicine, Inc. PS-2 ceramic microphone with a time constant of 1.2 seconds in the pulse position.

ligamentum arteriosum.[12] This internal ridge may or may not be obstructive. Clinical, roentgenographic and hemodynamic findings are dependent upon the degree of obstruction by this internal ridge. Consequently, some observers, finding anatomic evidence of an internal ridge in patients with roentgenographic findings of kinking of the aortic arch, conclude that these cases represent a variation of mild coarctation of the aorta.[10,12] Other observers have failed to document such an internal ridge in patients with kinking of the aortic arch.[9] Further elucidation of this problem awaits additional anatomic observation in patients with X-ray findings characteristic of kinking of the aortic arch. In the interim it seems reasonable to distinguish patients with such X-ray findings from those with typical coarctation, recognizing that they may have only a variant of mild anatomic coarctation of the aorta. We have outlined these differences in Table II. A bicuspid aortic valve, ventricular septal defect, atrial septal defect and patent ductus arteriosus all have been found in patients with X-ray findings typical of kinking of aortic arch.[2,9,11] This association of congenital anomalies lends support to the concept that coarctation of the aorta and kinking of the aortic arch may have a similar pathogenesis.[12]

Femoral pulse tracing as diagnostic aid: A delay in the femoral pulse when compared to the radial pulse has been a useful aid in diagnosing kinking of the aortic arch,[13,14] although some investigators have noted no such delay.[15] Indirect pulse tracings taken simultaneously from the right radial artery and the right femoral artery in our patient revealed that the clinically detected delayed femoral pulse is due to a prolonged build-up time resulting in a delayed systolic peak. As in normal persons, the onset of the upstroke in both the radial and femoral arterial pulses was simultaneous.[16,17] This finding

TABLE II

Comparison of Kinking of Aortic Arch and Coarctation of Aorta

		Coarctation of Aorta	
	Kinking of Aortic Arch	Subclinical[18] (mild)	Clinical (severe)
Kinking or buckling	+	−	−
High aortic arch	+	−	−
Distance between left common carotid artery and left subclavian artery	Long	Normal	Normal
Localized constriction with internal ridge	−[9] or +[10,12]	+	+
Pressure gradient	Usually −	−	+
Collateral circulation	−	−	+
Rib notching	−	−	+
Occasional association with a bicuspid aortic valve	+	+	+

\+ = present, − = absent.

suggests that there is some narrowing of the aortic lumen at the site of kinking. In experimental animals with a progressively constricted aorta, the delayed systolic peak in the distal aorta preceded the appearance of the peak systolic pressure gradient.[18] In that experiment, the contour of the distal aortic pulse wave began to change when the aorta was constricted to 40 percent of its original external cross-sectional area whereas the reduction in systolic pressure in the distal aorta did not occur until the aorta was constricted to less than 35 percent of its original cross-sectional area.[18]

These experimental data indicate that the differentiation between coarctation and kinking of the aorta cannot be based on mere demonstration of presence or absence of a peak systolic pressure gradient across the aortic lesion.[19] Coarctation of the

aorta may not produce a peak systolic pressure gradient so long as the constriction is mild; and, kinking of the aortic arch has been associated with peak systolic pressure gradient when the aortic lumen was significantly compromised by the kinking.[14,15] Presence or absence of a peak systolic pressure gradient, collateral circulation, rib notching, proximal hypertension and left ventricular hypertrophy reflect only the degree of constriction and not the underlying pathologic features. On the other hand, kinking of the thoracic aorta alone, by disturbing the relation of incident and reflected pressure waves, may reduce the normal systolic amplification, thereby leading to a prolonged build-up time in the distal aorta (Fig. 5).[16,17]

Embryology: One current view of the embryology of kinking of the aortic arch indicates that failure of the normal "compression" of the left fourth aortic arch and third to seventh dorsal aortic root segments during development results in an abnormally long aortic arch that kinks at the fixed point, namely, the insertion of the ligamentum arteriosum.[1] Failure of "compression" of the left fourth aortic arch may account for the abnormally long distance between the origins of the left common carotid artery and the left subclavian artery characteristic of this condition. On the other hand, the fact that the origin of the left subclavian artery in this condition is not in the midthoracic aorta but either proximal to or at the level of the ligamentum arteriosum, as in normal persons, does not make it likely that there was failure of the compression of the third to seventh dorsal aortic root segment. It also seems reasonable that the elongated segment of aorta could be formed by the third arch and a persistent left carotid duct.[3]

Clinical implication: Recognition of kinking of the aortic arch can avoid unnecessary irradiation or an exploratory thoracotomy. Although this condition is generally considered to be benign and to require no treatment, this may not always be true. Gay and Young[20] reported a fatal case in which the aorta distal to the kinking became aneurysmal and ruptured. Three other patients had timely and successful resection of aneurysms with graft replacement and are doing well 1 to 8 years after operation. It has also been advised[11] that patients with this condition should be protected from bacterial endocarditis or endarteritis because of the possibility of infection at the site of the kink or in the associated aortic valvular or other cardiac anomalies.

Demonstration of Dual Atrioventricular Nodal Pathways in Man

KENNETH M. ROSEN, MD, FACC
ASHWIN MEHTA, MD
ROBERT A. MILLER, MD

Chicago, Illinois

Electrophysiologic studies in a patient manifesting two P–R intervals revealed two ranges of atrioventricular (A–V) nodal conduction time (A–H intervals) and two A–V nodal effective and functional refractory periods. Similar demonstrations in patients with paroxysmal supraventricular tachycardia would strongly support the presence of longitudinal A–V nodal dissociation with reentry as a causative mechanism.

Recent studies suggest that atrioventricular (A–V) nodal reentry is a mechanism of paroxysmal supraventricular tachycardia in man.[1–3] The demonstration of A–V nodal reentry implies, but does not prove, the existence of functional dissociation of the A–V node into two pathways, one utilized for anterograde and the other for retrograde conduction.[4,5]

The direct demonstration of dual A–V nodal pathways is dependent upon evidence of dual A–V nodal conduction times and refractory periods. Mendez et al.[6] provided such evidence in dogs, utilizing premature His bundle stimulation. At critical coupling intervals, they noted sudden prolongation of retrograde A–V nodal conduction times (from His bundle to low atrium) with simultaneous occurrence of ventricular echoes. This suggested block in a fast A–V nodal pathway with conduction from the His bundle to the atria proceeding by way of a slow A–V nodal pathway. The impulse could return to the ventricles over the previously failed fast pathway. The critical coupling interval at which sudden prolongation occurred would be the effective refractory period of the fast pathway. Subsequent microelectrode studies in rabbit hearts by Mendez and Moe[7] suggested that functional dissociation into dual pathways occurred in the upper part of the A–V node.

The only previous experimental demonstration of a similar phenomenon in man has been indirect. Schuilenburg and Durrer,[8] using coupled ventricular stimulation in patients, demonstrated sudden prolongations of retrograde conduction time (from ventricles to atrium) with simultaneous occurrence of ventricular echoes at critical coupling intervals. Since His bundle electrograms were not recorded in their study, the exact sites of retrograde conduction delay could not be delineated.

The catheter recording of His bundle electrograms should allow demonstration of dual A–V nodal pathways, if these occur in man.[9] We recently performed such recordings in a child who, after repair of a ventricular septal defect, intermittently manifested two P–R intervals, one of 0.18 second and the other of 0.42 second. The changes from one P–R interval to the other were sporadic and unpredictable.

Electrophysiologic Study

The A–H interval, a measure of A–V nodal conduction time,[10] was 90 msec during spontaneous sinus rhythm (Fig. 1A). At an atrial paced rate of 90/min, two A–H intervals were recorded, one of 100

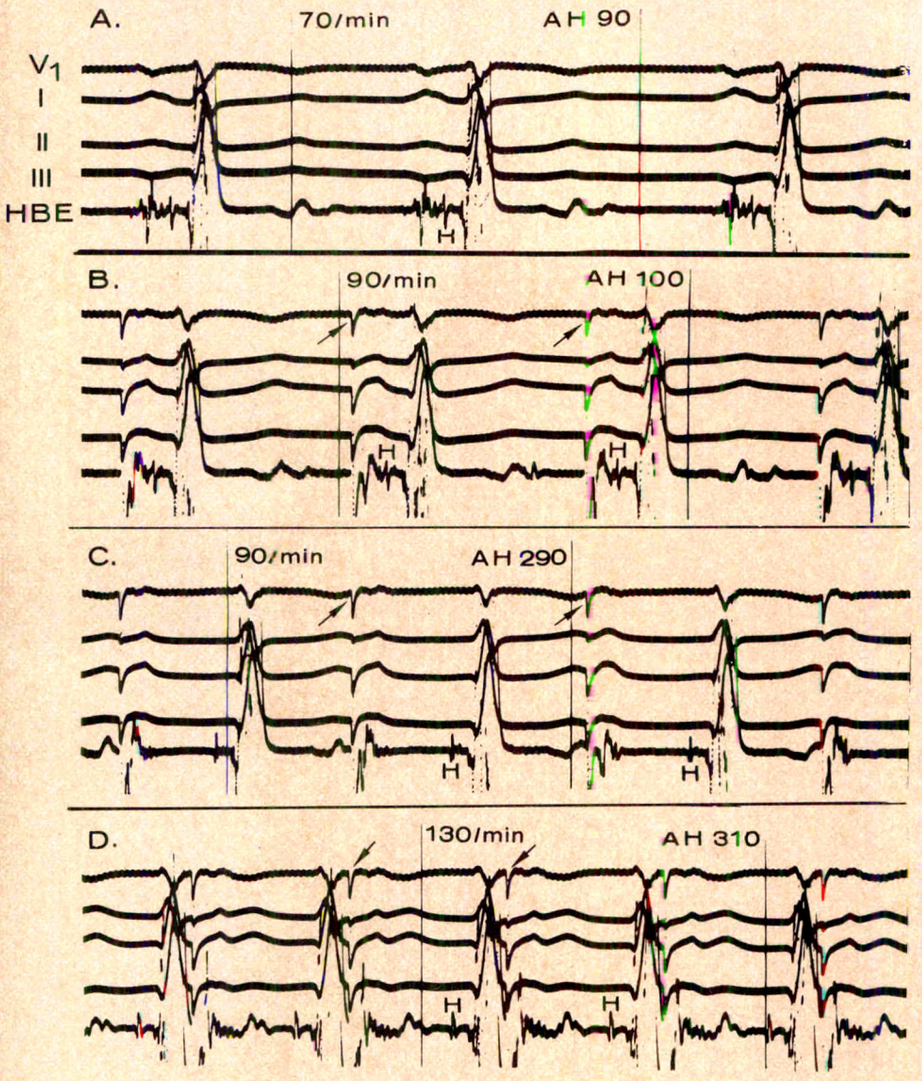

FIGURE 1. Demonstration of dual A–V nodal conduction times. Shown are electrocardiographic leads V_1, I, II and III and His bundle electrogram (HBE). Paper speed is 100 mm/sec and times lines are at 1 second intervals. His bundle potentials are labeled H. **A,** sinus rhythm with an A–H interval of 90 msec (fast pathway). **B,** atrial pacing at 90/min (pacing impulses labeled with **arrows**). The fast pathway is being utilized (A–H interval 100 msec). **C,** atrial pacing at 90/min. The slow pathway is being utilized (A–H interval 290 msec). **D,** atrial pacing at 130/min with conduction over the slow pathway (A–H interval 310 msec).

msec and the other of 290 msec (Fig. 1, B and C). The transition between shorter and longer A–H intervals was abrupt, with series of short A–H intervals being followed by series of long A–H intervals at identical cycle lengths. Series of long A–H intervals also changed abruptly to series of short A–H intervals. Each pathway maintained itself for various periods of time (up to 5 minutes). At paced rates above 100/min, A–H intervals were between 300 and 380 msec (Fig. 1D). Wenckebach periods proximal to the His bundle were noted at a paced rate of 145/min. The QRS configuration and H–V intervals were constant despite changes in the A–H interval.

Refractory periods were measured with an atrial extrastimulus introduced following every 10th sinus beat (Fig. 2).[11] The extrastimuli (A_2) were coupled to the atrial electrogram of the spontaneous beat (A_1) and were given progressively earlier (in 10 msec steps). The response to several extrastimuli was tested at each coupling interval. H_1 was the His bundle electrogram of the last sinus beat before the extrastimulus and H_2 was the His bundle electrogram of the coupled beat. The impulse was propagated along the fast pathway with A_1–H_1 intervals remaining between 90 and 100 msec during this portion of the study. Sinus rhythm was regular, allowing reproducible recordings.

The H_1–H_2 responses were plotted against the A_1–A_2 coupling intervals (Fig. 2 and 3). As the A_1–A_2 interval was shortened from 600 to 530 msec, the H_1–H_2 interval shortened from 600 to 565 msec (Fig. 2A). At an A_1–A_2 interval of 520 msec, one of two H_1–H_2 responses was noted, either fast (570 msec) or slow (715 msec) (Fig. 2, B and C). Similar fast or slow responses were noted at A_1–A_2 intervals of 520 to 460 msec (Fig. 2, D and E). At A_1–A_2 intervals of 450 msec or less, only slow responses were seen (Fig. 2, F and G). The limiting factor for A–V con-

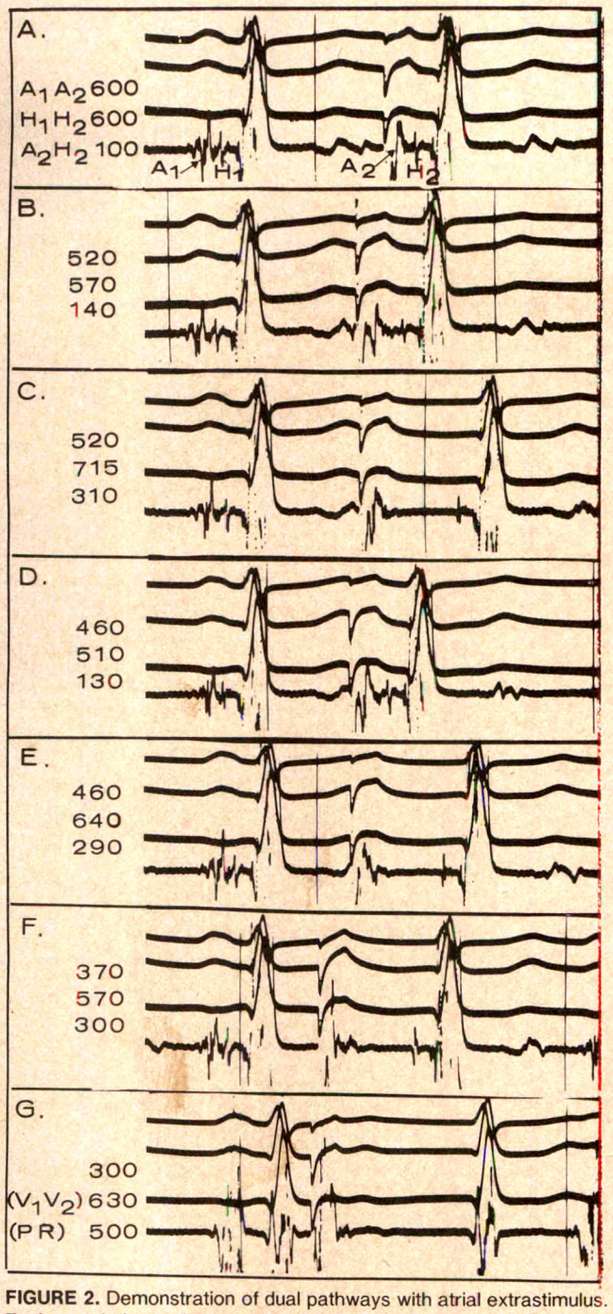

FIGURE 2. Demonstration of dual pathways with atrial extrastimulus. Each panel shows the last sinus beat before the extrastimulus. A_1, H_1, A_2 and H_2 are labeled in the upper panel. A_1–A_2, H_1–H_2 and A_2–H_2 are listed for each panel on the left. **A, B** and **D** show fast responses; **C, E, F** and **G** show slow responses. The His bundle electrogram was transiently lost toward the end of the procedure **(G),** so that leads V_1 and V_2 and the P–R interval are listed in that panel. See text for discussion.

duction was the atrial effective refractory period of 290 msec.

Examination of the graph (Fig. 3) suggested two A–V nodal refractory periods. The effective refractory period of the fast pathway was the longest A_1–A_2 interval at which A_2 failed to conduct to the His bundle by way of the fast pathway and ranged between 450 and 520 msec. The functional refractory period of the fast pathway was the shortest H_1–H_2 interval achieved utilizing this pathway and was 510 msec. Similar determinations for the slow pathway revealed an effective refractory period of less than 300 msec and a functional refractory period of 560 msec. Studies of the extrastimulus response after administration of atropine were incomplete but suggested that both fast and slow curves were shifted downward and to the left.

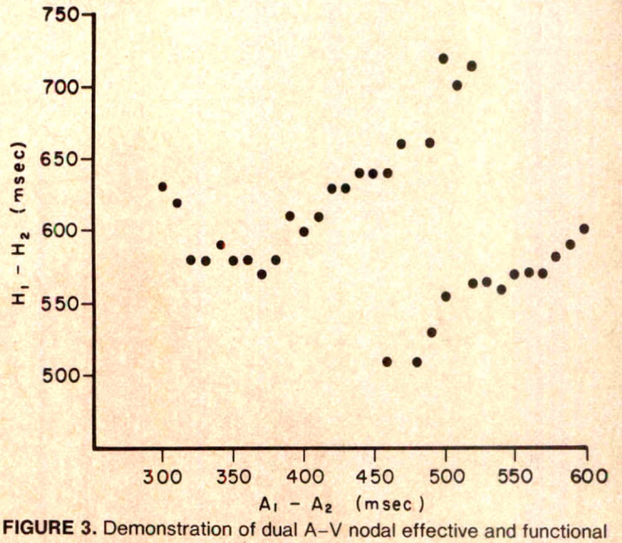

FIGURE 3. Demonstration of dual A–V nodal effective and functional refractory periods. A_1–A_2 coupling intervals are plotted on the **abscissa;** H_1–H_2 responses are plotted on the **ordinate.** Note the striking discontinuity in the fast pathway curve **(lower right)** and the slow pathway curve **(upper left).** At coupling intervals of 450 msec or less, only the slow pathway is utilized.

Discussion

The demonstration of two ranges of A–H intervals as well as dual A–V nodal effective and functional refractory periods suggests the presence of dual A–V nodal pathways. These could reflect a functional A–V nodal dissociation or an anatomic discontinuity in the node secondary to previous surgery. The possibility that the fast pathway is an accessory pathway[12] entering the distal node or His bundle is unlikely since the A–H interval of 90 msec does not suggest A–V nodal bypass. Both slow and fast pathways appeared to be under control of the parasympathetic nervous system.

The absence of echoes with premature stimulation may reflect retrograde refractoriness of the fast pathway. Despite the absence of echoes, the demonstration of dual A–V nodal pathways is relevant to paroxysmal supraventricular tachycardia in man. If similar A_1–A_2, H_1–H_2 curves could be demonstrated in patients with paroxysmal supraventricular tachycardia, this finding would strongly support the presence of longitudinal A–V nodal dissociation with reentry as a causative mechanism of the arrhythmia.

Pacemaker-Induced Cardiovascular Failure

Hemodynamic and Angiographic Observations

JOHN M. HAAS, LTC, MC
GAIL B. STRAIT, Major, MC

Tacoma, Washington

A 71 year old woman underwent permanent transvenous right ventricular pacemaker implantation for prolonged syncope and atrioventricular conduction defects. Each time the patient's heart rate spontaneously decreased to less than 70 beats/min, cardiovascular collapse with hypotension and reduced cardiac output occurred. Left ventricular cineangiography performed during both sinus rhythm and right ventricular pacing demonstrated reduced left ventricular end-diastolic volume, secondary to a loss of atrial contribution to left ventricular filling, and severe, acute mitral regurgitation with significantly decreased effective stroke volume and cardiac output. Pacing from the left ventricular endocardium had the same effect. The detrimental effects of cardiac pacing necessitated removal of the right ventricular pacemaker.

Since the introduction of artificial cardiac pacemakers the prognosis of patients with conduction disturbances and complete heart block has been improved. Nevertheless, the literature is replete with reports on problems associated with pacemaker implantation. Pulse-generator failure, infections at the site of generator implantation, malposition or dislocation of the endocardial electrode catheter, perforations of the septal and free right ventricular wall, arrhythmias, thrombus formation and pulmonary emboli represent the vast majority of complications in our experience and in several large series reported by others.[1–3] These reports have not mentioned the need to discontinue asynchronous ventricular pacing because of significant deleterious hemodynamic effects on cardiac output.

The loss of atrial contribution to ventricular filling and stroke volume has been studied, and the hemodynamic consequences of nonsequential atrioventricular output has been emphasized by Samet et al.[4] The deleterious effect of mitral insufficiency has been cited as a relative indication for atrial synchronous pacing by Furman and Escher.[5] In this report we document hemodynamically and cineangiographically similar complications requiring discontinuation of asynchronous right ventricular endocardial pacing.

Methods

Atrial pacing was accomplished with a Cordis temporary pervenous bipolar no. 4F pacing catheter and a Medtronic pulse generator (model 5837). Percutaneous retrograde right and left heart catheterization was performed, with pressures recorded using Statham P23DB transducers and an 8-channel Hewlett-Packard recorder. Left ventricular cineangiograms were obtained on 16 mm film at 30 frames/sec, using meglumine diatrizoate (Renografin-76®) as the contrast medium. Left ventricular volume was calculated according to the method of Sandler and Dodge[6] from the single plane cineangiogram obtained in the right anterior oblique projection and corrected with the regression equation of Kennedy et al.[7] Cardiac output was determined by the Fick method, with blood gas and air analysis performed on IL co-oximeter instru-

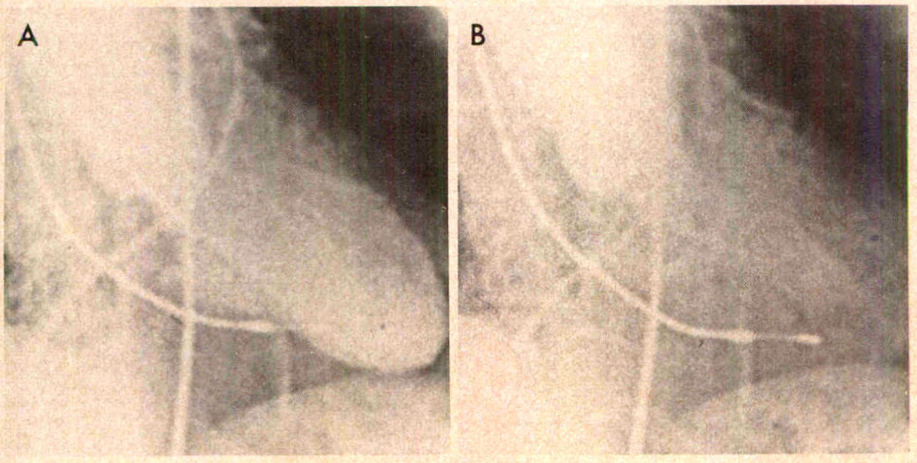

FIGURE 1. Left ventricular cineangiography during normal sinus rhythm. **A**, demonstrating left ventricular end-diastolic volume. **B**, demonstrating left ventricular end-systolic volume and absence of any mitral regurgitation.

ments (models 113 and 182). Right ventricular pacing during cardiac catheterization was accomplished with a bipolar endocardial catheter and a General Electric implantable ventricular inhibited standby pulse generator (model A2072D). Left ventricular pacing was performed using a no. 7F bipolar Zucker catheter to obtain simultaneous left ventricular pressures.

Case Presentation

The patient, a 71 year old white woman, had a significant history of several transient bouts of syncope the year before admission. Her current hospitalization was precipitated in October 1972 by a prolonged syncopal episode at home. En route to the hospital, the ambulance attendant noted a radial pulse of 30/min and no obtainable blood pressure. On arrival at the emergency room, the patient gradually regained consciousness, and an electrocardiogram disclosed normal sinus rhythm with a rate of 60/min; blood pressure was 200/70 mm Hg. History indicated possible previous angina pectoris but no definite documented myocardial infarction. The patient currently experienced shortness of breath and dyspnea on exertion but had no definite history of frank congestive heart failure. She had been treated previously with methyldopa and Dyazide® for hypertension.

Physical examination showed an elderly, alert and oriented white woman with a heart rate of 68 beats/min and blood pressure of 190/88 mm Hg. There was slight arteriovenous nicking on funduscopic examination. Jugular venous pulse and pressure were normal. The lungs were clear to auscultation and percussion. There was no hepatosplenomegaly or edema. Peripheral pulses were intact and full. Results of a neurologic examination were normal. Examination of the heart revealed normal sinus rhythm. The apical impulse was in the fifth intercostal space at the midclavicular line with a slight left ventricular impulse. A grade 2–3/6 systolic ejection murmur heard over the aortic outflow tract radiated to the carotid arteries. No gallop sounds were noted.

The electrocardiogram showed left ventricular hypertrophy by voltage criteria with slight sagging of the S–T segments. Chest X-ray films revealed slight cardiac enlargement with prominence and calcification of the aortic arch.

The patient was observed for 24 hours with an Avionics Holter monitor which revealed no arrhythmias or conduction disturbances. Diagnostic atrial pacing was performed. First degree atrioventricular (A–V) block occurred at a rate of 100/min and 2:1 A–V block as the rate was increased to 125/min. Sinus nodal recovery time was normal after abrupt discontinuation of atrial pacing. On November 15, a General Electric implantable ventricular inhibited standby pulse generator (model A2072D) with a bipolar endocardial electrode was inserted with use of 1 percent Xylocaine® and Valium®-induced anesthesia. Good ventricular capture was obtained at 0.5 milliamperes. During pacemaker testing, there was a transient reduction in blood pressure from 200/80 to 160–180/60 mm Hg. The patient was returned to the recovery room in satisfactory condition.

Postoperatively the patient's blood pressure during normal sinus rhythm was 180–190/80–90 mm Hg. On several occasions during the night, her inherent sinus rhythm fell below the pacemaker rate of 70/min and during effective artificial pacing the blood pressure level fell to 70–80/40–50

TABLE I

Cardiac Catheterization Data

	Normal Sinus Rhythm	Right Ventricular Pacing
Heart rate (beats/min)	72	70
Pressures (mm Hg)		
Right atrium	9/5 (6.5)	...
Right ventricle	29/0–3	...
Pulmonary artery	27/10 (15)	...

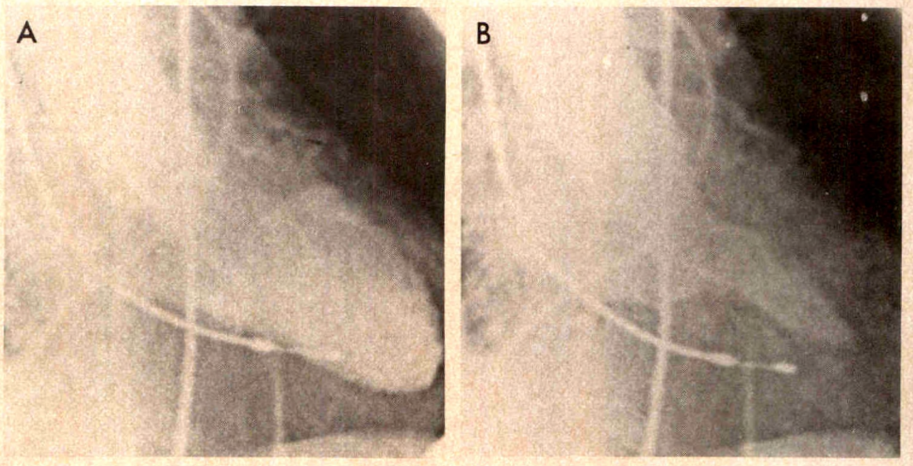

FIGURE 2. Left ventricular cineangiography during right ventricular endocardial pacing. **A,** demonstrating left ventricular end-diastolic volume. **B,** demonstrating left ventricular end-systolic volume and opacification of the left atrium consistent with significant mitral regurgitation.

mm Hg. During this time physical examination revealed mental obtundation and a small pulse pressure; the heart sounds became distant and the previously described aortic systolic ejection murmur disappeared. Mitral insufficiency could not be definitely heard at the bedside. The patient was treated with intravenously administered atropine and, with a return to normal sinus rhythm, the blood pressure quickly increased to 190/90 mm Hg and the mental condition cleared. On November 16, percutaneous right and retrograde left heart catheterization was performed (Table I).

Comment: Acute cardiovascular deterioration occurred repeatedly whenever the patient's inherent sinus rhythm fell below the preset right ventricular artificial pacemaker rate of 70/min, either spontaneously or by induction through carotid massage. Hemodynamic studies with left ventricular cineangiography were performed to determine whether this sequence of events resulted from a loss of atrial contribution to left ventricular filling, acute mitral regurgitation or ventricular asynchrony with impairment of left ventricular function. The results revealed a 23 percent reduction in left ventricular end-diastolic volume associated with a decrease of 5 mm Hg in left ventricular end-diastolic pressure during asynchronous right ventricular pacing compared to values during normal sinus rhythm, indicating a significant loss of atrial contribution to left ventricular filling.

No mitral regurgitation was noted during sinus rhythm, but it developed during right ventricular pacing. As a result, effective stroke volume was reduced by 30 percent to 37 cc, with an overall reduction in the cardiac index from

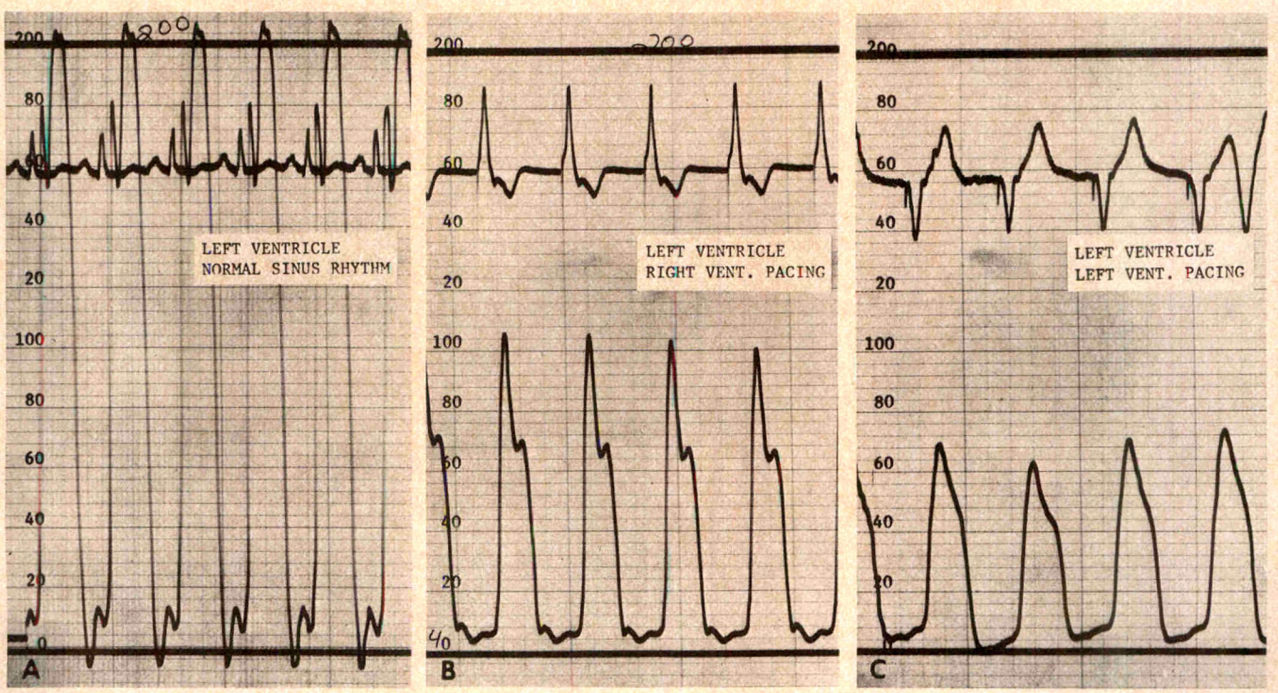

FIGURE 3. Left ventricular pressure curve. **A,** recorded during normal sinus rhythm. **B,** recorded during right ventricular endocardial pacing. **C,** recorded during pacing from the apex of the left ventricle.

3.38 to 1.75 liters/min per m^2. There was no asynchrony or dyskinesis of left ventricular contraction, and contractility and the systolic ejection fraction remained unchanged during right ventricular pacing from cineangiographic data obtained during normal sinus rhythm (Fig. 1 and 2). Pacing from the left ventricle showed the same deterioration in left ventricular and systemic pressures that occurred with right ventricular pacing (Fig. 3) and although left ventricular cineangiography was not performed, one must assume that the same phenomena with loss of atrial contribution to left ventricular filling and mitral regurgitation occurred.

The transvenous right ventricular endocardial pacemaker was removed. The patient refused thoracotomy and implantation of a synchronous atrioventricular pacemaker.

Discussion

Ventricular asynchrony, loss of atrial contribution to ventricular filling, and the deleterious effects of A–V valvular incompetence have all been mentioned as causes of ventricular dysfunction and reduced cardiac output with asynchronous ventricular pacing. The optimal site for ventricular pacing has also been studied in an effort to explain hemodynamic alterations with asynchronous pacing.

Role of ventricular asynchrony: There are conflicting reports concerning the role of ventricular asynchrony as a determinant of ventricular function. Several investigators[8–10] have presented evidence that cardiac performance does not vary with ventricular pacemaker site. Barold et al.[11] found no significant difference between endocardial pacing from the inflow and outflow tracts of the right ventricle. Lister et al.[12] and Finney[13] indicated that the left ventricular apex is the most favorable pacemaker site in relation to left ventricular function. Aberrant ventricular depolarization with alteration in papillary muscle function has been invoked as a probable cause of left ventricular asynchrony and A–V valvular insufficiency. In our patient, pacing from the apex of the right ventricular endocardium and from the apex of the left ventricular endocardium produced the same degree of cardiovascular deterioration and myocardial failure.

Role of loss of atrial contribution to ventricular filling: Our observations most closely resemble those of Samet et al.,[14,15] who demonstrated that the primary reason for the hemodynamic differences between atrial and ventricular pacing is the absence of synchronized atrioventricular activity during ventricular pacing. They concluded that aberrant ventricular depolarization in itself resulted in little decrease in cardiac indexes and showed that the hemodynamic sequelae of ventricular pacing were secondary to a significant loss of atrial contribution to ventricular filling. A consistent reduction in left ventricular end-diastolic pressure was thought to reflect a decrease in left ventricular volume. A similar sequence of events could be demonstrated during atrial fibrillation and during short bursts of ventricular extrasystoles. They demonstrated an increase in left atrial pressure when the P wave occurred slightly after or simultaneously with the QRS complex with ventricularization of the left atrial pressure curve suggesting regurgitation. The various degrees of A–V insufficiency caused by asynchronous pacing have been emphasized by Furman and Escher.[5] Mitchell et al.[16] noted a 19 percent reduction in ventricular stroke volume when ventricular contraction was not preceded by atrial systole. A 15 percent increment in cardiac output when atrial systole preceded ventricular activity was also noted by Sellers et al.[17] Samet et al.[14] demonstrated that cardiac output in patients with complete heart block studied during synchronous atrioventricular pacing increased 15 to 20 percent from values obtained during right ventricular catheter outflow tract pacing.

The findings in our case argue against ventricular asynchrony dyskinesis or impairment of ventricular contractility as a mechanism. They support the observations of others that a significant loss of atrial contribution to ventricular filling (approximating 23 percent) and significant mitral insufficiency (approximating 30 percent of stroke volume) is the cause of the cardiovascular deterioration.

The pacemaker syndrome resulting from asynchronous ventricular pacing has been long recognized to occur in various lesser degrees. Although we have not previously encountered a case similar to ours, we believe that the syndrome should be considered in any patient whose condition for unexplained reasons does not improve or deteriorates with ventricular pacing. Our observations favor performing synchronous atrioventricular pacing from the right atrium or coronary sinus whenever possible.

Double Opening Sound Related to Dysfunction in a Caged Disc Mitral Valve Prosthesis

EARL C. HARRISON, MD
E. JOHN ROSCHKE, PhD*
MASAYOSHI MATSUNO, MD
JOHN W. ALLEN, MD

Los Angeles and Pasadena, California

A grooved embolic fragment was removed from the femoral artery of a patient with a Kay-Shiley caged disc mitral valve prosthesis. An extra opening click that had been present before embolization disappeared coincidentally. This study demonstrates (1) the importance of establishing an expected range of normal systolic time intervals for a given prosthetic heart valve configuration, (2) the value of postoperative phonocardiograms in documenting the presence of an unexpected extra sound, and (3) the need for careful examination of embolic fragments recovered from patients with valve prostheses.

Approximately 40 different prosthetic heart valves are now commercially available in the United States.[1] Of these, approximately 10 are of the caged disc design used primarily for mitral valve replacement. Caged disc prostheses have been used clinically for about 10 years, but the normal opening and closing time intervals and the quality of valve sounds have been established for only a few of the prostheses in general use. Although each valve prosthesis may possess a distinct but typical acoustic signature arising from a particular combination of mechanical design features and materials of construction, these signatures may become modified postoperatively by alterations of blood flow and heart motion and by various pathologic conditions.

In cases of severe dysfunction the sounds of prosthetic disc valves may be significantly altered and are detected easily.[2–7] In other cases of valvular dysfunction the sounds may remain essentially normal.[8–10]

The case presented here demonstrates how meticulous clinical follow-up studies, which included serial phonocardiographic recordings, were used to detect the presence and clarify the origin of the double opening click of a caged disc mitral valve prosthesis. The significance of the double opening click, which we had not encountered previously, is discussed.

Case Report

A 39 year old housewife underwent mitral valve replacement in February 1967 for severe mitral regurgitation of rheumatic origin; there was no evidence of aortic valve disease. A size 8, series K, Kay-Shiley caged-disc mitral valve was implanted; this prosthesis model is no longer in commercial production. The patient's functional status improved from New York Heart Association class 4 to class 2 in spite of persistent atrial fibrillation. She was examined in the clinic every 4 weeks and phonocardiographic recordings were obtained periodically with a Siemens-Elema Mingograf recorder. Her medications included digoxin, 0.25 mg daily, hydrochlorothiazide, 50 mg daily, potassium supplement, and warfarin sodium to maintain prothrombin activity at less than 20 percent. In October 1970 (44 months postoperatively) a double opening click of the mitral prosthesis was first noted (Fig. 1, top). However, no murmur could be detected, and functional status had not altered. Although the double opening click was detected on subsequent visits, the patient refused further investigation.

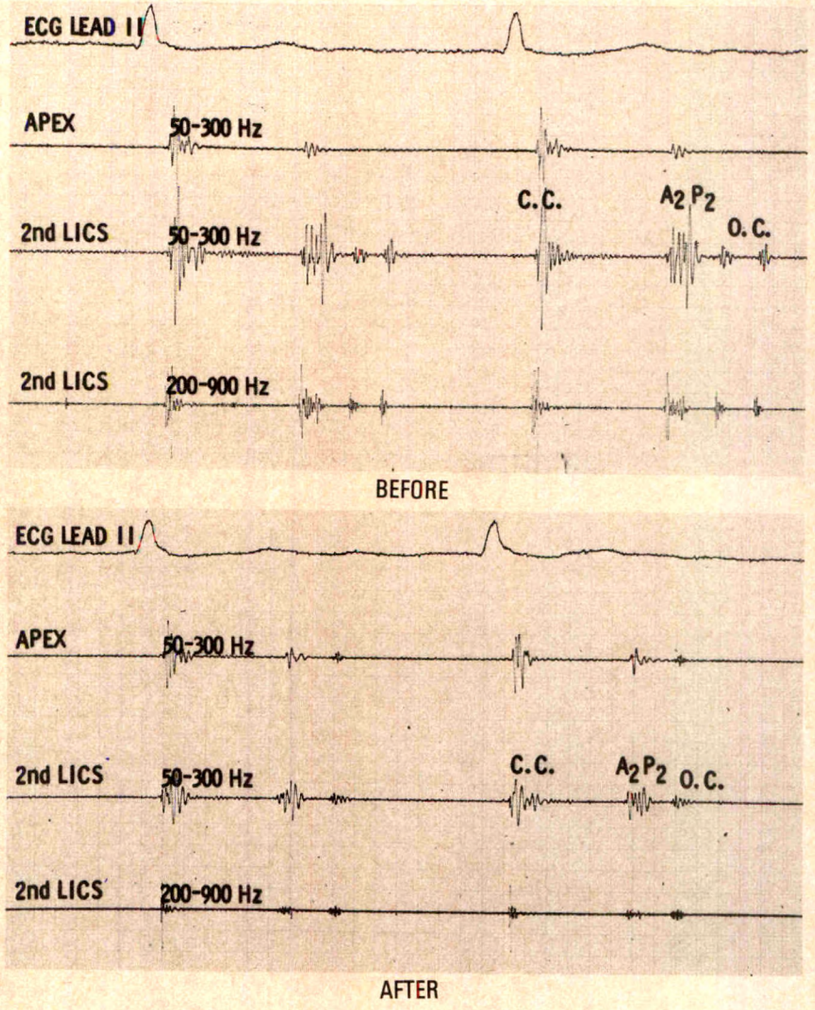

FIGURE 1. Phonocardiograms before **(top)** and after **(bottom)** embolic occlusion of the patient's left femoral artery. Note the disappearance of the second opening click of the mitral prosthesis after dislodgment of the thrombus fragment believed to have formed originally on a cage strut of the valve **(bottom).** A_2 and P_2 = closing sounds of the aortic and pulmonary valves, respectively; C.C. and O.C. = closing and opening clicks, respectively, of the mitral prosthetic Kay-Shiley disc valve. Each large time division is equivalent to 50 msec.

In August 1971 she was admitted to the hospital with a cold, pulseless left lower limb. The double opening click had disappeared (Fig. 1, bottom). An elongated embolic fragment removed from the patient's left femoral artery had an unusual groove along its entire length (Fig. 2, right). The embolic fragment was found to mate closely with the cage strut of a new prosthetic valve of the same size and model as that implanted 54 months earlier (Fig. 2, left). Additional thrombus was suspected to exist on the cage of the valve prosthesis; however, the patient refused to consider valve replacement. Subsequently she was discharged from the hospital with normal pulses in her left lower limb. She was readmitted in June 1972 in a comatose condition with flaccid right limbs and died the following day. The family refused autopsy.

Discussion

Results of previous studies on acoustic changes in prosthetic mitral disc valves[2–11] are summarized in Table I. Principal modes of dysfunction include (1) restricted motion or jamming of the disc due to obstruction by fibrinous tissue or thrombus on valve elements, (2) notching or uneven wear of the disc leading to eventual jamming, (3) disc cocking caused by uncorrected aortic regurgitation, and (4) valve detachment caused by suture disruption. Dysfunction can occur in nearly every type of caged-disc prosthesis, and it is not always accompanied by abnormal valve sounds. Auscultation is not always helpful in diagnosis because slight alterations in sounds and minimal regurgitation may not be detected, even when they exist. Undoubtedly, the durability of caged disc valves is enhanced when the disc rotates freely within the cage about an axis perpendicular to the disc surface so that wear is evenly distributed. If the disc motion is restricted by thrombus formation or other impediment,[8] uneven wear, notching of the periphery and eventual jamming may occur.

A previous phonocardiographic study[12] of 28 patients with Kay-Shiley caged disc mitral valves established a range of systolic time intervals expected for that valve series. Intervals measured were Q wave to closing click (range 31 to 100 msec, mean 67 msec, standard deviation [S.D.] ±16.8), A_2 to opening click (range 57–182 msec, mean 104 msec, S.D. ±32.4), and the duration of the opening click (range 18 to 58 msec, mean 34 msec, S.D. ±9.9). The Index of Wells, difference of Q wave to closing click minus A_2 to opening click expressed in hundredths of a second, was derived (range +1.7 to −10.3 units, mean −3.7

Acoustic Changes in Prosthetic Mitral Caged Disc Valves

Reference	Prosthesis	Prosthetic Valve Sounds	Murmurs	Comments
Carey and Hughes[8] (1968)	Kay-Shiley (obsolete model)	Normal	Absent	Autopsy showed disc edge severely grooved and motion restricted by misplaced suture
Mullen et al.[9] (1970)	Kay-Shiley (obsolete model)	Normal	Systolic	Patient reoperated upon to remove fibrin between sewing ring and disc
Stross et al.[10] (1971)	Starr-Edwards model 6500	Normal (2 cases)	Faint systolic (1 case)	Autopsies showed fibrinous material on struts prevented closure
Horsley et al.[2] (1969)	Starr-Edwards model 6500	Decreased intensity	Absent	Abnormal disc motion caused by fibrous tissue on struts
Demaney and Zimmerman[3] (1970)	Kay-Suzuki	Opening click almost absent	(Not stated); mitral regurgitation by cineangiography	Patient reoperated upon to remove massive clot obstructing orifice and causing disc to cock
Leachman and Cokkinos[4] (1969)	Cooley-Cutter (5 cases); Kay-Shiley (1 case)	Faint or absent opening click (6 cases)	Absent (4 cases); systolic (2 cases)	2 deaths, 4 reoperations; 5 cases of valve detachment
Edgett et al.[11] (1967)	Cross-Jones (2 cases); Hufnagel (2 cases)	(Not stated)	Loud systolic (in only case detailed)	Intermittent failure to close; disc cocking attributed to uncorrected aortic regurgitation in 3 cases
Low and Lefemine[5] (1967)	Kay-Suzuki	Absent	Loud systolic	Autopsy showed disc jammed in cocked position
Vasko and Leighton[6] (1968)	Hufnagel	Absent	Systolic	Reoperation for disc jammed in cocked position
Samaan[7] (1969)	Hammersmith	Absent	(Not stated)	Autopsy showed disc jammed in cocked position
This study (1973)	Kay-Shiley (obsolete model)	Double opening click	Absent	Double opening click disappeared after embolic episode; thrombus fragment recovered from patient's leg; patient later died (no autopsy)

units, S.D. ±3.3). For comparison, the data of von Klein[13] for eight patients with Kay-Shiley valves were Q wave to closing click 65 msec mean, A_2 to opening click 125 msec mean, and Index of Wells −4 to −8 units. The mean Q wave to closing click and A_2 to opening click intervals reported here for mitral caged disc valves are only slightly less than the corresponding intervals reported for mitral caged ball valves.[14]

The Q wave to closing click and the A_2 to opening click intervals were within the expected range in the patient's phonocardiographic tracings before and after embolization (Fig. 1). The additional sound occurring approximately 90 msec after the onset of the first opening click had not been observed previously. The extra opening click persisted for 10 months but disappeared after the patient's first embolic episode. The significance of this sound was not recognized until it was noted that the recovered embolic fragment mated closely with the cage strut of a new prosthetic valve of the same model and size as the patient's prosthesis (Fig. 2).

Mechanism and significance of double opening click: The Kay-Shiley series K prostheses have sili-

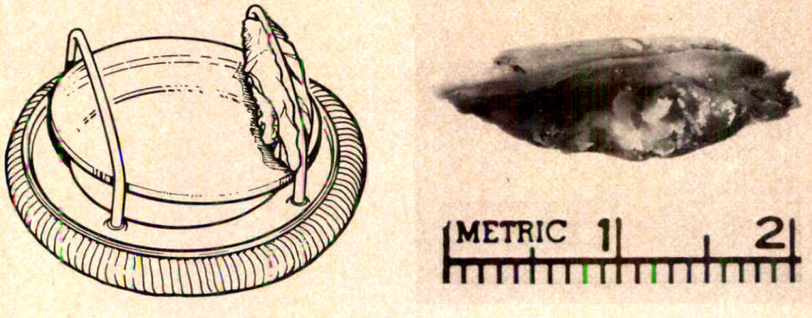

FIGURE 2. Thrombus fragment recovered from the patient's left femoral artery. At **right,** photograph of the elongated thrombus fragment; note the groove along the entire length. cone rubber discs. Other investigators[14,15] have observed double or multiple opening clicks caused by mitral caged ball valves with silicone rubber poppets. Usually, the extra opening sounds associated with the bounce or flutter of a ball poppet are of diminished intensity compared to the initial opening sound caused by impact of the ball and cage. In our case, the two opening clicks were of about the same intensity. It does not seem likely that a second disc-cage impact subsequent to disc rebound caused by elastic recoil was responsible for the second opening click, especially since the double sound was not present in the patient initially. Nor is it likely that the second click, which appeared and then disappeared after the embolic episode, was a third heart sound. Hultgren and Hubis[14] recorded a prosthetic third sound of diminished amplitude in nearly 80 percent of a series of patients with mitral caged ball valves. They suggest that the prosthetic third sound of ball valves is due to (1) relative motion between ball and cage caused by movements of the prosthetic valve and mitral annulus during atrial systole and early diastolic ventricular filling or, possibly, (2) transient reversal of the atrioventricular pressure gradient at the time of rapid ventricular filling. Double or multiple opening clicks normally do not occur in caged disc mitral valves. Because our patient had no evidence of aortic valve disease it is unlikely that the double sound noted was caused by a cocking phenomenon associated with uncorrected aortic regurgitation as suggested by Edgett et al.[11]

Autopsy was not performed, and thus the presence or extent of thrombus formation on the cage struts was not known. If thrombus was present and then partially dislodged, as the evidence suggests, the double opening click must have been associated with the impediment to disc motion (Fig. 2, left). Disc motion would have been greatly altered if: (1) Motion of the confined edge of the disc under the thrombus probably was very limited or nonexistent. (2) Uniform up-and-down motion of the disc was prevented, and its motion was similar to that of a cocked disc or pivoted leaflet, thus leading to (3) altered hemodynamics, the generation of transient and possibly highly asymmetric eddies, and the development of nonuniform forces on the surfaces of the disc.

It is reasonable to assume that the first opening click was caused by the free edge of the disc at the moment of its impact with the cage strut. The second opening click could have resulted from (1) another impact of the free edge on the cage strut, or (2) impact of the confined edge of the disc on the orifice of the valve during a retrograde motion of that edge. In the first mechanism, considered the most likely explanation, either of the two factors suggested by Hultgren and Hubis[14] and mentioned previously could have been responsible. It is also possible that a wobbling, erratic disc motion and altered hemodynamics could have led to the second mechanism. However, continued thrombus growth during the 10 month existence of the double opening click could have totally incarcerated the less mobile edge of the disc, and thus the second sound would have disappeared even without fragmentation and embolization of thrombus.

The results presented here illustrate that phonocardiography can often provide important information on dysfunction of mitral caged disc prostheses. More often than not, changes in prosthetic valve sounds are an ominous sign of impending, and perhaps catastrophic, malfunction. However, the absence of such altered sounds does not always preclude existing dysfunction.

Multiple Coronary Arteriosystemic Fistulas

KOTA REDDY, MD
MOHINDER GUPTA, MD
ROBERT I. HAMBY, MD, FACC

New Hyde Park, Jamaica and Stony Brook, New York

A 58 year old man presented with angina pectoris and no heart murmur. On selective coronary angiography, multiple coronary arteriosystemic fistulas involving all three major coronary arteries were found. This is the first such case reported. It is speculated that this vascular anomaly represents persistence of embryonic intertrabecular vessels that permit the coronary arteries to communicate with the left ventricular chamber through the Thebesian vessels.

Congenital coronary fistula is not a rare anomaly.[1] The majority of these fistulas form an arteriovenous connection between a coronary artery and the right heart chambers. In most reported cases, the abnormal fistula involves only one coronary artery. This report describes a unique case in which multiple arteriosystemic fistulas connected each of the coronary arteries with the left ventricle.

Case Report

A 58 year old man was admitted to the hospital for evaluation of recurrent chest pain of more than 10 years' duration. Retrosternal pain occurred with physical exertion and was relieved by rest and administration of nitroglycerin. For the previous 2 years, the pain had increased in frequency and duration, occurring at rest and after meals. The patient entered another hospital 3 weeks before this admission because of chest pain lasting 20 minutes. After acute myocardial infarction was ruled out, he was transferred for cardiac catheterization and selective coronary angiography. There was no history of dyspnea on exertion, paroxysmal nocturnal dyspnea, orthopnea, ankle swelling, high blood pressure or heart murmur. Past medical history and family history were negative.

Physical examination revealed a blood pressure of 130/70 mm Hg and a regular pulse of 70/min. The neck veins were flat and the lungs clear. Examination of the heart revealed no abnormal heaves or thrills. The point of maximal impulse was felt in the fifth left intercostal space and midclavicular line. A fourth heart sound was heard along the lower left sternal border. No murmurs were audible.

Multiple blood tests, which included complete blood count, lipid profile and cholesterol, urea, uric acid and serial enzyme determinations, were within normal limits. A glucose tolerance test indicated the presence of diabetes mellitus. Roentgenographic studies revealed no evidence of chamber enlargement. The electrocardiogram disclosed normal sinus rhythm and small R waves in leads V_1 to V_3 and nonspecific abnormal S–T and T waves in the left precordial leads.

Cardiac catheterization revealed a normal cardiac output and increased left ventricular end-diastolic pressure (19 mm Hg). Use of a platinum tip electrode and hydrogen inhalation studies ruled out intracardiac left to right shunts. A left ventricular angiogram demonstrated a normal end-diastolic chamber and contractile pattern. Selective coronary angiography revealed that all the coronary arteries were dilated, elongated and tortuous (Fig. 1). Calcification involved the main left coronary artery and the proximal left anterior descending and left circumflex arteries. Studies of the right coronary artery demonstrated a markedly dilated posterior descending branch. The contrast material streamed into and opacified the left ventricular chamber

These frames were taken during diastole. During systole, the contrast material in the left ventricular chamber was washed out in the aorta. Note that all the major arteries are dilated and elongated.

through a maze of fine vessels (Fig. 1A). Similarly, opacification of the left anterior descending and circumflex arteries delineated a maze or plexus of small, fine vessels surrounding these arteries, with contrast material streaming into the left ventricular chamber and completely opacifying the cavity (Fig. 1, B and C). This opacification of the left ventricle occurred only during diastole with injection of contrast material into the right or left coronary artery; during systole, the contrast material was washed out into the aorta.

Discussion

Coronary arterial fistulas usually arise from a single artery, most frequently the right coronary artery, and usually communicate with the right ventricle, right atrium or pulmonary artery.[1] A review[1] of 172 reported cases revealed only 4 in which the fistula involved both the right and left coronary arteries. In the case described here, all three major coronary arteries had fistulous connections with the left ventricle. A coronary arterial fistula emptying into the left side of the heart is uncommon; when it occurs, the fistulous connection tends to involve the left atrium rather than the left ventricle.[1]

In nine reported cases[1–6] of a coronary fistula emptying into the left ventricle, the right coronary artery was involved in three,[1–3] the left anterior descending artery in one[4] and the left circumflex artery in one.[1] The involved coronary artery was not specified[5] in one patient, and in three cases described by Abbott et al.,[6] only the presence of an aberrant vessel was indicated, with no mention of involvement of the major coronary arteries. Thus, the present case is unique in that all three major coronary arteries formed an arteriosystemic fistula.

Selective coronary angiograms demonstrated marked dilation of the right, left anterior descending and circumflex arteries. The diameter of these arteries at their origin (6, 7 and 6 mm, respectively) was almost twice that reported as normal by Baroldi and Scomazzoni.[7] Coronary fistulas may be formed by a well defined vessel emptying into a cardiac chamber or, as in our case, by a plexus of multiple fine vessels. This vascular maze probably represents persistence of embryonic sinusoids that are usually obliterated in normal development. The myocardial vessels in the

adult heart are derived embryologically from both endothelial protrusions into the myocardium and coronary arteries and veins.[8] This endothelial protrusion into the myocardium extends to the epicardial surface, forming an intertrabecular network. The outermost intertrabecular network becomes almost completely obliterated and forms a capillary network as the myocardium grows, whereas the innermost intertrabecular vessels retain their communication with the chambers of the heart, forming the Thebesians vessels of the adult heart. Investigators[4,5,9] reporting earlier cases, in which sinusoidal communication existed between involved coronary arteries and the heart chamber, ascribed the anomaly to persistence of the outermost intertrabecular space, thereby permitting a communication between the coronary artery and heart chamber through the Thebesian vessels. A similar mechanism can explain the angiographic findings and diffuse involvement in our case. The reason for abnormal communication only with the left ventricle is not clear.

In our case, no murmur was heard suggesting a coronary artery fistula. Such fistulas have been associated with continuous[1,3] or purely diastolic murmurs.[2] In the case reported by Lovitt and Lutz,[4] no heart murmur was mentioned and the fistula was discovered only on postmortem examination. The cause of death in that patient was not related to the fistula. The symptoms of angina pectoris in our case can be attributed to the coronary fistulas. The anticipated hemodynamic burden of arteriosystemic fistulas would be diastolic overload of the left ventricle. The normal pulse pressure and the absence of left ventricular hypertrophy in our case suggest that there was no hemodynamically significant volume overload on the left ventricle. The patient's symptoms should be treated medically.

Acknowledgment

We thank Dr. Irwin Hoffman for reviewing this manuscript and express gratitude for the assistance given by Mrs. Miriam Posner, Mr. Joshua Hamby and Mrs. Brenda Hamby.

Ventricular Dysfunction in Coronary Artery Disease

PETER F. COHN, MD, FACC
MICHAEL V. HERMAN, MD, FACC
RICHARD GORLIN, MD, FACC

Boston, Massachusetts

The past decade has seen increasing acceptance of both coronary arteriography and left ventriculography as integral to the evaluation of patients with suspected coronary artery disease. The former is essential for accurately mapping coronary pathologic anatomy whereas the latter serves two distinct purposes: (1) delineation of zones of abnormal ventricular wall motion, and (2) characterization of the overall performance of the ventricle by determination of changes in ventricular volume and shape throughout the cardiac cycle. Measurement of ventricular end-diastolic and end-systolic volumes allows the stroke volume to be normalized in relation to the volume at the onset of systole, that is, the ejection fraction. Thus, left ventriculography aids in the evaluation of the heart as a fluid-displacement pump. This of course is not a new concept, but one that has been overshadowed in the past by the more traditional hemodynamic view of the ventricle that is usually expressed in terms of end-diastolic tension-length and volume-work relations (Starling effect). In addition to these concepts, this discussion will also consider the applicability of measurements that characterize the heart as a force or pressure generating muscle, rather than as a volume pump.

Dynamic Morphology of the Left Ventricle

We can obtain important data about the size, shape and ejection pattern of the heart chambers from the ventriculogram. Studies of the motion of individual segments of myocardium can provide information about local disturbances in contraction (asynergy) as well as information about the residual contractile pattern of normal zones of the ventricle.

Ventricular wall motion abnormalities: Approximately 35 percent of patients referred to our department for the assessment of clinical coronary artery disease show a normal ventricular contraction pattern at rest.[1] The remaining 65 percent will demonstrate some type of resting left ventricular asynergy. Prior studies[1-5] have reported that these abnormalities are most commonly seen in patients with previous myocardial infarction, but asynergy can also occur without evidence of infarction. The patterns may range from the classic well demarcated bulging left ventricular aneurysm to various types and degrees of abnormal motion of a segment of the heart without change in overall contour. Asynergic segments may be dyskinetic, akinetic or hypokinetic (asyneretic),[1] and the area may be composed of muscle or scar, or both. A disturbed temporal sequence of contraction (asynchrony) may also be observed.

Stress-induced asynergy: One might hypothesize that a pattern of ventricular contraction which is normal at rest could be disrupted during acute ischemia, at which time segmental or global wall motion may abruptly become abnormal. This has been observed experimentally in animals.[6] In man, wall motion may be studied during a stress known to precipitate ischemia, such as tachycardia induced by rapid atrial pacing.[7,8] The demonstration of a new asynergic zone on a ventriculogram under such conditions suggests deficient perfusion of that myocardial segment. This can provide critical information about the severity or significance of a given local coronary arterial obstruction. Such stress-induced asynergy may be the mechanical equivalent of other signs of ischemia, such as alterations in the repolarization phase of the electrocardiogram, or the production of lactate by the myocardium as evidence of glycolysis.

Wall motion augmentation during inotropic stimulation: Conversely, when the resting ventriculogram is abnormal, the effect of an intervention that augments contraction might provide valuable information. Although the abnormal zone in some patients may appear isolated and surrounded by normally contracting muscle, in others poor contraction of ventricular wall may be quite extensive without clear-cut demarcation between normal tissue, viable but nonfunctioning ischemic muscle and frank avascular scar. Furthermore, overall contractile activity may be depressed below its usual level for a variety of reasons. The differentiation of those segments of muscle potentially capable of being stimulated has great clinical importance. Two inotropic interventions are under investigation: *l*-epinephrine, and the potentiated postextrasystolic beat. *L*-epi-

ıephrine was selected because it increases stroke 'olume and ejection rate without inducing major 'hanges in blood pressure or heart rate. Further- nore, it has little primary effect on the coronary vas- ulature so that coronary blood flow increases pari)assu with oxygen demand. In normal subjects given ın infusion of 1 to 3 μg/min, *l*-epinephrine uniformly ıugmented the segmental contraction pattern in all :ones of the ventricle.[9] This was associated with an ncrease in stroke volume and ejection fraction. In he subjects with coronary artery disease, all zones hat were normal in the control ventriculogram ex- ıibited an augmented contraction pattern, whereas :ones of asynergy showed either improved contrac- ion, no change or, rarely, a worsening of contrac- ion. Thus, in certain patients with coronary artery lisease, *l*-epinephrine unmasked zones of previously ıoncontracting muscle that appeared capable of shortening with inotropic stimulation. In others, this agent demonstrated zones that were apparently in- capable of any contractile response and presumably were irreversibly damaged. Similar results have re- cently been obtained by analysis of the augmented (potentiated) contraction that occurs after a ventric- ular premature beat.[10] Using a pulse generator with an impulse appropriately timed for the QRS cycle, a ventricular premature beat can be safely introduced during the course of the initial resting ventriculo- gram. The augmented beat can be compared with a control beat during the same ventriculogram.

Both of the techniques described define potential contractile reserve not only in normal segments, but also in marginal or even apparently scarred zones. These data may be of help in determining which areas to revascularize, although it is not known if muscle that responds to an inotropic stimulus will have a similar response solely if local blood supply is improved. These techniques may also be useful in in- dicating which patients will require augmentation of contractile state after cardiopulmonary bypass, and even in indicating clearly which ventricular wall seg- ments are totally refractory to inotropic stimulation and may conceivably be excised.

Ventricular volume measurements: Ventricular wall motion can be analyzed quantitatively as well as qualitatively. For quantitative analysis the ventri- cle is assumed to be ellipsoidal and both long (base to apex) and transverse diameters are drawn from angiographic silhouettes. (A catheter in the coronary sinus can be used to provide a fixed reference point.[5]) Wall motion can thus be described in terms of axial or hemiaxial shortening of the base, body and apex of the ventricle. If the film is calibrated to life size (by a grid system, for example) volumes can be measured throughout the cardiac cycle using the area-length method of Dodge et al.[11] These investi- gators noted close agreement between ventricular volume determined by biplane angiograms of post- mortem casts, and the known volume of the casts. However, in the beating heart with abnormal wall motion, the ventricle is often asymmetrical, particu- larly in its minor axes, and the relation of angio- graphic to true volumes may be less certain. In addi- tion, considerable scatter can occur between volumes calculated from biplane and single plane data in pa- tients with ventricular asynergy.[2] (Addition of the left anterior oblique view is useful in such patients since it allows analysis of two zones, septal and post- erolateral, not visualized in the conventional right anterior oblique view.) It had been hoped that echo- cardiography could be used to determine ventricular volumes in patients with coronary disease, as has been done in other cardiac diseases, but the presence of asynergy makes echo-angiographic correlations ten- uous and the value of echocardiograms in measuring volume often questionable.[12]

Relation of Morphology to Hemodynamics

Ventricular diastolic (filling) pressure: In many patients with ventricular asynergy, left ventricular end-diastolic pressure is often elevated and cardiac output reduced. This is more common in patients with global than in those with regional abnormalities of wall motion, and least common in patients with a normal contractile pattern.[1] Even in patients with normal hemodynamic status at rest, exercise or pac- ing-induced tachycardia may precipitate elevations in left ventricular end-diastolic pressure (and asyner- gy) with or without clinical angina.[13] Whether these abnormalities reflect alterations in ventricular com- pliance (due presumably to ischemia or fibrosis, or both) or are a sign of true left heart failure is un- clear. Certainly, when filling pressure is increased throughout diastole, cardiac output is more likely to be reduced and clinical failure more obvious. Such an increase in mean diastolic pressure is often associ- ated with a filling gallop (the third heart sound), ob- viously a helpful clue for the clinician.[14] When filling pressure is increased only at end-diastole, clinical congestive failure is less common. It may be that the fourth heart sound heard in many of these patients heralds the presence of a stiff rather than a failing ventricle.

Ejection fraction: The basis for abnormal ventric- ular function curves in patients with coronary artery disease also remains unclear. Even though the re- sponses to atrial pacing, exercise, pharmacologic in- terventions and angiographic contrast medium serve as useful stress tests,[15] the clinical and prognostic importance of a depressed ventricular function curve obtained under these circumstances has not been re- solved. Because of technical problems in defining pressure-volume relations in the intact ventricle (for example, distinguishing alterations in ventricular compliance from transient episodes of left heart fail- ure), it may be more useful to characterize the ven- tricle mainly in terms of fluid displacement. Fluid displacement has traditionally been thought of in terms of cardiac output, but cardiac output is a product of both heart rate and stroke volume and is influenced by the peripheral circulation as well as the autonomic nervous system. An index that ap- pears potentially more useful is the systolic ejection fraction obtained from ventriculography. (Since ven-

triculography provides a *continuous* record of ejection it has advantages over other techniques that measure only end-diastolic and end-systolic volumes.) As a function of both stroke volume and end-diastolic volume, the ejection fraction is normalized for each ventricle. Thus, a reduced ejection fraction can be due to a reduced stroke volume with a normal end-diastolic volume, or to a normal stroke volume delivered from an increased end-diastolic volume, as in dilatation. Because it is the slope of the ventricular function curve, the ejection fraction can be considered a rough index of myocardial contractility (at normal afterloads). It may be of help in defining expected risks for immediate and intermediate term survival after coronary artery bypass procedures, as well as in assessing the degree of myocardial decompensation in the face of borderline or questionable values for left ventricular end-diastolic pressure and cardiac output. This index also has value in patients with valvular heart disease since changes in the ventricular size, shape and contraction patterns of such patients may aid in the preoperative evaluation of myocardial reserve. When considering ejection fractions in either coronary or valvular heart disease, however, it is important to remember that these values can vary ±0.05 percent from one study to the next in the same patient, even when hemodynamic states are comparable.[16] Differences in interpretation of silhouettes by observers may also lead to similar disparities. Displacement can also be measured as a function of time: the normalized mean velocity of circumferential (transverse axis) fiber shortening, or VCF.[17] Although readily obtainable from continuous ejection-phase ventriculographic silhouettes, the value of either the ejection fraction or VCF in cases of gross asynergy is uncertain. In such instances, extensive aneurysmal segments may obscure the contribution of normally contracting zones, thereby yielding falsely low values for both of these variables. In these patients direct measurement of *segmental* hemiaxial shortening is a preferable method for evaluating regional myocardial performance.

Contractility indexes: Another approach in assessing ventricular dysfunction is to consider the ventricle as a force or pressure generating muscle, rather than as a pump. Contractility indexes derived from isovolumic (preejection) phase pressure recordings are based on the assumption that there is symmetrical contractile effort and uniform fiber length throughout the duration of isovolumic systole. While theoretically applicable in ventricles free of segmental disease, and with normal impulse conduction, such an assumption may not be tenable in patients with coronary artery disease, although promising results with one such index have recently been reported.[18] As noted previously, patients with coronary artery disease often lack topographic and temporal uniformity of ventricular contraction. In addition, the extent to which mechanical asynergy alters series elasticity is not known, and normal values for myocardial contractility may actually be due to a falsely low coefficient of series elasticity. Thus, it is critical to know the ventricular contraction patterns in any patient whose cardiac function is to be judged by isovolumic indexes.

TABLE I

Hemodynamic Abnormalities Correlated with the Extent of Vessel Disease in 100 Patients with Coronary Artery Disease

	Vessels Involved*		
	1 (29 Cases)	2 (33 Cases)	3 (38 Cases)
LVEDP (mean ± SEM) (% of patients with > 12 mm Hg)	16.0 ± 2.5 (41%)	15.5 ± 2.4 (53%)	17.1 ± 3.0 (53%)
Ejection fraction (mean ± SEM) (% of patients with < 0.50)	0.60 ± 0.04 (25%)	0.58 ± 0.07 (23%)	0.51 ± 0.05 (37%)
Cardiac index (mean ± SEM) (% of patients with <2.51/min per m²)	2.8 ± 0.1 (25%)	2.8 ± 0.1 (25%)	2.5 ± 0.2 (35%)
Asynergy (% of patients)	49%	68%	72%

* >75 percent stenosis.
LVEDP = left ventricular end-diastolic pressure.

Interrelations Among Morphology, Hemodynamics and Arterial Lesions

Regional ischemia is the hallmark of coronary heart disease, with metabolic and electrocardiographic abnormalities related to the areas of myocardium subserved by the obstructed vessel.[19] This is also true of abnormalities of ventricular wall motion. In general, the frequency of asynergy increases with the severity of the vascular disease, and collateral vessels do not protect against either the development of asynergy or of hemodynamic abnormalities.[20] On the other hand, akinetic regions may be associated with single vessel disease, and normal contractile patterns can persist despite multivessel disease. Similarly, hemodynamic abnormalities are not always correlated with the extent of vessel disease.[20] This is true not only in terms of mean values for left ventricular end-diastolic pressure, cardiac index and ejection fraction, but more importantly in relation to individual subjects with hemodynamic abnormalities. Thus, in a recent series of 100 consecutive patients studied in our department, mean values for these variables were not significantly different in patients with one, two or three vessel disease (Table I). Although there *was* a greater frequency of these hemodynamic abnormalities in patients with more extensive disease, these differences also did not achieve statistical significance. In the patients with a normal left ventricular end-diastolic pressure at rest, the response to angiographic contrast medium was also similar in all three subgroups. It would appear that even after stress the development of abnormal dynamic morphology and hemodynamics may bear no direct relation to the extent of vessel involvement. This is different from the positive correlation often

observed between multivessel disease and the frequency and severity of postexercise ischemic electrocardiographic changes.[21] Therefore, the clinician cannot be sure of the extent of coronary artery disease in patients with obvious ventricular dysfunction (cardiomegaly, diastolic heart sounds, for example) and, conversely, multivessel disease suggested by findings on the resting[22] or postexercise electrocardiogram[21] does not preclude normal ventricular function.

Future Directions

The preceding discussion has emphasized the importance of left ventriculography in evaluating ventricular dysfunction, in relation both to wall motion abnormalities and to the ability of the heart to displace fluid adequately. What are needed in the future are: (1) Better clarification of the underlying pathophysiology of this dysfunction. Is it due to altered compliance, transient failure, incomplete relaxation, or a combination of these abnormalities? (2) More stringent determination of the *clinical* usefulness of the various indexes of ventricular performance, including those obtained by noninvasive techniques. This is especially important for evaluating the results of medical and surgical therapy. (3) Finally, new techniques that define as accurately as possible irreversibly scarred or nonfunctioning areas of ventricular wall.

Milwaukee, Wisconsin

Clinical Heart Block. Dropped beats: When the grade of block is higher the ventricle fails to respond to occasional auricular impulses. This form is rarely simple.

Sir Thomas Lewis
The Mechanism and Graphic Registration of the Heart Beat (1925)

The use of His bundle and other intracavitary recordings[1] in recent years has led to a greater understanding of abnormal atrioventricular (A–V) conduction and has made possible exceptionally accurate diagnoses.[2] However, most clinical decisions on treatment and prognosis are made on the basis of conventional surface electrocardiograms. The question then arises whether the traditional classification of second degree A–V block into two types is clinically adequate considering the recently reported exceptions[3] to the old dictum that the lesion resides in the A–V node in type I second degree A–V block and in the His-Purkinje system in Mobitz type II block. This leads to a further question: Exactly what constitutes each type?

At the beginning of this century, John Hay[4] and Wenckebach[5]—working without an electrocardiograph—independently recognized two types of second degree A–V block. From an analysis of venous and arterial pulses, Hay inferred that one type was a disturbance of conduction and the other a disturbance of excitability. In 1924, Mobitz,[6] introducing the terms type I and type II, described his type II as "the first step to Adams-Stokes attacks and complete permanent dissociation." Thus, the prognostic significance of this distinction has been known for nearly 50 years.

Treatment and prognosis of a patient with second degree A–V block depends on many factors including the patient's history and the degree of block and its lowest site. Because a decision may have to be based on the manner in which beats are dropped, it is essential to define very strictly the type with a poor prognosis.

Definitions

Katz and Pick[7] wrote in their classic text, "In Type II, which is rare, dropping out of ventricular beats takes place without warning, that is, it occurs after a series of beats with a constant, either normal or prolonged P–R duration." Outlining the salient diagnostic features of A–V block, they noted that in second degree A–V block (as opposed to advanced A–V block), ". . . each QRS can be related to a preceding P wave but intermittently a *single* P wave is not followed by a QRST." Of type II they wrote, ". . . there is a constant duration of P–R (normal or prolonged) in all beats *except for the first one (or two) after the pause—which may show variation.*" More recently, many authors have come to refer to Mobitz type II A–V block as an arrhythmia characterized by failure of a *single* impulse to conduct to the ventricles in the absence of antecedent prolongation of the P–R interval (normal or prolonged). This definition unfortunately lends itself to more than one interpretation. Moreover, block in the His-Purkinje system does not necessarily qualify as a type II block.[8] Several points need to be clarified.

1. *Constancy of the P–R intervals before and after the dropped beat*[4,6,9–14]: Hay[4] and Mobitz[6] appreciated this point and indicated it in ladder diagrams in which the ventricular intervals containing the blocked beat are twice the basic cycle length (Fig. 1D). Consequently, shortening of the P–R interval after a blocked impulse represents either a type I sequence or an escape beat in an otherwise typical Mobitz type II pattern[14] (Fig. 1E).

2. *Lack of progressive lengthening of the P–R intervals before the dropped beat:* Long type I sequences are often atypical (Fig. 1B) and may exhibit several constant P–R intervals before the dropped beat[14–16] (Fig. 1C). In this situation, type I block simulates type II block, and, indeed, the pattern has been called type II block by several authors.[17–21]

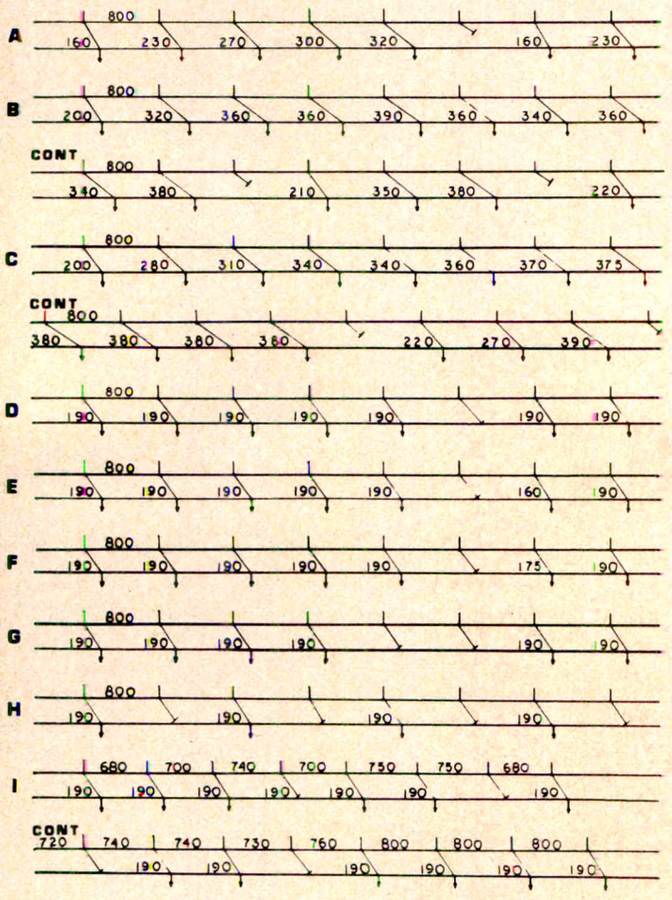

FIGURE 1. Second degree A–V block. The three levels represent activation of the atria, A–V junction (P–R intervals are shown between the lines) and ventricles, respectively. All values are in milliseconds. **A,** classic type I A–V block. **B,** relatively long and atypical type I sequence. Note the irregular fluctuations of the P–R intervals before the dropped beat. **C,** relatively long and atypical type I sequence with several constant P–R intervals before a dropped beat. Note the shorter P–R interval after the blocked P wave. This pattern has been confused with type II block. It is essential to examine *all* the P–R intervals in long rhythm strips and not merely several P–R intervals (as in the lower part of **C**) preceding a blocked impulse. **D,** true type II A–V block. Every impulse traverses the A–V node successfully, and therefore the structure is not afforded a long recovery time as in the classic Wenckebach phenomenon.[12] **E,** dropped beat without warning followed by a 30 msec shortening of the P–R interval. This may represent either type II block with an escape beat or a type I block with an unmeasurable increment in the second P–R interval. **F,** type II A–V block according to the criteria of Langendorf et al.[32] **G,** high degree A–V block: Failure of conduction of two consecutive P waves without warning. The unchanged P–R interval of the first conducted beat after the blocked impulse suggests infranodal block. **H,** fixed 2:1 A–V block. This cannot be classified, but persistence of the fixed conducting ratio associated with a normal P–R interval suggests infranodal block. **I,** sinus arrhythmia with type II block. Note the constancy of the P–R intervals despite the changing sinus cycles.[9]

Close inspection of *long* rhythm strips permits differential diagnosis. Narula[14] recently emphasized the following points: (1) Marked prolongation of the P–R interval suggests A–V nodal disease. (2) Examination of all the P–R intervals reveals distinct shortening of the P–R interval in the first conducted beat (and perhaps subsequent beats) after the blocked beat (Fig. 1C). The purist might argue that an escape beat can never be excluded in this situation, but the same unrealistic argument would also apply to the opening beat of every typical type I sequence. (3) Long type I sequences often change their conducting ratios spontaneously (for example, from 15:14 to 4:3) and then show classical type I behavior (Fig. 1C). (4) Interventions such as administration of carotid sinus pressure, atropine, amyl nitrite or performance of exercise or atrial pacing may be helpful if conducting ratios do not change spontaneously.[22,23] Clinically these measures are rarely required if sufficiently long rhythm strips are taken.

3. *2:1 and higher degrees of block:* To be certain that the P–R intervals are not progressively prolonged, it is essential to have at least two consecutive conducted P waves. It follows that a fixed 2:1 or higher degree of A–V block should not be classified as either type I or type II, regardless of the site of block or the duration of the QRS interval[24] (Fig. 1H). Yet, isolated 2:1 A–V block has recently been labeled type II.[25,26] Mobitz[6] pointed out that 2:1 or higher degrees of A–V block could originate from either a type I or type II sequence. In an individual case, the significance of such block can usually be evaluated by noting the company it keeps, particularly during the relatively frequent change in conducting ratios.

4. *Block, without warning, of two or more consecutive atrial impulses:* This type of block has been called Mobitz type II A–V block by some investigators,[13,14,27–30] and Langendorf and Pick[31] suggested calling it a "more advanced form" of Mobitz type II block. It is probably best designated simply as block of high degree. In this situation, regardless of nomenclature, a constant P–R interval before and after the blocked beats suggests an infranodal lesion (Fig. 1G). In addition, to avoid further confusion, classification of block as type I or II should be restricted to second degree block and should not be extended to complete A–V block.

5. *Sinus arrhythmia:* The influence of changes in sinus rate upon type II A–V block is rarely commented upon. Relatively small fluctuations of rate during spontaneous sinus arrhythmia do not affect the typical Mobitz type II pattern of constancy of all P–R intervals before and after the dropped beat[9] (Fig. 1I).

Langendorf et al.[32] recently stated that " . . . it is strange that the differentiation of the two types of second degree A–V block has not received more at-

tention. This is partly due to the imperfect definition of Type I." The imperfect definition of type II has also detracted from its prognostic significance as originally conceived by Mobitz. Consequently, the differentiation of type I and type II second degree A–V block should be focused on a more rigid definition of type II block. Accordingly, an arrhythmia that does not fit the rigid definition of type II block may well be type I block and thus requires further evaluation.

We may now arrive at a strict clinical definition of type II A–V block, as follows: Type II A–V block may be diagnosed from the conventional electrocardiographic tracing if the P–R intervals of all beats (provided there are at least two consecutive conducted P waves to be examined) *before* and *after* a single blocked beat are not measurably different.

The Wenckebach phenomenon is not completely synonymous with type I A–V block. Although a progressive increase in the P–R interval in successive beats is usually followed by a dropped beat, the sequence may terminate with an echo beat, reciprocating tachycardia or other arrhythmia. The P–R intervals may be variable and apparently haphazard when there is marked sinus arrhythmia, fluctuating vagal tone or a long series of conducted beats before the dropped beat. We can now quite simply define type I A–V block as follows: It is the intermittent failure of A–V conduction of a single beat (known not to be of type II) associated with inconstant A–V conduction times. There will, of course, be cases in which the distinction cannot be made confidently; these cases should not be classified until more evidence is available. Usually such evidence can be provided by sufficiently long electrocardiographic tracings or by fairly simple interventions such as administration of carotid sinus pressure, amyl nitrite, or other agents. In rare cases, complicated procedures such as atrial pacing and intracavitary recordings may be necessary.

Clinical Significance

Type I block generally occurs in the A–V node and type II in the common bundle or its branches. There are rare exceptions. The occurrence of the Wenckebach phenomenon in the His-Purkinje system has now been established beyond question in experimental animals,[33,34] man (surface electrocardiogram[35–38] and His bundle recordings[8,12,14,39–46]) and microelectrode studies of isolated fibers.[47–49]

His bundle studies have demonstrated a strong correlation of type II A–V block (according to the proposed definition) with His-Purkinje (infranodal) lesions.[12,14,39,40,50–59] The type II pattern has not yet been established as arising from the A–V node in experimental animals[18–21] or man[17] despite recent claims,[17–21] for in the cases cited atypical type I sequences are likely because the P–R (or A–H) interval shortens after the dropped beat. Langendorf et al.[32] recently reported an example of type II block occurring above the site of recording of the His potential, but His electrograms cannot distinguish a lesion in the lowest part of the A–V node from one in the proximal His bundle. The diagnosis of type II A–V block from the conventional electrocardiogram therefore has considerable clinical usefulness because the data closely reflect the anatomic site of disease.

Recent studies have further blurred the distinction between type I and type II block. In over 200 microelectrode experiments on conduction in the peripheral His-Purkinje system, Anderson et al.[48] found true type II block in only 2 studies. However, they recorded numerous examples of *apparent* type II block in which a type I pattern with very small increments of conduction (less than 10 msec) could be demonstrated when the data were displayed at very rapid speeds. El-Sherif et al.[34] came to similar conclusions on experimentally induced second degree A–V block. They pointed out that a recording speed of 200 mm/sec could not detect increments of a few milliseconds in the H–V interval; however, at this speed they were able to demonstrate increments of 5 to 15 msec invisible on the conventional electrocardiogram.

Decremental conduction thus appears to be the common denominator of depressed conduction. In the A–V node the increments of conduction are usually large and recognizable on a conventional electrocardiogram. In the His-Purkinje system, the increments are often very small and may be detectable only with special recording techniques. Consequently, the observation of type I A–V block with consistently small increments in conduction time should suggest the possibility of infranodal block. In this situation His bundle recordings are particularly helpful. Clinically, however, block in the His-Purkinje system usually appears as an all-or-none phenomenon on the conventional electrocardiogram[14,60] and rarely exhibits visible type I sequences. Some authorities have allowed slight shortening of the first (and second[8]) P–R interval, [7,24,61,62]—duration of no more than 20 msec according to Langendorf et al.[32]—in diagnosing type II block. If the phrase "type II block" is replaced by "infranodal block," the statement becomes more appropriate and less ambiguous.

Concealed His bundle extrasystoles may mimic type II block. Rosen et al.[63] used His bundle recordings to document the existence of pseudo A–V blocks secondary to premature nonpropagated (concealed) His bundle depolarization.[64] Damato et al.[65] subsequently demonstrated in elegant dog experiments that concealed His bundle extrasystoles could produce an electrocardiographic pattern indistinguishable from typical Mobitz type II block. More recently, Narula,[14] who studied six such cases with His bundle recordings, emphasized that concealed His bundle extrasystoles have essentially the same significance as Mobitz type II block because they are almost invariably associated with severe disease of the His bundle. His contention is supported by similar findings in the six cases of Grolleau et al.[66]

Clinical implication: When considered in perspective, these rare but interesting exceptions lend further credence to the value of the ordinary electrocardiogram as a reasonably accurate way of evaluating A–V block at the bedside. The overwhelming ma-

jority of type I blocks occur in the A–V node, and true Mobitz type II blocks represent infranodal lesions. In this context, His bundle recordings play a relatively small part. Despite the challenges of new methods of investigation, the old concept of two types of A–V block has emerged unscathed although the need for stricter definitions and provocative discussion is clear and pressing.

Current Status of Circulatory Assist Devices

LAWRENCE S. COHEN, MD

New Haven, Connecticut

Although it has been over a decade since Clauss and collaborators[1] described a counterpulsation pump for patients with cardiogenic shock, there is still no uniform agreement that this form of therapy has a role in the management of these critically ill patients. Theoretical considerations lead to a conclusion that counterpulsation should be able to affect favorably the balance between myocardial oxygen supply and demand. Ventricular afterload and wall tension are decreased by the sudden reduction in aortic systolic pressure during pump diastole, thus leading to a reduction in oxygen demand by the myocardium.[2] Coronary blood flow and oxygen delivery to the myocardium increase as the level of central aortic diastolic blood pressure is raised during pump systole.

Since the introduction of a counterpulsation pump, many devices have been developed to support the failing myocardium. These have ranged from pump oxygenators such as those utilized during open heart surgery to totally noninvasive external pressure suits that compress the limbs. Several questions may be asked: (1) What have we learned about the syndrome of cardiogenic shock in recent years? (2) What is the role of cardiac assist devices in the management of cardiogenic shock? (3) Do cardiac assist devices have applications other than in patients with cardiogenic shock?

Syndrome of Cardiogenic Shock

Use of the Swan-Ganz catheter has allowed a more precise characterization of patients with true cardiogenic shock as opposed to those with myocardial infarction and hypovolemia. In both conditions systemic arterial pressure and cardiac output are decreased and calculated peripheral vascular resistance is almost always increased. In hypovolemic shock, however, central venous pressure is nearly always reduced and pulmonary arterial wedge pressure is usually less than 10 mm Hg. In cardiogenic shock the central venous pressure is either normal or increased, and the pulmonary arterial wedge pressure usually exceeds 18 mm Hg.

Although patients with cardiogenic shock have a poor prognosis, the precise mortality rate varies from series to series. It is likely that at least part of the reason for this variability is the grouping of patients with hypovolemia and hypotension together with those who have true cardiogenic shock. Knowledge of filling pressures on the left side of the heart has helped to identify and separate these two subsets of patients. Replacement of the osmotic or colloid volume, thereby raising left-sided filling pressures, is often sufficient to increase arterial pressure and cardiac output in the patient with hypovolemia. Volume replacement in the patient with true cardiogenic shock is to no avail. For a diagnosis of true cardiogenic shock, the systolic arterial pressure should be less than 80 mm Hg or at least 80 mm Hg less than the patient's normal blood pressure; the cardiac index should be less than 2.1 liters/min per m^2 and urinary output less than 20 ml/hour; perfusion to the brain and periphery should be diminished so as to cause mental obtundation, cold clammy skin, ashen color and pre-terminal appearance. The mortality rate in true cardiogenic shock so defined is almost 100 percent. To the degree that patients with hypovolemia are included in reports of patients with cardiogenic shock, the mortality statistics diverge from 100 percent.

The pathologic changes in the heart of patients who die with cardiogenic shock were described by Page et al.[3] Their study demonstrated that cardiogenic shock is related to the extent of myocardial damage and that, during prolonged severe shock, continuing focal myocardial necrosis occurs. Nineteen of 20 patients with acute myocardial infarction and cardiogenic shock had lost 40 to 70 percent of left ventricular myocardium. In contrast, 12 of 14 patients with myocardial infarction but without evidence of shock had lost 30 percent or less of left ventricular muscle.

The study further demonstrated a border zone between clearly infarcted muscle and normal muscle. This zone was characterized by cells in various stages of damage and necrosis, thus indicating that cellular injury is likely to be progressive during the period of shock. These findings can be reproduced in the experimental production of acute infarction in animals, as shown by Cox et al.[4] After ligation of a coronary artery, three distinct zones can be identified by histochemical staining techniques. A central area shows disruption of the normal myocardial architecture and complete absence of all demonstrable

From the Yale University School of Medicine, New Haven, Conn.

enzymatic activity. This area is surrounded by a second, intermediate zone that shows evidence of mitochondrial swelling but, in general, preservation of normal myocardial architecture. A third zone is normal. Cox et al. demonstrated that the intensity of the changes and the size of the zones increase over time and that the combined area of necrosis and injury reaches maximal size 18 hours after infarction. Between 18 hours and 1 week after infarction, the total size of affected muscle remains stable but the necrotic zone enlarges at the expense of ischemic tissue. One week after infarction only a narrow ring separates necrotic tissue from normal myocardium. It is possibly in the boundary zone that techniques to salvage myocardium may have their most important implications for the prevention and therapy of cardiogenic shock.

Role of Cardiac Assist Devices in Therapy of Cardiogenic Shock

The introduction of intraaortic balloon pumping added a new dimension to the therapy of patients with cardiogenic shock secondary to acute myocardial infarction.[5] Over the past decade this technique has been utilized by several investigators, and their results can now be placed in clinical perspective.[6-8] The early hope that this form of cardiac assistance would markedly alter the prognosis of the patient with cardiogenic shock has not been realized. Although some patients are undoubtedly alive because of this device, the mortality rate associated with this syndrome still exceeds 75 percent. Recognition that intraaortic balloon pumping alone was not sufficient to assure salvage of a larger number of patients led to efforts to offer appropriate candidates aortocoronary saphenous vein bypass grafts with the hope of salvaging sufficient myocardium to help the patient survive the acute myocardial infarction.[9] Again, although a small number of patients have been saved by this procedure, the overall mortality rate is still 75 percent. This approach should be considered in appropriate patients, however, since it is likely that the mortality rate would be close to 100 percent without it.

Other Applications of Cardiac Assist Devices

Pathologic study of myocardial tissue after an acute myocardial infarction suggests that there is a demonstrable gradation of damage.[4] An identifiable zone of ischemic injury surrounds the necrotic area of myocardium. Over the course of approximately a day the area of necrosis enlarges as ischemic muscle undergoes irreversible changes due to anoxia. The area of ischemic tissue has been referred to as the boundary zone. There is recent experimental evidence that myocardium from the ischemic zone may be salvaged after a myocardial infarction.[10] Interventions that cause an increase in myocardial oxygen consumption, such as administration of isoproterenol and digitalis, led to an enlarged zone of ischemic change on the epicardial electrocardiogram. Conversely, increase of arterial pressure, even though it augmented myocardial oxygen consumption, decreased the extent of ischemic injury. It was concluded from these observations that in the presence of coronary occlusion the changes in coronary perfusion pressure exert a greater and more deleterious influence on the extent of myocardial ischemia than do the changes in myocardial oxygen consumption resulting from increased arterial pressure.

Successful counterpulsation usually results in a reduction of aortic systolic pressure, ventricular afterload and myocardial oxygen requirements. Counterpulsation also leads to an augmentation of aortic diastolic pressure and coronary perfusion pressure. These effects were demonstrated in a series of experimental animals subjected to coronary arterial occlusion and studied by epicardial electrocardiogram.[11] The use of propranolol to decrease myocardial oxygen requirements during intraaortic balloon pumping was also studied.[12] This combination greatly reduced myocardial oxygen consumption. Whether pharmacologic interventions, counterpulsation or combined techniques will ultimately prove salutary to the patient with myocardial infarction and cardiogenic shock is still not certain but the idea of salvaging ischemic myocardium deserves considerably more investigation. The possibility that counterpulsation may one day be utilized to salvage ischemic myocardium not only in patients with myocardial infarction and cardiogenic shock, but also in patients with uncomplicated myocardial infarction is intriguing. Toward this end there has been increasing interest in the development of a noninvasive technique of counterpulsation that might have application to a larger number of patients.

In 1963 several investigators reported on a method of external counterpulsation that did not involve cannulation of blood vessels.[13-15] The external method of counterpulsation can be applied rapidly and requires no operative manipulation. There is no extracorporeal handling of blood, thus obviating the need for anticoagulant agents. This method applies pulsed pressures to the lower limbs during diastole, thereby returning blood to the central circulation and augmenting aortic pressure. Synchronous with the R wave of the electrocardiogram, the cuffs are deflated so that the left ventricle does not eject against increased peripheral resistance. In 1968 work began on an external counterpulsation device that applies pressure initially at the ankle and then in a sequenced manner to the thigh.[16] The rationale for sequenced pulsation in contrast to nonsequenced external pulsation is based on theoretical considerations on the effect of externally applied pressure to various-sized vessels in the limb. Large vessels with a small ratio of wall thickness to lumen size collapse more readily in response to externally applied pressure than do smaller vessels with a large ratio of wall thickness to lumen size. A uniformly applied external pressure to a limb would be anticipated to collapse the larger, proximal vessels first, thereby impeding return of blood to the central aorta. In man it is not known whether one method of external coun-

terpulsation will have an advantage over the other. Sequenced external counterpulsation was compared with intraaortic balloon pumping in a series of animal studies before and after induction of cardiogenic shock.[17] Although the degree of diastolic augmentation was equivalent with both modes of cardiac assistance, the increase in cardiac output was greater in the studies using external counterpulsation. This finding may reflect the augmentation in venous as well as arterial blood during external assistance.

A report[18] of alleviation of angina pectoris after treatment with external counterpulsation warrants special notice since the number of potential candidates for this form of therapy is legion. Twelve patients with severe angina pectoris were pain-free after 4 days of treatment with counterpulsation for 1 hour a day. In addition, improvement in the angiographic appearance of the coronary arteries was noted in approximately half of the patients studied 4 to 8 weeks after counterpulsation.

If this aspect of external cardiac assist proves to be of value as a mode of therapy for patients with angina pectoris, an enormous number of patients may benefit. This event would also signal an unanticipated evolution in the development of cardiac assist devices. Originally intended solely for the most critically ill patient with cardiogenic shock, early use of cardiac assistance to salvage ischemic myocardium has become a distinct possibility. Its use in the patient with angina pectoris extends its application far beyond that originally conceived. It may be that the largest group of patients who might benefit from cardiac assistance were not considered as candidates until recently.

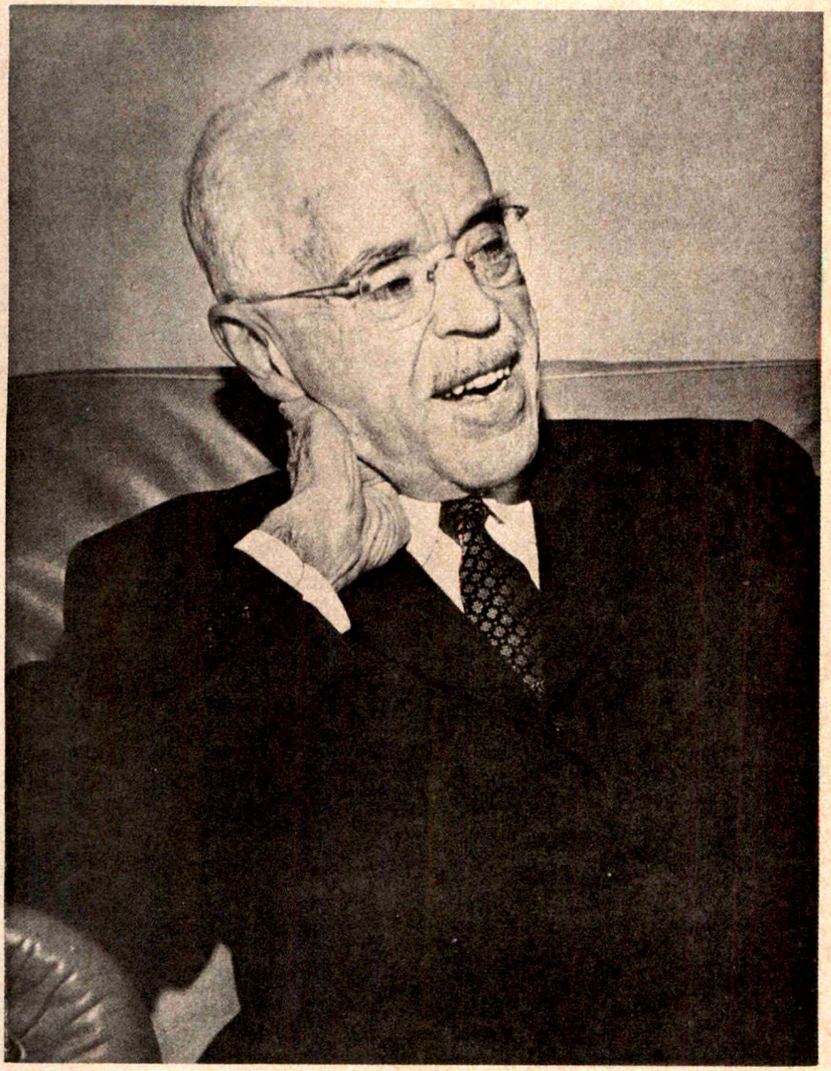
Paul Dudley White 1886–1973



J. M. Gauthier

Paul Dudley White

The Full Life

Paul Dudley White is dead and in the fullness of my thoughts I cannot say a single remark of sadness or grief. Dr. White's life was an exuberant one and he lived a wonderful span of 87 years and 5 months. His ability to perform, to think, to stimulate, to savor, to be agile and active continued to the very end. He began as the neophyte in American cardiology and became its father and grandfather. His sense of joy, his gaiety, his energy, his curiosity carried him and his message of *optimism* throughout the world.

Paul White's passing marks the end of the era in which American cardiologists had their origin in England and Europe. The remarkable galaxy who returned from their experience with Thomas Lewis included Paul White, Sam Levine, Frank Wilson, Louis Katz, Roy Scott, Robert Stroud, William Kerr, Arthur Master and other memorable workers. That era ends and another generation picks up the torch.

All of us now on the scene are, in a real sense, students of Paul Dudley White. Between his house staff years beginning in 1914 at Massachusetts General Hospital and his death there on October 31, 1973, he was the Dean of the world of cardiology. The man goes, the legend remains.

ECHOCARDIOGRAM IN *d*-TRANSPOSITION OF GREAT VESSELS

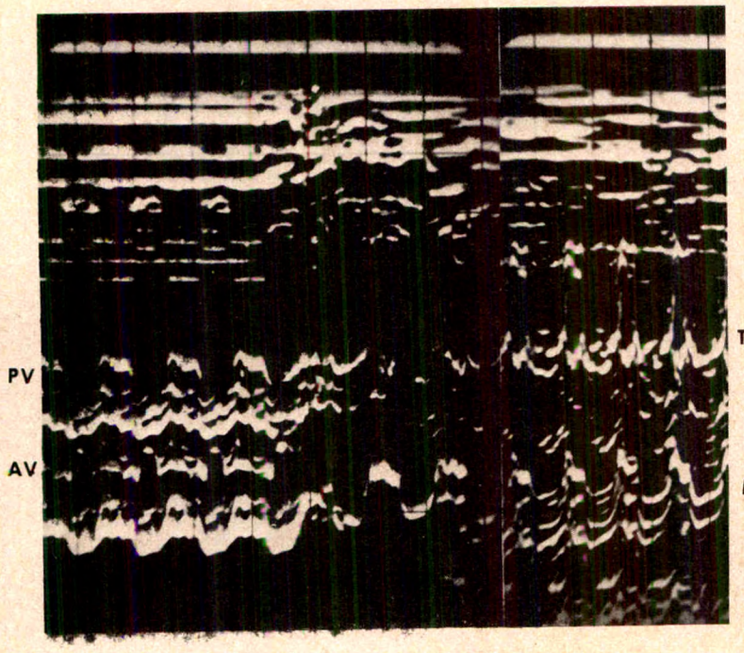

FIGURE 1. Case 1, a normal 30 hour old premature infant. The echocardiogram demonstrates simultaneous recording of the aortic valve (AV)—the posterior semilunar valve in this normal infant—and the pulmonic valve (PV). MV = mitral valve; TV = tricuspid valve.

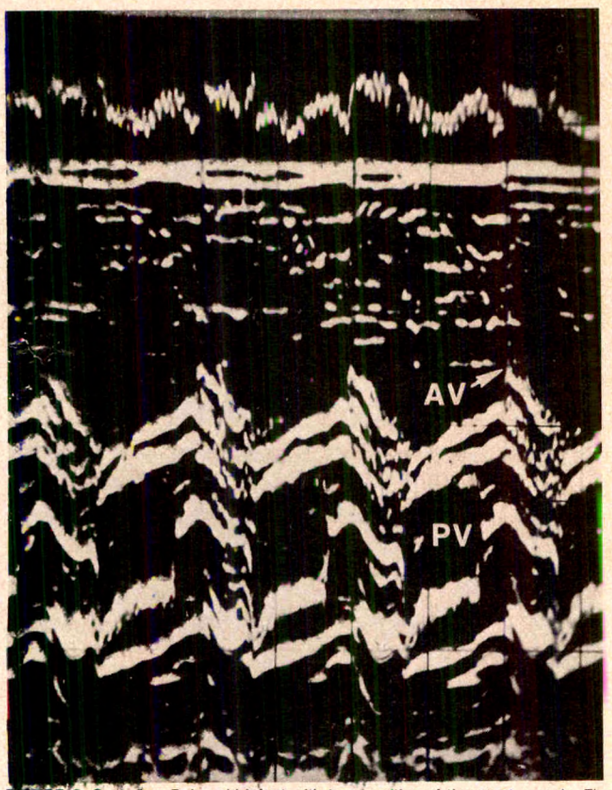

FIGURE 2. Case 2, a 7 day old infant with transposition of the great vessels. The echocardiogram demonstrates simultaneous recording of both semilunar valves: the posterior, pulmonic valve (PV) and the anterior aortic valve (AV).

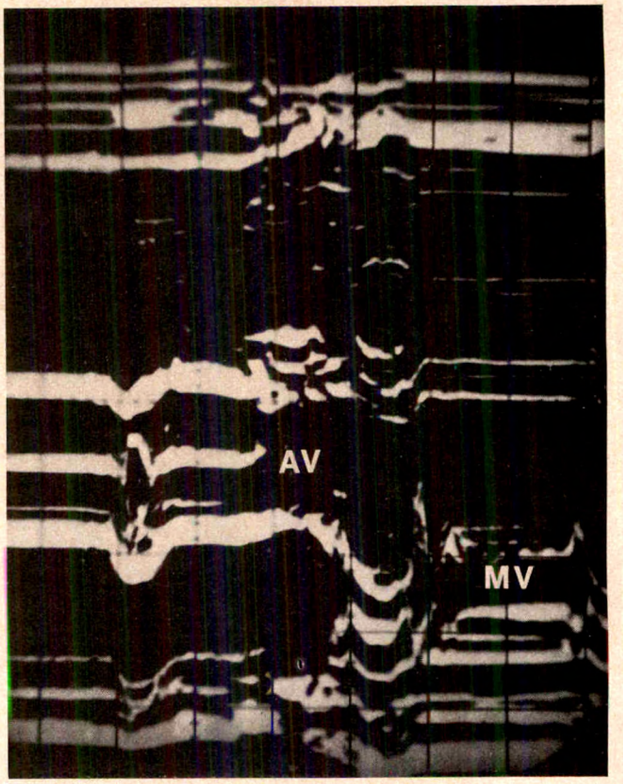

FIGURE 3. Case 1. The echocardiogram demonstrates normal aortic-mitral valve (MV) continuity.

Dillon et al.[1] in their recent article on *d*-transposition of the great vessels state that "the echocardiographic finding of superimposition of the great vessels without intervening crista together with simultaneous recording of the semilunar valves is diagnostic for transposition of the great vessels." They stress the importance of simultaneous semilunar valve echoes in the diagnosis of transposition.

In a group of 6 patients with *d*-transposition of the great arteries proved by cardiac catheterization, we had similar findings. The patients' ages were 16 hours, 4 days, 6 days, 7 days, 20 months and 8 years, respectively. In all six, we demonstrated superimposition of the great arteries as well as simultaneous recordings of the semilunar valves.

Although these findings are almost invariably seen in transposition we have also observed them in a 30 hour old twin premature baby with an autopsy-proved normal heart obtained shortly before he died of streptococcal sepsis. In an echocardiographic examination (Fig. 1) we were able to demonstrate simultaneous semilunar valve echoes similar to those occurring in transposition (Fig. 2). Since the infant had a normal heart, the posterior semilunar valve is the aortic valve, and the anterior valve is the pulmonic valve; in transposition (Fig. 2), the posterior valve is the pulmonic valve, and the anterior is the aortic valve. We were also able to demonstrate normal aortic-mitral continuity in this infant (Fig. 3).

This is the first and only case in which we were able to record simultaneously the two semilunar valves in a normal infant. The phenomenon could have been due to rotation and malformation of the heart after repeated external cardiac massage.

DR. DILLON REPLIES

I agree with Glaser et al. that positional or rotatory changes within the chest may lead to abnormal echocardiographic findings and we alluded to this in our recent paper. In review of their three illustrations, I have the following comments: In Figure 1 I am not convinced that the top echo labeled PV is in fact the pulmonic valve. I think this is the chordo-reminense of the tricuspid valve. We see this often in adults, and certainly the view to the right preceding the white line indicates that this top structure is not the pulmonic valve but probably part of the posterior leaflet of the tricuspid valve or part of the supporting chordae of that valve. In addition, I see no anterior wall structure that I would interpret as an artery. Above what is labeled pulmonic valve there is a 2 1/2 to 3 1/2 cm area in which there is no anterior "vessel" wall. I think this would be present in a truly double-barreled situation. In Figure 2 I am less convinced than the authors on the basis of one Polaroid snapshot that this is a case of transposition. I agree with the authors' interpretation of Figure 3.

I am in no way trying to be critical of the work of Drs. Glaser, Whitman and Liebman, and I want them to be encouraged to try to prove or disprove our recent thesis. But I honestly believe that Figure 1 cannot be given the interpretation they have provided.

BOOK REVIEWS

MYOCARDIAL INFARCTION, by Eliot Corday, MD and H. J. C. Swan, MD. Baltimore, Williams & Wilkins, 1973, 398 pages, $26.50

A plethora of changing concepts, new techniques and old theories concerning myocardial infarction have stimulated two authorities to expand the knowledge on this major clinical problem. Their book logically proceeds with the pathophysiologic findings, diagnosis, arrhythmias, prognosis and early care of the patient with coronary disease. Chapters on cardiogenic shock, therapeutics and surgery are comprehensive and cautiously optimistic. The primary authors have harnessed the talents of many experts in their respective specialties.

The practicing physician with an intellectual curiosity in basic physiology will find the section on pathophysiology beautifully written and a necessary prelude to understanding the remaining text. The chapters on diagnosis commence with an analysis of noninvasive techniques and summarize present knowledge on altered enzymes. Flotation catheters receive more critical discussion by a pioneer in their development, Dr. Swan. In another excellent chapter, radioisotopic dynamic imaging is well illustrated as a reliable noninvasive technique capable of detecting many of the complications of myocardial infarction such as mitral insufficiency, aneurysm or pericardial effusion.

Brief chapters on contractile performance, echocardiography in determining left ventricular dimension and mass as well as the clinical application of left ventricular pressures are pertinent, practical and devoid of minutiae. The section on diagnosis is terminated by several chapters on cardiac arrhythmias. Reciprocal rhythm as a form of reentry is succinctly covered and well illustrated. A weaker chapter on aberrant conduction versus ventricular tachycardia includes no graphic material. To the electrocardiographer, this chapter is superfluous and to the student, abstruse. A more comprehensive chapter on cardioversion is followed by a brief one on cardiac pacing. This latter section is somewhat superficial; little mention is made of fascicular blocks and their management.

A major section on cardiogenic shock attacks this problem from multiple aspects. Unfortunately, there is some duplication in the discussion of positive inotropic agents as well as circulatory assistance using ascending aortic synchronized pulsation, but the overall analysis is complete and current.

The final section on therapeutics heralds the latest views on the growing armamentarium of medical and surgical treatments and includes a discussion of the psychological management of the patient with coronary disease. Perhaps it may be a surprise to some and gratifying to all that use of oxygen and morphine is experimentally efficacious and clinically sound. Nitroglycerin and phentolamine are given separate chapters, whereas digitalis ignominiously occupies a brief paragraph in a section on intractable heart failure. At least a chapter on digitalis toxicity in myocardial infarction might have been appropriate. The discussion of surgical management in myocardial infarction covers the gamut of acute infarctectomy, aneurysmectomy and revascularization. The final chapter attempts to identify the patient whose cardiogenic shock is a manifestation of profound ischemia, resulting from severe proximal arterial occlusion, the focal point for emergency revascularization.

This book represents a well written, well illustrated and timely analysis of the literature on myocardial infarction blended with personal observations by keen, clinical cardiologists. It is primarily directed to the internist and clinical cardiologist. Its comprehensiveness should mark it as a standard reference in the field today.

Wilmington, Delaware

RECENT ADVANCES IN CARDIOLOGY, edited by John Hamer. Baltimore, Williams & Wilkins, 1973, 424 pages, $21.75

Though it resembles a yearbook or annual review, this volume is both more ambitious in depth and broader in its scope than the usual book of this genre. The 16 chapters, written by 12 contributors each of whom is, or has been, associated with the "British school" of cardiology, make up a well written survey of selected topics ranging from "Pediatric Cardiology" and "Surgery of Ischaemic Heart Disease" to chapters on "Myocardial Metabolism."

Most chapters represent a useful survey of recent, or historical, developments. Each is provided with a long bibliography; however, the references lack titles, which somewhat diminishes their usefulness. The writing is lucid, the text unmarred by the unpleasant staccato rhythm characterizing the yearbook chapter that is sometimes merely a pastiche made from the summaries of other articles. It is gratifying to this reviewer to find that at least 4 of the 16 chapters deal with the application of basic biochemical, biophysical and pharmacologic principles to clinical cardiology. One hopes that this emphasis will, if continued, permit the British to maintain their great heritage, exemplified by Sir James MacKenzie, Sir Thomas Lewis, Paul Wood and others, of utilizing newly emerging scientific knowledge to improve the care of the patient with cardiac disease.

Because this book is not intended to be a comprehensive review of cardiologic topics, it cannot be compared to heavier and more detailed textbooks. Neither is it a monograph of limited scope, and thus it cannot replace the many volumes devoted to one or another of the specialized areas in cardiology. With few exceptions, notably a thorough and most informative chapter on the "Pharmacology of Beta-Adrenoceptive Antagonists," each chapter represents a survey, so that the reader who wishes to obtain a detailed picture of the topic must utilize the bibliography. Yet as a "practical guide for postgraduate students and physicians" this book is successful and so can be recommended to the internist who wishes to review the background of modern cardiologic practice.

Arnold M. Katz, MD, FACC
New York, New York

AN INTRODUCTION TO RESPIRATORY PHYSIOLOGY, by Frederick F. Kao. Excerpta Medica, Amsterdam, American Elsevier, New York, 1972, 325 pages, $20.00

The omnipotence of Bates et al. and Comroe et al. in the area of pulmonary physiology may cause a new author to hesitate before entering the field. Dr. Kao need not have

paused; he has written a gem. Although his book is an outgrowth of a lecture course in respiratory physiology given to medical students over the course of a decade, it is by no means of value only to the medical student; it can compete with the well established texts for the attention of physicians and physiologists with a specific interest in the lungs.

The twelve chapters range from a simple introduction and a chapter on principles, in which Dr. Kao displays a mastery of physics, to the truly sublime—"Respiration in Deep Sea, at High Altitudes, and in Outer Space." Each chapter builds logically upon its predecessor. Introductory paragraphs and clear diagrams present an overall concept to be elucidated in the ensuing pages. "Working questions" follow, which help the reader gauge his grasp of the preceding material (answers are provided at the end of the book). Finally, each chapter contains an exhaustive list of reference and reading material. The chapter on "Regulation of Ventilation" contains ten pages of references, and Dr. Kao's brilliant review of this complicated subject is reason enough to own this book.

Although Dr. Kao almost fanatically avoids the clinical (imagine a book about pulmonary physiology without one mention of bronchitis or emphysema!), his book will serve as a constant source of reference to clinicians. Each new issue of our journals adds to the rapidly changing knowledge about pulmonary function in disease. We must turn to texts for our knowledge of fundamentals, and in this volume these foundations have been superbly presented.

Alvin S. Teirstein, MD
New York, New York

ECHOCARDIOGRAPHY, by Harvey Feigenbaum, MD, assisted by Sonia Chang, BS. Philadelphia, Lea & Febiger, 1972, 239 pages, $11.00

The recent surge of interest in clinical echocardiography has been hampered by the absence of any single source of information in this field. This volume amply fills that void.

After a short historical overview, a simplified description of the underlying physical principles of echocardiography and the equipment available is presented. There is a well illustrated chapter on the techniques and pitfalls in obtaining good echocardiograms. Technique pertinent to examining individual structures is reemphasized in subsequent chapters dealing with specific structures. Heavy emphasis is rightly placed on the mitral valve and on pericardial effusion which are areas of prime clinical diagnostic interest. Separate chapters are also devoted to the "state of the art" in evaluating the aortic, tricuspid and pulmonic valves, right ventricle, left atrium and atrial tumors, with a brief introduction to congenital heart disease included. Two important chapters deal with the echocardiographic contribution to the study of left ventricular function and coronary artery disease, both areas of intensive investigation.

Central to the success of this book are the illustrations and photographs, both of excellent quality. However, more detailed labeling of some photographs would be helpful for beginners. A very useful feature is the large number of photographs in general and of difficult-to-examine structures in particular, such as the posterior mitral leaflet and atrial myxoma. The listing of references within the text and the appendix containing normal values are useful additions.

This book is highly recommended for all interested in echocardiography whether they wish to learn the technique themselves or just the basic diagnostic features and potential for clinical diagnosis.

Monte Bodenheimer, MD
New York, New York

VECTORCARDIOGRAPHY, by Alberto Benchimol, MD. Baltimore, Williams & Wilkins, 1973, 223 pages, $18.50

This volume is intended to define the role of vectorcardiography in clinical cardiology and clearly sets forth the criteria for the diagnosis of specific abnormalities. Although it is primarily based on observations with the Frank system, various other lead systems are compared and many of the data can be extrapolated to them. The usual chapters devoted to fundamentals of atrial and ventricular activation, chamber hypertrophy, bundle branch block and myocardial injury are profusely and clearly illustrated. Of particular interest is the well organized chapter devoted to hemiblocks, which appears to be quite up to date and complete. The value of timed vectorcardiography or "running loops" in identification of arrhythmias and in interpretation of interventricular conduction disturbances is nicely shown. The use of simultaneously recorded His bundle electrograms provides clear documentation of the author's presentation. The bibliography following each chapter appears to have been thoughtfully selected. In its entirety, this book clearly reflects the extensive experience of the author and his familiarity with the techniques described. Although too sophisticated for a primer or introductory text, it is highly recommended to all those with an interest in electrocardiography or vectorcardiography, or both, as a worthwhile learning experience and reference book.

Melvin Kahn, MD
New York, New York

CARDIO-RESPIRATORY RESUSCITATION, by Alan Gilston and Leon Resnekov. Philadelphia, F. A. Davis, 1971, 310 pages, $16.00

Refinements and advances in the care of the cardiac and respiratory patient over the past 10 years have created a vast literature on the subject. Therefore, it is a welcome relief to find a text that neatly combines the pertinent elements of cardiac and pulmonary resuscitation with the basic points required in each area to manage properly the problems that arise. The approach is clinical and physiologic, with major emphasis on the practical elements of both as applied to patients requiring resuscitation.

Gratifying, also, is the attention focused on the use of mechanical ventilators, a subject not often emphasized, even in some of the better training programs. The section on arterial blood gas analysis and the presentation of the pros and cons of endotracheal intubation and tracheostomy are informative and succinctly correlated with the important applications of mechanical ventilation and effective weaning of patients from respirators. However, I am not in agreement with the authors' statement (page 199) that "measurements of ventilation and blood gas analysis are not important in a conscious patient during weaning" and that "what really matters is the patient's clinical state." The clinical assessment of effective venti-

lation should continue to depend on arterial blood gas monitoring as well as evaluation of the clinical state of the patient.

The text is of specific value to medical students, physicians in training, practicing physicians and paramedical personnel employed in intensive and coronary care units. For those physicians well versed in the elements of cardiopulmonary resuscitation, the book provides a useful general review.

Leonard D. Epifano
Yonkers, New York

CARDIAC SURGERY, edited by John C. Norman, MD. New York, Appleton-Century-Crofts, 1972, 703 pages, $20.00

The second edition of this volume presents significant detail on all aspects of cardiac surgery in 34 chapters by 54 contributors. The organization of chapters will help the student find pertinent topical information.

Many of the chapters are outstanding. The physiologic basis of cardiac surgery is presented in admirably balanced detail. The chapter on anesthesia for cardiac surgery clearly reflects the author's large experience and mastery of the field. The discussion of the mechanics of cardiopulmonary bypass provides a sound background for the beginner. Material on surgical techniques for cardiopulmonary bypass and perfusion techniques is pertinent and vivid. Other good chapters from the general section deal with metabolic responses to extracorporeal circulation, preservation of myocardial metabolism, hyperbaric oxygenation and the treatment of cardiac arrest. The remainder of the book is divided into five sections on cardiac surgery in infants and children, and in adults, complications, recent developments and future prospects. With one notable exception, the chapters in all of these sections succinctly present the background position of the cardiac surgical art today. The chapter on surgery for coronary artery disease is written in a dogmatic tone that is inappropriate to this rapidly developing field. Categorical statements about techniques of coronary arteriography, the prognosis of arteriographic lesions, indications for operation and preferable surgical techniques will probably be misleading to the inexperienced. The quality of the illustrative angiograms is poor. With the exception of this chapter, the new edition of Norman's Cardiac Surgery is a useful guide to the field.

George E. Green
New York, New York

BIOMEDICAL ELECTRONICS, second edition, by Howard N. Yanof, PhD. Philadelphia, F. A. Davis, 1972, 545 pages, $22.00

The first half of this volume, entitled "Fundamentals of Electronics," is a valuable and well written treatise couched in terms easily understood by a physician with some familiarity with the subject. The second half, entitled "Biomedical Instruments," covers a few important subjects on a more practical level. There are chapters on transducers and bioelectric measurements. One, on "The Output Signal and What To Do with It," is essentially a discussion of recorders.

The treatment of transducers is exhaustive and excellent, and particularly valuable to the cardiologist, although echocardiography is given short shrift. The chapter on measurements enters into inappropriate details of neuroanatomy. In the review of recorders, there is a surprising absence of reference to the Electronics for Medicine oscillograph, an instrument that has contributed much to the development of cardiac catheterization, from Cournand and Richards to the present day.

Dr. Yanof's book is particularly recommended for the cardiologist interested in acquiring a basic understanding of modern electronics. The subject of biomedical electronics is, of course, too extensive to be covered by a single volume of 565 pages and thus this book does not succeed as a reference text.

Calendar of Continuing Medical Education Programs

The National Committee for Continuing Medical Education, William Likoff, MD, FACC, Chairman, announces the following calendar of programs.

Each program is designed to enlarge knowledge and clarify the endlessly changing frontiers which mark scientific achievements in the recognition and treatment of cardiovascular disease. Although the disciplined objective of each program as well as its content, format and faculty are primarily determined by the Program Director, the National Committee for Continuing Medical Education always exercises the prerogative of final review and approval, whether the program is sponsored solely by the College or in collaboration with universities, colleges, hospitals and other professional societies.

Subject matter reflects national interest and needs in the fields of patient care, research and teaching. The program structures vary in method of education.

The National Committee for Continuing Medical Education of the College earnestly solicits the interest of member and nonmember physicians alike in continuing education for the clear reason that participation provides a unique opportunity to deepen one's understanding of heart disease, the most formidable and challenging health problem of our time.

Programs and faculty are subject to change. For further information write Mary Anne McInerny, Director, Department of Continuing Education Programs, American College of Cardiology, 9650 Rockville Pike, Bethesda, Md. 20014.

FEB. 11–14 **Twenty-third Annual Scientific Session.** H. J. C. Swan, FACC, president. Americana Hotel and New York Hilton, New York, N. Y.

FEB. 15–17 **1974 Reconvened Annual Scientific Session.** Carlos E. Bertran, FACC, director. Hyatt Hotel, San Juan, P. R.

MAR. 18–22 **Consultant's Course in Cardiology.** Simon Dack, FACC, director. Mt. Sinai Medical Center, New York, N. Y.

MAR. 21–23 **Core Curriculum: Pathology of the Heart.** Maurice Lev, FACC, and Jesse E. Edwards, FACC, directors. Palmer House, Chicago, Ill.

MAR. 25–27 **Electrocardiographic Interpretation of Arrhythmias: A Physiological Approach.** Charles Fisch, FACC, director. Indiana University Medical Center, Indianapolis.

MAR. 28–30 **High Blood Pressure—When and How To.** Robert S. Eliot, FACC, director. Gerald L. Wolf and Francis L. Land, co-directors. University of Nebraska Center for Continuing Education, Omaha.

APR. 17–19 **Core Curriculum—Vectorcardiography (A Basic Workshop).** Alberto Benchimol, FACC, director. Scottsdale Hilton Hotel, Scottsdale, Ariz.

APR. 22–25 **Current Concepts in Cardiology—1974.** Philip R. Akre, director and John A. Bowers and Masato Takahashi, FACC, co-directors. MGM Grand Hotel, Las Vegas, Nev.

MAY 6–9 **The Treatment of Coronary Syndromes.** J. Willis Hurst, FACC and Robert C. Schlant, FACC, directors. Royal Coach Motor Hotel, Atlanta, Ga.

MAY 9–11 **The Ventricular Ectopic Beat: Heart-throb or Harbinger of Death.** Bernard Tabatznik and J. O'Neal Humphries, FACC, directors. Cross Keys Inn, Baltimore, Md.

MAY 15–17 **Clinical Auscultation of the Heart.** W. Proctor Harvey, FACC, director. Georgetown University School of Medicine, Washington, D. C.

MAY 17–19 **Core Curriculum: Rational Drug Therapy in Cardiovascular Disease.** Robert J. Lee, PhD., director. The Nassau Inn, Princeton, N. J.

MAY 23–25 **Cardiologist's Appraisal of Operable Heart Disease.** Arthur Selzer, FACC and Keith E. Cohn, FACC, directors. St. Francis Hotel, San Francisco, Calif.

JUNE 6–8 **Core Curriculum in Echocardiography: New Developments in Cardiac Ultrasound.** Arthur D. Hagan, director and Robert A. O'Rourke, FACC, co-director. Town and Country Hotel, San Diego, Calif.

BLOOD FLOW

for clinical applications

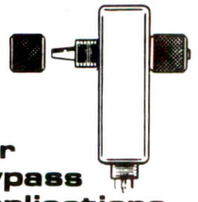
- Designed for clinical O.R. or cath lab use
- Easily applied handle-type probe
- Patient safety assured through isolation circuitry
- Simple to operate - minimum controls - direct meter readout in milliliters per minute

FLOW PROBES

for clinical applications

- Convenient, handle-type probe with positive capture slide
- Designed for O.R. and cath lab use
- For rapid analysis of flow through exposed blood vessels
- Use with Biotronex clinical blood flowmeter

FLOW PROBES



for bypass applications

- Use with heart-lung machine, artificial kidney or similar systems
- Iron core construction provides high sensitivity and accuracy
- Operates with BLI research and clinical blood flowmeters
- Available in sizes to fit most tubing

BLI **Biotronex Laboratory, Inc.** 9153 Brookville Road Silver Spring, Maryland 20910 Phone: 301/588-6400

Introducing CLINIFLOW™. The clinical blood flowmeter from CME.

CLINIFLOW is a precision instrument designed specifically for clinical applications where patient safety and simplicity of operation are of paramount importance. A truly isolated input circuit provides the ultimate in patient isolation, even when external recording devices are connected.

The CLINIFLOW System offers a new level of convenience and ease of operation. The operator simply dials the given pre-calibrated probe factor and adjusts the zero if needed. Volumetric flow rate is displayed directly in ml/min on a large, easy-to-read digital indicator. Range and decimal point settings are automatically established.

CME's long recognized standard of quality is uncompromised in the CLINIFLOW System.

CME — First in Flowmeters.

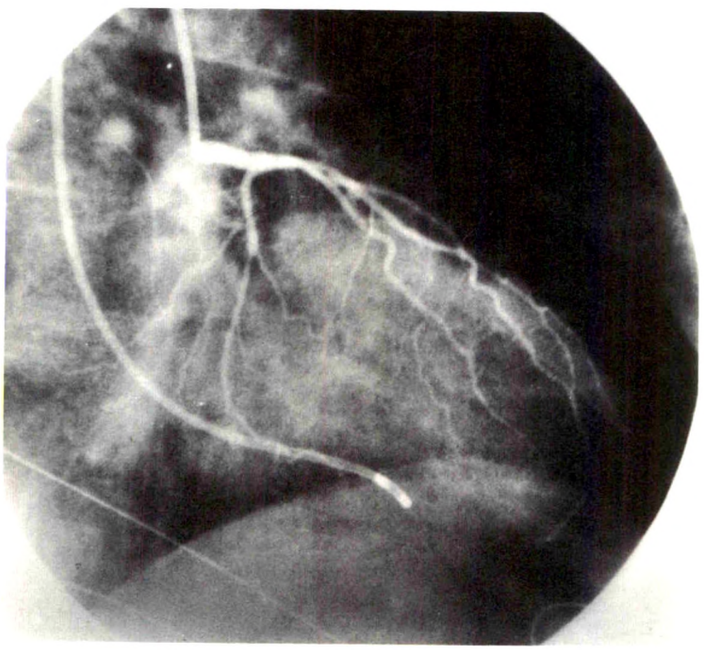
What you see is what you can get

Improved resolution

Fluoroscopic images that let you see your way far more clearly in catheterization procedures is the immediate visible difference you'll note with the Fluoricon® 300 image system. This improved resolution is a result of a total system design incorporating a cesium iodide image tube (optional triple field), and television chain specifically designed for radiology. The result is a new standard of image quality for a wide choice of recording media, including video tape at both fluoro and enhanced levels.



Larger format photospotting

A GE 105 mm photospot camera can be integrated with the system as a perfect complement to cine. The camera produces images almost 4x4 inches large, for definitive diagnoses on any viewing box; even in surgery. Life-size images are also possible, using the intensifier's 4½ inch magnified mode.

The 105 covers all rapid filming technics, and makes optimum use of all generator mA stations up to 1200 mA. With shorter exposure time and better stop motion. Exposure rates range from one frame every 2 seconds, through 12 frames per second.

Choice of cine systems

The Fluoricon 300 system offers a choice of cine integration: 35 mm cameras; or Cine 180 that provides more than double the per-frame recording area compared with standard 16 mm cine, plus frame rates to 240 per second. Automatic exposure control permits operation at peak mA and optimum kilovoltage, with the shortest possible exposure time per cine frame.

Let your GE representative give you an eye-opening demonstration with a short movie. Get in touch.

EDITORIALS:

Coronary Thrombosis and Fatal Myocardial Ischemia. William C. Roberts
The Fourth Heart Sound—A Premature Requiem. Morton E. Tavel

ORIGINAL ARTICLES:

The Initial Attack of Acute Rheumatic Fever During Childhood in North India. Shyamal K. Sanyal, Mohinder K. Thapar, Syed H. Ahmed, Vijaya Hooja and Promila Tewari

Chagasic Cardiopathy: Demonstration of a Serum Gamma Globulin Factor Which Reacts with Endocardium and Vascular Structures. Patricio M. Cossio, Carlos Diez, Ana Szarfman, Eduardo Kreutzer, Bartolomé Candiolo and Roberto M. Arana

Patterns of Ventriculo-Atrial Conduction in the Wolff-Parkinson-White Syndrome. Hein J. Wellens and Dirk Durrer

The Effects of Cycle Length on Cardiac Refractory Periods in Man. Pablo Denes, Delon Wu, Ramesh Dhingra, Raymond J. Pietras and Kenneth Rosen

A Balloon Tipped Catheter for Obtaining His Bundle Electrograms without Fluoroscopy. Stephen G. Meister, Vidya S. Banka, Kul D. Chadda and Richard H. Helfant

Left Ventricular Function and Coronary Artery Anatomy Before and After Myocardial Infarction: A Study of Six Cases. Douglas K. Stewart, Glen W. Hamilton, John A. Murray and J. Ward Kennedy

Differentiation of Physiologically Significant Coronary Artery Lesions by Coronary Blood Flow Measurements During Isoproterenol Infusion. Lawrence D. Horwitz, George C. Curry, Robert W. Parkey and Frederick J. Bonte

Gas Endarterectomy of Right Coronary Artery: The Importance of Proximal Bypass Graft. Jack H. Klie, Lewis Johnson, Harold Smulyan, James L. Potts, Anis I. Obeid, Thomas Fruehan, Robert H. Eich, Frederick B. Parker and Watts R. Webb

Left Main Coronary Stenosis: Results of Coronary Bypass Surgery. Howard J. Zeft, Jack C. Manley, John H. Huston, Alfred J. Tector, James E. Auer and W. Dudley Johnson

The Long-Term Follow-Up of Patients Undergoing Saphenous Vein Bypass Surgery. David S. Cannom, D. Craig Miller, Norman E. Shumway, Thomas J. Fogarty, Pat O. Daily, Marie Hu and Donald C. Harrison

Role of the Vagus Nerves in the Cardiovascular Changes Induced by Coronary Occlusion. Peter B. Corr and Richard A. Gillis

Plasma Volume Prior to and Following Volume Loading During Shock Complicating Acute Myocardial Infarction. Protasio L. daLuz, Max Harry Weil, Vinnie Y. Liu and Herbert Shubin

Hemodynamic Effects of Plasma Volume Expansion and Prognostic Implications in Acute Myocardial Infarction. H. Leon Greene, David T. Kelly, Dean R. Taylor and Bertram Pitt

Lung Water in Patients with Acute Myocardial Infarction. Theodore L. Biddle, Purshottam K. Khanna, Paul N. Yu, Morrison Hodges and Pravin M. Shah

Acute Effects of Ethanol on Left Ventricular Performance. Lawrence D. Horwitz and James M. Atkins

Wall Thickness and Diastolic Properties of the Left Ventricle. William Grossman, Lambert P. McLaurin, Sally P. Moos, Miltiadis A. Stefadouros and Daniel T. Young

Left Ventricular Volume Changes After Amyl Nitrite and Nitroglycerin in Man as Measured by Ultrasound. Gary W. Burggraf and John O. Parker

Selection of Patients with Truncus Arteriosus for Surgical Correction: Anatomic and Hemodynamic Considerations. Douglas D. Mair, Donald G. Ritter, George D. Davis, Robert B. Wallace, Gordon K. Danielson and Dwight C. McGoon

Experimental Pulmonary Embolism: Effect on Pulmonary Blood Volume and Vascular Compliance. Joseph S. Alpert, Florence W. Haynes, James E. Dalen and Lewis Dexter

Incorporation of Radiolabelled Fibrinogen into Venous Thrombi Induced in Dogs. Thomas C. Kravis, Elaine M. Shibel, John D. Brooks and Kenneth M. Moser

Analysis and Correction of Pressure Wave Distortion in Fluid-Filled Catheter Systems. Herman L. Falsetti, Robert E. Mates, Robyn J. Carroll, Ramji L. Gupta and Adam C. Bell

CLINICOPATHOLOGIC CORRELATIONS:

Conditions Simulating the Tetralogy of Fallot. B. N. Satyanarayana Rao and Jesse E. Edwards

RADIOLOGY:

The Complementary Roles of Chest Radiography, Lung Scanning, and Selective Pulmonary Angiography in the Diagnosis of Pulmonary Embolism. David C. Moses, Terry M. Silver and Joseph J. Bookstein

Laragh's Hypertension Manual

Edited by John H. Laragh, M.D., of the College of Physicians and Surgeons, Columbia-Presbyterian in New York.
A classic treatise for understanding, diagnosing and treating hypertension.

Approximately 900 pages, 150 illustrations.
Price: $37.00
Ready January, 1974.

Chapters by:

- ☐ John Laragh on The Renin System in Causation and on Evaluation of Hypertensive Patients.
- ☐ Sir George Pickering on Definitions, Natural Histories and Consequences.
- ☐ Louis Tobian on Experimental Mechanisms
- ☐ Arthur Guyton on Control Mechanisms
- ☐ Edward Freis on Why, When, and How to Treat.
- ☐ Edward Biglieri on Diagnosis of Adrenocortical Hypertension
- ☐ Harriet Dustan on Hemodynamic Mechanisms
- ☐ Jay Cohn on Hypertension and the Heart
- ☐ Hans Brunner on Renin as a Risk Factor

Partial list of contributors:

John H. Laragh	J. C. Hunt
Sir George Pickering	F. R. Buhler
E. A. Lew	E. G. Biglieri
E. D. Freis	D. R. LaBarthe
H. R. Brunner	K. Engelman
A. C. Guyton	J. E. Sealey
L. Tobian, Jr.	C. R. Ayers
H. P. Dustan	J. A. Wilber
J. N. Cohn	J. Koch-Weser
V. DeQuattro	P. Kincaid-Smith
J. Giese	F. A. Finnerty
A. R. Christlieb	E. D. Vaughan
A. F. Lever	

Dr. Laragh's Hypertension Manual will undoubtedly become the standard reference work in Hypertension. Use the attached form to place your order. This is the first in a series of Yorke Medical Books—from the publishers of The American Journal of Cardiology, The American Journal of Medicine, The American Journal of Surgery, and Cutis.

FUKUDA

The Model FJC-7110 single channel, portable electrocardiograph is the most advanced and versatile ECG available. It performs at the highest professional standards for diagnostic accuracy and meets AHA specifications. Truly portable, it weighs only 10 lbs. and measures 11″ x 7½″ x 3¾″. Operating on 115V AC it also has an optional interchangeable battery pack which provides 8 hours of continuous DC use.

New modular plug-in construction makes it easier to use and service. To replace the recording paper simply lift out the "cassette loader," insert the paper without threading and you're ready to record. It has both 25 and 50 mm/sec recording chart speeds and uses a rugged, heavy duty stylus to provide clear, defined ECG tracings.

ELECTRO / PHONO / VECTOR

CARDIOGRAPHS

SCC-1A

All solid state single channel ECG direct heat writing stylus 115V line operation.

Two channel direct writing Phonocardiograph for simultaneous mitral, aortic and ECG recording.

DP-2S

SCC-1

Portable ECG operates on both AC 115V line or built-in rechargeable battery.

Vectorcardiograph three channel simultaneous photorecording including vector and scalar monitor display.

VA-3D

SA-1

Portable ECG with automatic switch selector and lead marker, with built-in programmer for preset automatic time sequencing of lead selector.

TE-1

Triangular electrode for emergency hookup.

UE-1

Universal clamp electrode.

DV-35

Three channel ECG. All solid state, light weight, compact.

Other Available Products:
- Heartscopes & Monitoring Scopes
- Electrodes & Sensors
- ECG Recording Paper
- Electrode Paste

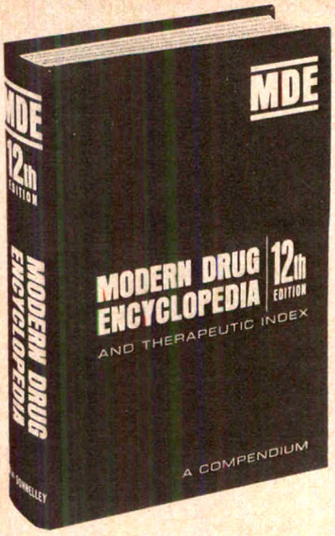
Now more than ever . . . essential guidance for every physician involved in prescribing, testing, administering modern drugs and diagnostic aids



ALL NEW 1973

12th EDITION MODERN DRUG ENCYCLOPEDIA

and THERAPEUTIC INDEX

Thousands of changes since the previous edition . . . hundreds of brand new entries . . . gives brand names . . . generic names . . . chemical names . . . descriptions . . . indications . . . pharmacological actions . . . indications and contra-indications . . . precautions . . . warnings . . . adverse reactions . . . dosage and administrations . . . availability . . . Bureau of Narcotic and Dangerous Drug Schedules and Ratings . . . Blood serum level toxicity schedules . . . for over 3,000 currently used ethical drugs.

In short, everything you need for quick, comprehensive referencing in one ruggedly bound, easy to handle volume.

PLUS—Special Chapters on pharmacologically similar drugs.

PLUS—The All-important therapeutic index . . . for the widest possible therapy selection.

PLUS—A Manufacturers Index, listing Company Names, Addresses and their products.

AND our editorial staff of physicians and pharmacists has compiled a NEW GENERAL INDEX for your convenience. It's scientifically designed for first hit look ups by both generic and brand names.

MODERN DRUG ENCYCLOPEDIA is always up-to-date . . . with your purchase of MDE-12 you will receive FREE of charge a two year supplement service — MODERN DRUGS.

Please order now . . . make sure your copy of MDE-12 is earmarked for your office.

Ultrasound: Can you get by without it?

Yes, but why should you with the clinically proven techniques available in the fields of obstetrics/gynecology, cardiology and abdominal organ imaging.

An average of only 2½ patients per day justifies the cost of most ultrasound installations. Your Picker representative has detailed studies of operating costs to help you with economics for your own particular medical practice.

Picker pioneered ultrasound in this country over a decade ago. And as the leader, Picker follows through with teaching aids and seminars . . . with continuing operator training . . . and with rapid repair service through Picker's own nationwide service organization. With Picker Ultrasound you need have no fear that your equipment will be down because of reliance on third parties for service.

Picker Ultrasound completes the circle of diagnostic visualization, and complements Picker's universally accepted x-ray and nuclear diagnostic imaging systems. Contact your Picker representative or Picker Corporation, 595 Miner Road, Cleveland, Ohio 44143.

INSTRUCTIONS FOR AUTHORS

The editors and publishers of THE AMERICAN JOURNAL OF CARDIOLOGY welcome concise articles devoted to cardiovascular disease. Articles must be contributed solely to THE AMERICAN JOURNAL OF CARDIOLOGY and become the property of the Publisher. The Publisher reserves copyright and renewal on all published material, and such material may not be reproduced in any form without the written permission of the Publisher. Statements in articles are the responsibility of the authors. Authors will assist the editors in the prompt processing of manuscripts if these instructions are followed:

THE WHOLE PAPER

- **Address manuscript** to Simon Dack, MD, American Journal of Cardiology, 666 Fifth Ave., New York, NY 10019.
- **Submit two copies** of all elements of the article: text, references, legends, tables and figures.
- **Arrange the paper** in this order: (1) title page; (2) abstract; (3) text; (4) references; (5) legends; (6) tables; and (7) figures.
- **Number all pages** in above sequence, beginning with title page as 1, abstract as 2, etc.
- **Type all matter:** (1) on 8½ × 11 opaque white bond paper; (2) in duplicate; (3) on **one side** of each sheet only; (4) double-space; (5) leave wide margins, all four sides.

THE TITLE PAGE

- **Number title page** as page 1.
- **Include first names,** degrees and, where applicable, FACC for all authors.
- **Insert at bottom:** name and address of institution from which work originated plus information about grants.
- **Add at bottom** the phrase "Address for reprints: . . ." followed by full name and address with zip code.

THE ABSTRACT

- **Limit words as follows:** 100 to 250 words for major articles; 50 to 100 words for case reports.
- **Add at end of abstract:** an alphabetical list of 2 to 6 key words and subjects for indexing.

THE TEXT

- **Number pages** in sequence after abstract.
- **Type in duplicate;** double-space.
- **Do not use abbreviations** such as SVC, WPW: write out; superior vena cava, Wolff-Parkinson-White.

Abbreviate measurements (mm, kcal and the like) as recommended in the Style Manual for Biological Journals, American Institute of Biological Sciences, 3900 Wisconsin Avenue, N.W., Washington, D. C.

- **Cite in numerical** order every reference, figure and table. (Order of mention in text **determines the number** given to each.)
- **Place acknowledgments** at end of text, before references.

THE REFERENCES

- **Type in duplicate;** double-space.
- **Place immediately** after text, and number pages in sequence after text page numbers.
- **Number the references** in order in which they are mentioned in text.
- **Follow the general** arrangement, abbreviations and punctuation styles shown below.

THE FIGURE LEGENDS

- **Start at top** of new page.
- **Type in duplicate;** double-space.
- **Number pages** in sequence after last page of references.
- **Identify** at the end of each legend and **in alphabetical order** all abbreviations in the figure described.

THE TABLES

- **Start each** table at top of new page.
- **Type in duplicate;** double-space.
- **Number pages** in sequence after last page of legends.
- **Give each table** a number (in roman numerals: Table I, II, etc.) and a title. Number the tables in order in which they are mentioned in the text.
- **Provide a footnote** to each table—identifying **in alphabetical order** all abbreviations used.

THE FIGURES

- **Submit 2 glossy prints** (not originals) of each photo and drawing.

Please note that art work of published articles will not be returned.

- **Use black ink** for all charts (line drawings). Make decimals, broken lines, etc. strong enough for reproduction.
- **Use arrows** to designate special features.
- **Crop photomicrographs** to show only essential field.
- **Identify figures** on back by number and author's name.
- **Number figures** in order in which they are mentioned in the text.
- **Indicate top** of each figure.
- **Submit written permission** from publisher and author to reproduce any previously published figures.
- **Limit figures** to number necessary for clarity. The publisher allows a limited sum toward reproduction.

(Author: please note that no periods are used after authors' initials.)

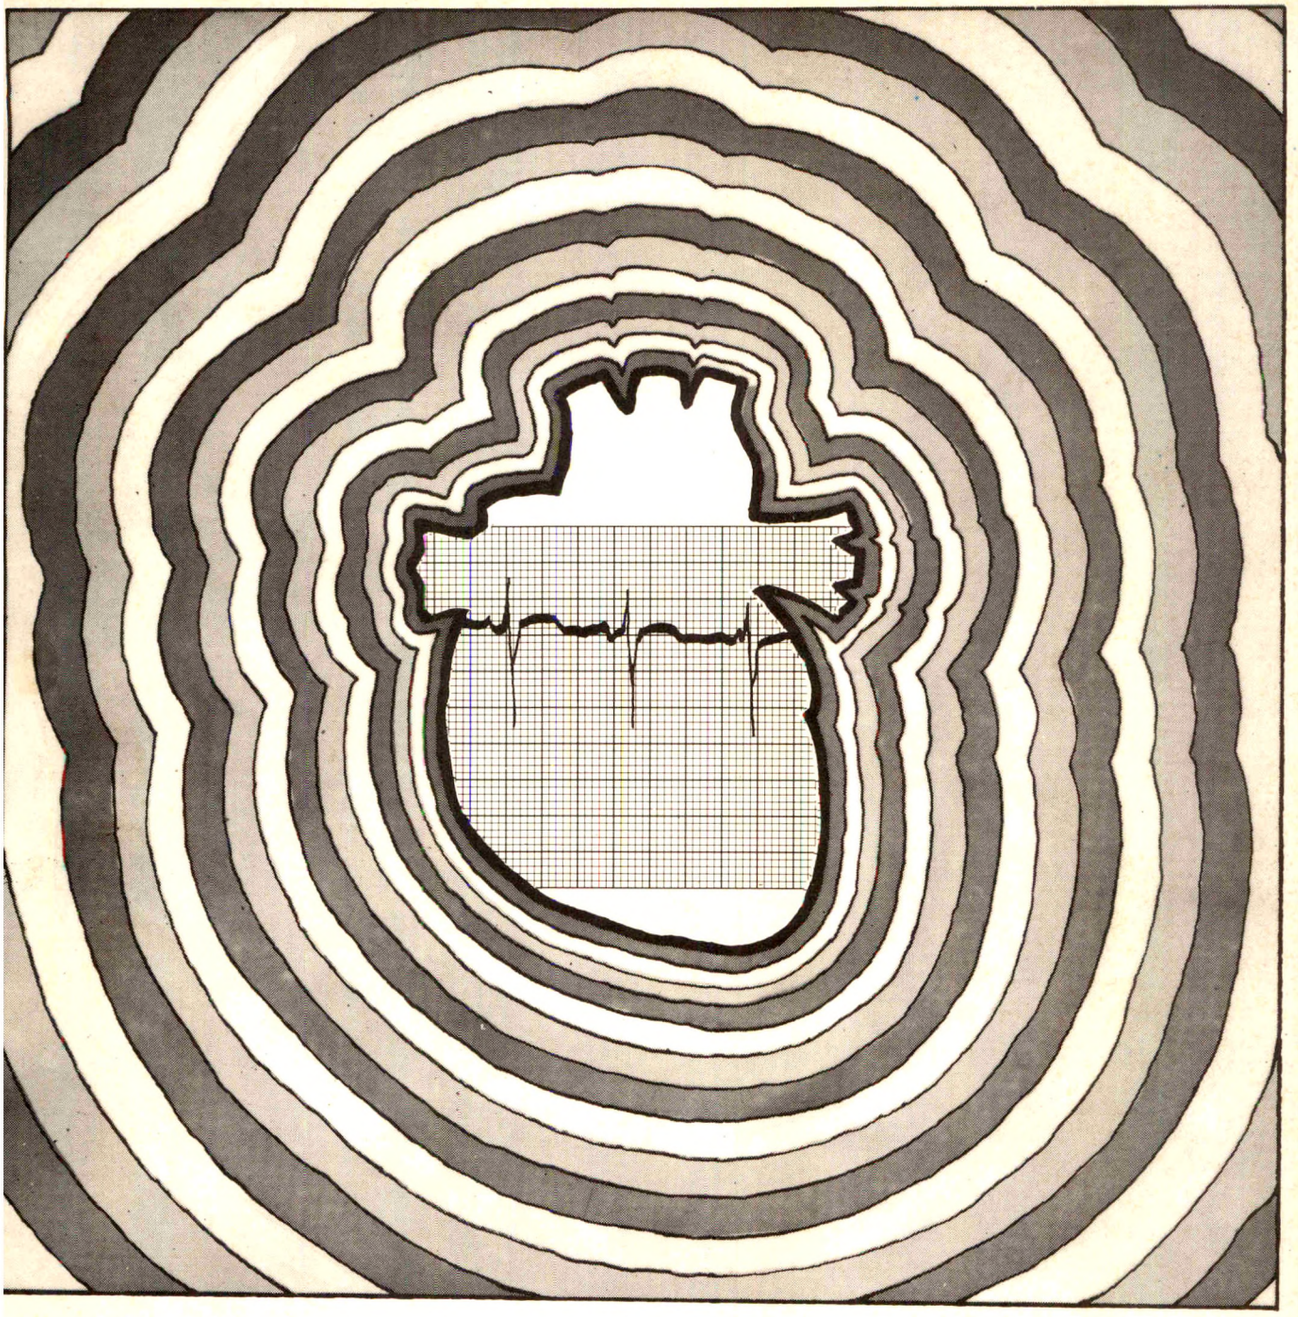
For books (edited by other than author of article):

28. Schiebler GL, Van Mierop LHS, Krovetz LJ: Diseases of the tricuspid valve, chap 20. In, Heart Disease in Infants, Children and Adolescents (Moss AJ, Adams F, ed). Baltimore, Williams & Wilkins, 1968, p 134

For books (with identical author and editor):

36. Berne E: Principles of Group Treatment. New York, Oxford University Press, 1966, p 26

(Author: all book references should have specific page numbers)



the heart of your electrocardiograph diagnosis is made of paper

Accurate interpretation of analytical data presented by your electrocardiograph and subsequent proper diagnosis is manifested by the chart paper.

If there's a chance the chart paper is lacking in quality or accuracy, an inaccurate recording may well be the result.

Why take the chance. Specify the paper designed and produced expressly for the manufacturer of your instrument. The cost of total assurance simply isn't worth the few pennies substitutes may save.

This message was prepared in the interest of better recording instrument performance by . . .

The Instrument Manufacturers' Chartmaker

"The drug of choice for oral replacement of potassium is potassium chloride solution."

AMA Drug Evaluations 1971, First Edition, Chicago, American Medical Association, p. 121.

Kay Ciel® Elixir is potassium chloride... tastes good too!

COMPOSITION: Each 15 cc. (one tablespoonful) contains potassium chloride 1.5 Gm., supplying 20 mEq. of elemental potassium, in a cherry-flavored, palatable base, alcohol 4%. Contains no sugar.
INDICATIONS: Treatment of potassium deficiency occurring especially during thiazide diuretic or corticosteroid therapy, digitalis intoxication, low dietary intake of potassium or as a result of excessive vomiting and diarrhea.
CONTRAINDICATIONS: Impaired renal function, untreated Addison's Disease, dehydration, heat cramps, and hyperkalemia.
PRECAUTIONS: Potassium chloride should be administered with caution and adjusted to the requirements of the individual patient, since the amount of deficiency and corresponding daily dose is often not known. Excessive or even therapeutic dosages may result in potassium intoxication. Patients should be frequently checked and periodic ECG and/or plasma potassium levels made. High plasma concentrations of potassium ion may cause cardiac depression, arrhythmias or arrest. Use with caution in patients with cardiac disease. In hypokalemic states, attention should be directed toward the correction of the frequently associated hypochloremic alkalosis.
SIDE EFFECTS: Vomiting, nausea, abdominal discomfort and diarrhea may occur. Symptoms and signs of potassium intoxication include listlessness, mental confusion, paresthesia of the extremities, weakness of the legs, flaccid paralysis, fall in blood pressure, cardiac arrhythmias, and heart block. When hyperkalemia exists, it should be promptly treated with the discontinuance of potassium administration or other steps to lower serum levels if indicated, since sudden shift in plasma levels may induce potentially dangerous cardiac arrhythmias.
DOSAGE AND ADMINISTRATION: Adults, one tablespoonful (15 cc.) diluted in one glass of water, twice daily after the morning and evening meal. Larger doses may be indicated according to the individual patient's requirements but should be administered under close supervision due to the possibility of potassium intoxication. Patients should be cautioned to follow directions explicitly in regard to dilution of Kay Ciel Elixir to prevent gastrointestinal injury.
HOW SUPPLIED: One pint and one gallon bottles.

Cooper Cooper Laboratories, Inc., Wayne, N.J. 07470/Ste. Therese, P.Q., Canada

A YORKE MEDICAL JOURNAL

The patient with cardiac arrhythmia may need medication most when he's least likely to take it...

while he's sleeping.

Quinaglute® Dura-Tabs® (quinidine gluconate) "a pharmacologic pacemaker":

- produces sustained serum quinidine levels, thus providing a convenient 8 or 12 hour dosage schedule
- usually insures uninterrupted therapeutic quinidine gluconate levels during sleep
- avoids peaks and valleys in plasma levels during which time the arrhythmias may recur
- maintains normal sinus rhythm following conversion by other techniques
- well tolerated to enhance patient cooperation — few G.I. disturbances

Contraindications: Quinaglute Dura-Tabs are contraindicated in patients with partial A-V or complete heart block, or intraventricular conduction defects, especially those exhibiting a marked grade of QRS widening; in patients manifesting idiosyncrasy or sensitivity to quinidine (e.g. febrile reactions, skin eruptions, thrombocytopenia, etc.), in patients with renal disease resulting in significant azotemia, or those developing cardiotoxic effects such as conduction defects; ventricular premature beats, ventricular tachycardia or flutter while on the drug. It may be contraindicated in certain patients who have marked cardiac enlargement, particularly with congestive failure, poor renal function, and especially renal tubular acidosis.

Precautions: The precautions to be observed include all those applicable to quinidine. A preliminary test dose of a single tablet of quinidine sulfate should be administered to determine if the patient has an idiosyncrasy to quinidine. Hypersensitivity to quinidine, although rare, should constantly be considered; especially during the first weeks of therapy.

Signs of idiosyncrasy include febrile reactions, skin eruptions, thrombocytopenic purpura, and respiratory embarrassment. Extreme caution should be exercised in using the drug in patients with severe heart disease and congestive heart failure, with digitalis intoxication, or renal insufficiency. It should be administered cautiously, if at all, to senile patients. Hospitalization for close clinical observations, electrocardiographic monitoring, and possibly plasma quinidine levels, is indicated when large doses are used, or with patients who present an increased risk.

As with all quinidine preparations, the titrating of the exact quinidine dosage will vary with each individual patient. With the dosage regimen of 2 tablets every 8 hours, higher blood levels than necessary for maintenance of normal sinus rhythm could be reached, whereas with 1 tablet every 12 hours, the blood levels may be too low to maintain normal sinus rhythm.

As with other quinidine products, Quinaglute Dura-Tabs should not be used during pregnancy.

Adverse Reactions: The patient should be advised to report immediately to the physician any symptoms of cinchonism (including tinnitus, decreased auditory acuity, vertigo, blurred vision, color perception disturbances, photophobia, diplopia, night blindness, scotomata, reduced visual fields, mydriasis and respiratory distress).

Where such symptoms develop, or if evidence of hypotension appears, the drug should be discontinued. Gastrointestinal disturbances have only rarely been reported. If they occur, they may be minimized by administering the drug with food. If they persist, dosage should be decreased.

Dosage: For the prevention of premature atrial, nodal or ventricular contractions, the dose usually ranges from 1 to 2 tablets every 8 or 12 hours.

Before prescribing or administering, please refer to QUINAGLUTE full product information.

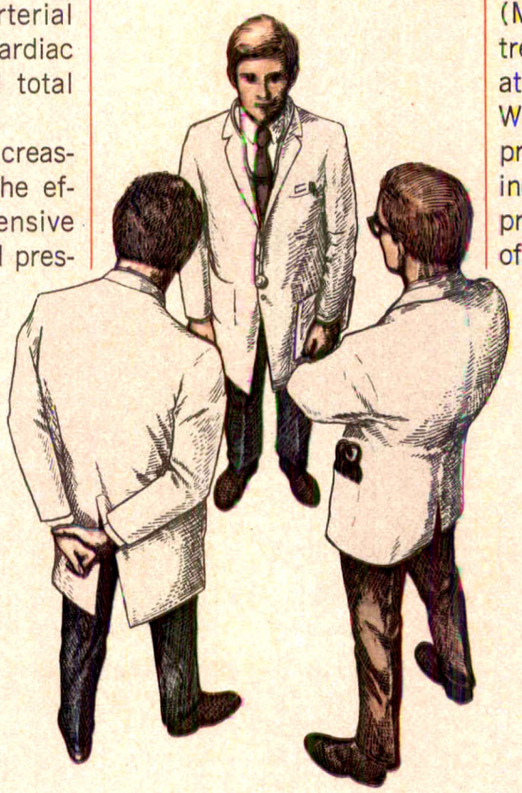
The more physicians consider the hemodynamics of lowering blood pressure...

Most physicians now agree on the importance of reducing blood pressure in the hypertensive patient. But high blood pressure exists, of course, only as part of a complete clinical picture. The hemodynamic profile of well-established essential hypertension is characterized by elevated arterial blood pressure, normal cardiac output, and increased total peripheral resistance.

And so, physicians are increasingly concerned with the effects of an antihypertensive agent not only on blood pressure itself but also on the hemodynamic pattern—in short, with the total effect of the drug. *Does* it indeed help lower blood pressure effectively? *Is* peripheral resistance reduced? *Are* cardiac output and renal functions maintained? And, also, is there likely to be drug-induced postural hypotension serious enough to pose a threat to the patient's cerebrovascular status?

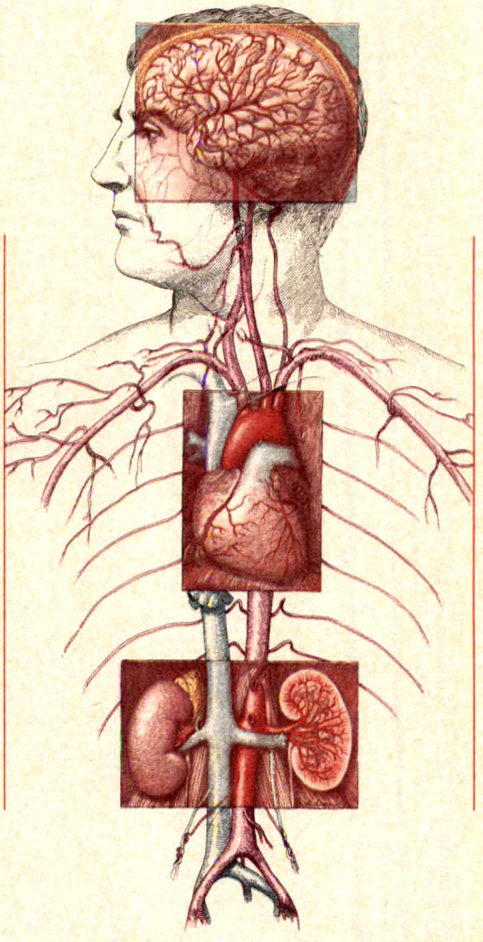


With this emphasis on overall drug performance has come a growing reliance on ALDOMET® (Methyldopa, MSD) in the treatment of sustained moderate hypertension.

With its unique hemodynamic profile, ALDOMET has drawn increasing attention and approval from physicians. First, of course, for its efficacy in

S. 8. 74

the more physicians rely on this unique antihypertensive



lowering blood pressure. But there are other considerations as well. Cardiac output is usually maintained with no cardiac acceleration; in some patients the heart rate is actually slowed. Peripheral resistance is apparently reduced. ALDOMET does not usually compromise existing renal function; it generally does not reduce renal blood flow, glomerular filtration rate, or filtration fraction. And ALDOMET usually does not cause symptomatic postural or exercise hypotension.

Some patients on continuous methyldopa therapy may develop a positive direct Coombs test. For more details, see the brief summary of prescribing information.

Contraindicated in active hepatic disease and known sensitivity to the drug. Not recommended in pheochromocytoma or pregnancy. It should be used with caution in patients with a history of liver disease or dysfunction. Discontinue the drug if fever, abnormal liver function, jaundice, or acquired hemolytic anemia occurs.

In most cases of sustained moderate hypertension

TABLETS, 250 mg

ALDOMET®

(METHYLDOPA | MSD)

smoothly lowers blood pressure

For a brief summary of prescribing information, please see following page.

In most cases of sustained moderate hypertension

TABLETS, 250 mg

ALDOMET® (METHYLDOPA | MSD)

smoothly lowers blood pressure

Contraindications: Active hepatic disease, such as acute hepatitis and active cirrhosis; known sensitivity. Not recommended in pheochromocytoma. Unsuitable in mild or labile hypertension responsive to mild sedation or thiazide therapy. Use cautiously in patients with history of previous liver disease or dysfunction.

Warnings: Acquired hemolytic anemia has occurred rarely in association with therapy with methyldopa. Should clinical symptoms indicate the possibility of anemia, hemoglobin and/or hematocrit determinations should be performed. If anemia is present, appropriate laboratory studies should be done to determine if hemolysis is present. Evidence of hemolytic anemia is an indication for discontinuation of the drug. Discontinuation of methyldopa alone or the initiation of adrenocortical steroids usually results in a prompt remission of the anemia. Rarely, however, fatalities have occurred.

Some patients on continued therapy with methyldopa develop a positive direct Coombs test; incidence reported has averaged between 10% and 20%. It rarely occurs in first six months of therapy, and if not seen within twelve months, is unlikely to develop with continued administration. Positive Coombs test is dose-related; lowest incidence occurs in patients on 1 g methyldopa or less per day. Reversal of the positive Coombs test occurs within weeks to months after discontinuation of methyldopa. Prior knowledge of a positive Coombs reaction aids in evaluation of cross match for transfusions. Patients with positive Coombs tests at time of cross match may exhibit incompatible minor cross match. When this occurs, an indirect Coombs test should be performed. If negative, transfusion with blood otherwise compatible in the major cross match may be carried out. If positive, advisability of transfusion with blood compatible in major cross match should be determined by hematologist or expert in transfusion problems.

Fever has occurred within first three weeks of therapy, sometimes with eosinophilia or abnormalities in liver function tests, such as serum alkaline phosphatase, serum transaminases (SGOT, SGPT), bilirubin, cephalin cholesterol flocculation, prothrombin time, and bromsulphalein retention. Jaundice, with or without fever, may occur, with onset usually in the first two to three months of therapy. Rare cases of fatal hepatic necrosis have been reported. Liver biopsy in several patients with liver dysfunction has shown microscopic focal necrosis compatible with drug hypersensitivity. Rarely, reversible reduction in leukocyte count with primary effect on granulocytes has been seen; reversible agranulocytosis has been reported. Methyldopa may interfere with measurement of creatinine by alkaline picrate method and of uric acid by phosphotungstate method. When used with other antihypertensive drugs, potentiation of antihypertensive action may occur.

Usage in Pregnancy and Childbearing Age—Not recommended in pregnancy. In women of childbearing age, weigh potential benefits against possible fetal hazards.

Precautions: Perform periodic hepatic function tests and white cell and differential blood counts during first six to twelve weeks of therapy or in unexplained fever. Discontinue if fever, abnormalities in liver function tests, or jaundice appears. Since methyldopa causes fluorescence in urine samples at the same wavelengths as catecholamines, spuriously high levels of urinary catecholamines may be reported. This will interfere with the diagnosis of pheochromocytoma. Discontinue drug if involuntary choreoathetotic movements occur in patients with severe bilateral cerebrovascular disease. Anesthetics requirements may be reduced; hypotension occurring during anesthesia usually can be controlled with vasopressors. Hypertension may occur after dialysis because methyldopa is removed by this procedure.

Dosage should be limited initially to 500 mg daily when following previous antihypertensive agents other than thiazides. Do not exceed recommended daily dose of 3.0 g. Patients with impaired renal function may respond to smaller doses than patients with normal kidney function. Syncope in older patients has been related to increased sensitivity in those with advanced arteriosclerotic vascular disease; this may be avoided by lower doses. Tolerance occasionally seen either early or late, but more likely between second and third month after initiation of therapy; increased dosage or combined therapy with a thiazide frequently restores effective control.

Adverse Reactions: Sedation, usually transient, may be seen during initial therapy or when dosage is increased. Headache, asthenia, or weakness may be noted as early, transient symptoms. Symptoms associated with effective lowering of blood pressure, including dizziness, lightheadedness, and symptoms of cerebrovascular insufficiency, are seen occasionally. Angina pectoris may be aggravated. Symptoms of orthostatic and exercise hypotension may occur; if symptoms occur, reduce dosage. Bradycardia, nasal stuffiness, mild dryness of mouth, and gastrointestinal symptoms including distension, constipation, flatus, and diarrhea occur occasionally; these can be relieved by reducing dosage. Nausea and vomiting have been reported in only a few patients. Sore tongue or "black tongue," pancreatitis, and inflammation of salivary glands may occur.

Weight gain and edema occur infrequently; if edema progresses or signs of pulmonary congestion appear, discontinue drug. Rarely, urine exposed to air may darken due to breakdown of methyldopa or its metabolites. Other rare reactions include breast enlargement, lactation, impotence, decreased libido, skin rash, mild arthralgia, myalgia, paresthesias, parkinsonism, psychic disturbances including nightmares, reversible mild psychoses or depression, reversible thrombocytopenia, drug-related fever and abnormal liver function studies with jaundice and hepatocellular damage (see **Warnings** and **Precautions**), rise in BUN, and a single case of bilateral Bell's palsy.

Supplied: Tablets, containing 250 mg methyldopa each, in single-unit packages of 100 and bottles of 100 and 1000.

ADDENDUM

MSD MERCK SHARP & DOHME

Let's make blood pressure "required reading" for all physicians.

With recent estimates that about 23 million Americans have high blood pressure—and that half of them are not even aware of it—detection of the problem in asymptomatic persons has become an issue of national importance.

Family physicians are being urged to take blood pressure readings as a matter of office routine, regardless of the presenting complaint or the reason for the visit. And because many people do not see a family physician for relatively long periods of time, some experts are suggesting that ophthalmologists, gynecologists, dermatologists, orthopedists, psychiatrists, dentists, school nurses, family planning counselors, and other health-care personnel make blood pressure reading a routine part of every examination or consultation.

Of course, a diagnosis of hypertension cannot be made on the basis of a single reading, but routine blood pressure readings can uncover potential trouble in a certain proportion of patients. And when trouble is suggested, further evaluation can be pursued more effectively.

Blood pressure—"required reading" for all physicians.
